14      if  $\bar{\sigma} \geq \epsilon_u$  then
15         $\sigma \leftarrow \text{PPJ-B}(D_u, D_{u'}, G, \epsilon_{doc}, \epsilon_{loc}, \epsilon_u)$ 
16        if  $\sigma \geq \epsilon_u$  then
17           $R.\text{add}(\langle u', u \rangle)$ 
18 return  $R$ 

```

S-PPJ-F is outlined in Algorithm 2. It operates on top of a spatio-textual index structure that is constructed at runtime. In every iteration, the algorithm selects a new user u , searches for potential matches with the users that have been selected in previous steps, and updates the spatio-textual index with the objects in D_u .

The spatio-textual index is a dynamic grid enhanced with an inverted index for every cell. This list maintains for every token that appears in objects in a cell, the users that are associated with these objects. An example is depicted in Figure 3. The grid structure additionally maintains the objects associated with every user within a cell.

The search for matches follows the filter and refine principle. After a user u is selected, the algorithm traverses through every cell $c \in C_u$ which contains objects associated with u , and calculates the set of tokens T that appear in any one of these objects. This set is then utilized to identify candidate users in c and its surrounding cells (lines 6-9). Every user u' with objects that appear in one of these cells that at least one keyword from T is considered to be a candidate. $M_{u'}^u$ maintains cells that contain objects from u that potentially match (both spatially and textually) with objects from u' . Respectively, $M_{u'}^{u'}$ maintains the relevant for u' .

For every user u and candidate user u' , the algorithm calculates an upper bound $\bar{\sigma}$ of their user similarity score (lines 12-13). This is performed by assuming that all of their objects which are contained in the same or adjacent cells match. Formally, $\bar{\sigma}$ is computed as follows:

$$\bar{\sigma} = \frac{\sum_{l \in M_{u'}^u} |D_u^l| + \sum_{l' \in M_{u'}^{u'}} |D_{u'}^{l'}|}{|D_u| + |D_{u'}|}.$$

If $\bar{\sigma} < \epsilon_u$, then this pair can be safely pruned. Otherwise, a refinement step follows, during which the PPJ-B algorithm is executed to identify whether the exact similarity score for the pair exceeds the user similarity threshold.

4.1.4 The S-PPJ-D Algorithm

In the following, we consider databases that are already partitioned by a data partitioning scheme. In particular, we consider data partitioning schemes induced by an R-tree structure combined with a textual index similar in fashion to the index outlined with respect to S-PPJ-F. The main difference is that instead of indexing grid cells, in this case, we index the leaf nodes of the R-tree.

S-PPJ-D implements a filter and refinement strategy similar to S-PPJ-F, based on a given data partitioning and a spatio-textual index I that is constructed at runtime. I maintains an entry for every leaf node l in the tree. This entry holds an inverted list that maps a token t U_t^l (i.e. users with objects in l that contain t). In addition, every leaf node l maintains a mapping between users and their objects within l , denoted by D_u^l . Finally, the intersections among the extended MBRs of the leaf nodes in the tree are precomputed by performing a spatial join using the process described in [8].

The filter step iterates over the leaf nodes L_u of a user u . For every leaf node l , it calculates the set of tokens T that appear in objects within l that are associated with u (i.e. D_u^l). These tokens are then used to probe the spatio-textual index and identify the candidate users that are associated with objects containing tokens from T . This is performed for each leaf node that intersects with the ϵ_{loc} -extended bounding box of l . To avoid duplicates, we only search for candidate users which are higher in the user ordering. M maintains for every candidate u' the leaf nodes of u' containing objects that can potentially match objects associated with user u $M_{u'}^u$, as well as the leaf nodes of the relevant objects from u $M_{u'}^{u'}$. S-PPJ-D calculates for every candidate u' a bound on the similarity score between u and u' . This is calculated by considering the extreme case in which all objects from $M_{u'}^u$ and $M_{u'}^{u'}$ match. The refinement step uses PPJ-D in order to calculate the exact similarity between candidate users.

Algorithm 3 outlines PPJ-D. PPJ-D leverages the spatio-textual index in combination with an appropriate leaf node traversal strategy in order to return the similarity score between two users. PPJ-D functions similar to PPJ-B for the context of a data-driven partitioning scheme. Given two users u_1 and u_2 , two lists L_1 and L_2 are maintained for their leaf nodes ordered with respect to a predefined ordering (e.g. in ascending order of their ids). The algorithm proceeds iteratively, and selects the lowest (with respect to the ordering) unvisited leaf node l from L_1 and L_2 .

Let user u be the user from which the element was selected, and u' the other user. The index is used to identify every leaf node l' that is spatially relevant to l , and contains objects from u' . Spatially relevant leaf nodes are nodes with intersecting ϵ_{loc} -extended MBRs. For every l' we execute PPJJoin to identify the exact similarity between the objects D_u^l and $D_{u'}^{l'}$. This is performed by focusing only on objects that belong within the intersection A of the ϵ_{loc} -extended MBRs of l and l' (lines 11-12, 18-19). This optimisation is based on the observation that objects which are not contained in A do not satisfy the spatial threshold ϵ_{loc} .

PPJ-D follows a similar pruning strategy with PPJ-B. The

Algorithm 3: PPJ-D Algorithm

Input: $D_{u_1}, D_{u_2}, I, \epsilon_{doc}, \epsilon_{loc}, \epsilon_u$
Output: Similarity score for users u_1, u_2

```

1  $\beta \leftarrow (1 - \epsilon_u) \cdot (|D_{u_1}| + |D_{u_2}|)$ 
2  $J \leftarrow \emptyset$  // joined objects
3  $L_1 \leftarrow I.getLeaves(u_1)$  // sorted
4  $L_2 \leftarrow I.getLeaves(u_2)$ 
5  $i_1 \leftarrow 0, i_2 \leftarrow 0$ 
6  $t \leftarrow 0$ 
7 while  $i_1 < |L_1|$  or  $i_2 < |L_2|$  do
8   if  $L_1[i_1] \leq L_2[i_2]$  then
9     foreach  $l_2 \in I.getRelevantLeaves(l_1)$  do
10      if  $l_2 \geq l_1$  and  $l_2 \in L_2$  then
11         $A \leftarrow I.extend(l_1, \epsilon_{loc}) \cap I.extend(l_2, \epsilon_{loc})$ 
12         $PPJoin(D_{u_1}^{l_1} \cap A, D_{u_2}^{l_2} \cap A, J)$ 
13         $t \leftarrow t + |D_{u_1}^{l_1}|$ 
14      else if  $L_{u_2}[i_2] \leq L_1[i_1]$  then
15         $l_2 \leftarrow L_2[i_2]$ 
16        foreach  $l_1 \in I.getRelevantLeaves(l_2)$  do
17          if  $l_1 > l_2$  and  $l_1 \in L_1$  then
18             $A \leftarrow I.extend(l_1, \epsilon_{loc}) \cap I.extend(l_2, \epsilon_{loc})$ 
19             $PPJoin(D_{u_1}^{l_1} \cap A, D_{u_2}^{l_2} \cap A, J)$ 
20             $t \leftarrow t + |D_{u_2}^{l_2}|$ 
21      if  $t - |J| > \beta$  then
22        return 0
23      if  $L_1[i_1] \leq L_2[i_2]$  then  $i_1 \leftarrow i_1 + 1$ 
24      if  $L_2[i_2] \leq L_1[i_1]$  then  $i_2 \leftarrow i_2 + 1$ 
25  $\sigma \leftarrow |J| / (|D_{u_1}| + |D_{u_2}|)$ 
26 if  $\sigma \geq \epsilon_u$  then return  $\sigma$ 
27 else return 0

```

objects of every leaf node for user u are evaluated against every potential candidate from $D_{u'}$ that falls within a leaf node that is higher in the given ordering. Therefore, after an iteration that visits an object, candidate matches from leaf nodes, both higher and lower in the ordering, are considered. This observation is the basis of a pruning step (lines 21-22) that calculates the number of objects $t - |J|$ that are already found to fail to satisfy the thresholds. If this number is lower than a computed bound, the search is pruned since the users fail to satisfy the user similarity threshold.

4.2 Algorithms for top-k STPSJoin

Next, we extend our methods to support the top- k STPSJoin query. The main intuition behind our approach is that the algorithm must keep track of the top- k pairs identified thus far, and utilise the exact user similarity score of the k th best pair to update the user similarity threshold.

4.2.1 TOPK-S-PPJ-F

Algorithm 4 outlines TOPK-S-PPJ-F, which modifies S-PPJ-F for the purposes of the top- k STPSJoin query. The main modifications with respect to S-PPJ-F relate to the maintenance of intermediate results and the update of the user similarity threshold. Results are stored in a fixed capacity priority queue of size k , which is updated whenever a pair that is better than the k th pair in the queue is identified. The user similarity threshold ϵ_u is set as the similarity score of the k th best pair in the queue. Accordingly, the

Algorithm 4: TOPK-S-PPJ-F Algorithm

Input: $D, U, \epsilon_{doc}, \epsilon_{loc}, k$
Output: Top- k Pairs of matched users R

```

1  $R \leftarrow \emptyset$ 
2  $\epsilon_u \leftarrow -1$ 
3  $G \leftarrow initialiseSTGridIndex(D, \epsilon_{loc})$ 
4 foreach  $u \in sorted(U)$  do
5   foreach  $c \in C_u$  do
6      $T \leftarrow calculateTokens(u, c)$ 
7     foreach  $c' \in G.getRelevantCells(c)$  do
8       foreach  $t \in T$  do
9         foreach  $u' \in G.getTokenUsers(c', t)$  do
10           $M_{u'}^u.add(c), M_{u'}^{u'}.add(c')$ 
11       $G.addUser(u)$ 
12      foreach  $u' \in M.keys()$  do
13         $m \leftarrow \sum_{c \in M_{u'}^u} |D_u^c| + \sum_{c' \in M_{u'}^{u'}} |D_{u'}^{c'}|$ 
14         $\bar{\sigma} \leftarrow \frac{m}{|D_u| + |D_{u'}|}$ 
15        if  $\bar{\sigma} > \epsilon_u$  then
16           $\sigma \leftarrow PPJ-B(D_u, D_{u'}, G, \epsilon_{doc}, \epsilon_{loc}, \epsilon_u)$ 
17          if  $\sigma > \epsilon_u$  then
18             $R.update((u', u))$ 
19          if  $|R| = k$  then
20             $\epsilon_u \leftarrow R.getTail()$ 
21 return  $R$ 

```

threshold ϵ_u is updated whenever a new pair is introduced in the results queue (lines 18-20). The user similarity threshold is used in the filtering phase of the algorithm in a similar manner with S-PPJ-F. The same principle can be straightforwardly applied to S-PPJ-D. Pseudocode for the resulting algorithm is omitted due to lack of space.

TOPK-S-PPJ-F orders users in an ascending order of the size of their object-sets. This strategy is based on the observation that the treatment of users with larger object-sets requires more computations than the evaluation of users with fewer objects. By the time the algorithm reaches the most computationally demanding users, the user similarity threshold has been updated to reflect the best pairs identified so far, increasing the possibility that pairs that do not belong to the top- k result set are filtered out.

4.2.2 TOPK-S-PPJ-S

TOPK-S-PPJ-S operates similarly with TOPK-S-PPJ-F. However, it uses a heuristic strategy in order to decide the order by which users are evaluated. User objects are placed in a spatial grid and each cell in the grid c is given a score by counting the amount of users whose object-sets belong to c or its adjacent cells. Users are then assigned a score by summing, for every object o associated with them, the score of the cell that o is contained in. Formally, cell scores s_c are calculated as follows:

$$s_c = |\cup_{c' \in G.getRelevantCells(c)} G.getUsers(c')|$$

where G is the spatial grid, c is a cell in the grid, $G.getUsers$ returns the users with objects in c and $G.getRelevantCells(c)$ returns the cells that are adjacent to c (including c).

Accordingly, users are assigned scores s_u according to the

following formula:

$$s_u = \sum_{o \in D_u} s_{o_c}$$

D_u denotes the object-set for user u and o_c describes the cell that object o is located in.

Therefore the rationale behind TOPK-S-PPJ-S is to start the search with users whose objects are placed in popular areas. This strategy aims at quickly identifying high scoring pairs, in order to increase the user similarity threshold quickly, and improve the efficiency of the filtering step.

4.2.3 TOPK-S-PPJ-P

The TOPK-S-PPJ-P algorithm introduces an additional filtering step. Users are selected in ascending order of the size of their object-sets. For every user u , we calculate an upper bound on the similarity score between u and any user u' that was selected in a previous iteration. To do so, we identify the objects from D_u that match with any object from $D_{u'}$, i.e. the union of the objects of every user that was selected in previous iterations. This is denoted as $M(D_u, D_{u'})$. This allows the calculation of an upper bound on $\sigma(u, u')$ for every u' that was selected prior to u . Formally, this bound is calculated as follows:

$$\bar{\sigma}_u = \frac{|\bigcup_{u' \in U'} M(D_u, D_{u'})| + \max_{u' \in U'} |D_{u'}|}{|D_u| + \max_{u' \in U'} |D_{u'}|}$$

If the users are selected in an ascending order of the size of their object-sets, we show that $\bar{\sigma}_u$ is an upper bound on the similarity score between u and a user u' with fewer or equal objects.

LEMMA 2. *Let a user u and a set of users U' . If for every user $u' \in U'$ $|D_{u'}| \leq |D_u|$, then it holds that $\sigma(u, u') \leq \bar{\sigma}_u$.*

PROOF. Let for any user $u' \in U'$, $m_u = |\bigcup_{u'' \in U'} M(D_u, D_{u''})|$, $m_{u'} = |M(D_u, D_{u'})|$, $m_{u''} = |M(D_{u'}, D_u)|$, $d_u = |D_u|$ and $d_{u'} = \max_{u'' \in U'} |D_{u''}|$. Then, since $m_u \geq m_{u''}$ and $d_{u'} \geq d_{u''}$ it holds that

$$\frac{m_u + d_{u'}}{d_u + d_{u'}} \geq \sigma(u', u).$$

We show that:

$$\bar{\sigma}_u = \frac{m_u + d_{u''}}{d_u + d_{u''}} \geq \frac{m_u + d_{u'}}{d_u + d_{u'}}.$$

$$\begin{aligned} \frac{m_u + d_{u''}}{d_u + d_{u''}} &\geq \frac{m_u + d_{u'}}{d_u + d_{u'}} \Rightarrow \\ m_u \cdot d_u + m_u \cdot d_{u''} + d_{u''} \cdot d_u + d_{u''} \cdot d_{u'} &\geq \\ m_u \cdot d_u + m_u \cdot d_{u''} + d_{u'} \cdot d_u + d_{u'} \cdot d_{u''} &\Rightarrow \\ (d_{u''} - d_{u'}) \cdot d_u &\geq (d_{u''} - d_{u'}) \cdot m_u, \end{aligned}$$

This holds since $d_{u''} \geq d_{u'}$ and $d_u \geq m_u$. \square

In order to avoid the computation of exact similarity scores among user objects, and speed up the bound calculation process, we follow the same principle with the filtering step from the S-PPJ-F algorithm. We utilise the spatio-textual index described in Figure 3 and place in $M(D_u, D_{u'})$ every object with a token that appears (due to a previously selected user) in the same or adjacent cell. This process provides a fast estimation of the $\bar{\sigma}_u$ bound. Since this process overestimates, the resulting score is still an upper bound on the actual user

similarity score and can be used to prune the search space. This process yields relaxed bounds, which are irrelevant for a fixed user similarity threshold (as in the case of STPSJoin). However, it is useful with respect to the top- k algorithms that quickly increase the user similarity threshold.

5. EXPERIMENTAL EVALUATION

Next, we present our experimental evaluation of the proposed algorithms. We first describe the datasets used and the parameters involved, and then we present the results.

5.1 Experimental Setup

Datasets. We have used three real-world datasets of spatio-textual web objects for our experiments. The *Flickr* dataset is derived from the Flickr Creative Commons dataset provided by Yahoo [35]. The whole dataset contains about 99.3 million images, about 49 million of which are geotagged. For our experiments, we concentrate on objects from the geographical boundaries of London, UK and we filtered out images that do not contain coordinates or tags as well as those that are created by stationary users. The resulting dataset contains 11,306 users and 1,116,348 objects. The *GeoText* dataset [18] is a geotagged microblog corpus available online.¹ It comprises 377,616 posts by 9,475 different users within the US. Finally, the *Twitter* dataset is a collection of geotagged tweets from the geographical area of London, UK, that we have collected and is part of the dataset used in [17]. It contains 9,724,579 tweets generated by 40,000 different users in 2014.

The NLTK toolkit² was employed to identify named entities from the text associated with the objects. The extracted named entities were used in combination with other related information, such as tokens, hashtags and mentions, as keywords associated with the respective objects. The characteristics of the three datasets are summarized in Table 1.

Evaluation measures and parameters The purpose of the experimental evaluation is to compare the performance of the proposed algorithms in terms of the execution time in different settings. For the case of the STPSJoin query, we investigate the effect of the following parameters: (a) the dataset size N in terms of number of users, (b) the query thresholds for spatial distance (ϵ_{loc}), textual similarity (ϵ_{doc}) and user similarity (ϵ_u) and (c) the *fanout* parameter of the R-tree structure. The effect of these parameters on the results of the STPSJoin query in the experimental datasets are described in Table 2. The largest deviation is observed on the Flickr dataset. This is consistent with the nature of this dataset, since popular POIs are often described using similar textual descriptions as well as photographs depicting these POIs are usually captured in nearby locations. On the contrary, the other datasets contain tweets, which are significantly more diverse both with respect to spatial locations and textual descriptions. For the top- k STPSJoin query, we investigate the effect of the parameter k on execution time.

All algorithms were implemented in Java, and the experiments were executed on a machine with an Intel Core i5 2400 CPU and 16GB RAM, running on Ubuntu Linux. During the experiments, 15GB of memory were allocated to the JVM. All plots report running time in a logarithmic scale.

Table 2: Mean (std-dev) of result-set sizes

5.2 Scalability

The scalability experiments evaluate the performance of our methods in datasets of different sizes. We divided the Twitter, Flickr and GeoText datasets for variable numbers of users. The resulting datasets range from 4,000 users with 72,094 objects to 40,000 users with 9,724,579 objects. Different parameter values are used for different datasets, in order to account for different sizes and token selectivity across datasets. Lower thresholds are set for the GeoText dataset in order to avoid empty result sets, whereas higher thresholds are set for the Flickr dataset to account for the higher similarity between user objects. This is due to the fact that a large amount of Flickr photos represent popular POIs that are described by similar textual content and are geo-located close to the location of the corresponding POIs.

Figure 4 shows the scalability evaluation results. The results clearly show that S-PPJ-F outperforms the other methods by several orders of magnitude. This is consistent for all datasets, irrespective of size. The efficiency of S-PPJ-F compared to the other approaches is attributed to the effect of the filter and refinement scheme, in combination with the suitability of the dynamic grid partitioning over the objects. The grid partitioning is tailor made to the spatial threshold parameter ϵ_{loc} , which allows the search for matching objects to be limited exclusively in adjacent cells. Additionally, the inverted lists maintained within each cell of the grid, allow the effective filtering of candidate user pairs associated with spatially similar, but textually diverse, objects.

The performance of S-PPJ-B does not compare favourably against S-PPJ-F. This result is expected since S-PPJ-F builds on S-PPJ-B by leveraging the filter and refinement scheme.

Nevertheless, the comparison between S-PPJ-B and S-PPJ-C allows the evaluation of the early termination strategy, as well as the traversal mechanism, differentiating S-PPJ-B from S-PPJ-C. The results indicate that S-PPJ-B offers a consistent improvement in execution time compared to S-PPJ-C, confirming that the proposed techniques manage to prune the search space for similarity search among two point sets.

Finally, the results show that S-PPJ-D outperforms the baseline methods, but it is not comparable to the grid-based S-PPJ-F, which follows the same principles. The discrepancy in execution time can be attributed to the use of different spatial indexes. The data driven-partitioning imposed by the R-tree is independent of the spatial threshold given as a parameter to the STPSJoin query. As a result, the imposed partitioning leads to an ineffective division of the database. Inspection of the performance of S-PPJ-D shows that both partition size and overlap may lead to subpar performance, since objects within large partitions tend to be spatially irrelevant, and overlaps require the evaluation of multiple join operations. We revisit this issue in Section 5.4.

5.3 Effect of similarity thresholds

In the following experiments, we vary the parameters and evaluate the proposed algorithms for different combinations of textual, spatial and user similarity thresholds. Similar to the scalability experiments, different ranges in threshold values are used across datasets.

Figure 5 presents the results. We observe that the dominant parameter is the spatial threshold ϵ_{loc} . High values on ϵ_{loc} result in significantly higher execution times. This is particularly obvious for the Flickr and Twitter datasets, which contain significantly larger amounts of objects. When the spatial distance threshold reaches metropolitan level distances, the majority of the objects fall into adjacent partitions. As a result, the filtering step of S-PPJ-F and S-PPJ-D returns a high number of candidates. In these cases, the overhead imposed by the additional indexing maintained by S-PPJ-F and S-PPJ-D is apparent. We observe a peak in the case of S-PPJ-D, especially with respect to the Flickr

Figure 5: Results for varying similarity thresholds (GeoText: 6,000 users, 107,941 objects; Flickr: 6,000 users, 597,008 objects; Twitter: 20,000 users, 4,988,090 objects).

dataset. In this case, inspection shows that the R-tree partitioning does not manage to result in an efficient partition of the object database.

This does not apply for GeoText, mainly due to the fact that the objects in GeoText are scattered in the significantly larger area of the whole of USA. The results show that the proposed pruning strategies are highly functional in combination with a grid-based partitioning scheme. S-PPJ-F outperforms the other methods in every scenario, and apart from the case of the Flickr dataset with $\epsilon_{loc} = 0.01$, its performance is independent of the parameter values.

5.4 Effect of Fanout on S-PPJ-D

An important parameter for data partitioning schemes based on R-trees is the *fanout* parameter. This parameter is associated with the number of objects that reside in a node of the R-tree. The effect of the fanout parameter on the performance of S-PPJ-D is twofold. First of all, S-PPJ-D executes a spatial distance join in order to identify spatial relations among the leaf nodes of the tree, which are treated by the algorithm as spatial data partitions. Since the fanout parameter affects both the depth and the breadth of the R-tree, it also affects the performance of the spatial join. Second, S-PPJ-D is built on top of the partitioning imposed by the leaf nodes. Therefore, the fanout affects both the number and the size of leaf nodes, which are relevant to S-PPJ-D.

In order to experimentally evaluate the effects of the fanout parameter, experiments with values ranging from 50 to 250 were conducted. The results are shown in Figure 6. The results verify that S-PPJ-D is sensitive to the fanout value. Even though no single fanout value achieves the best results in all datasets, we observe that an appropriate fanout value for STPSJoin queries falls within the range of 100 to 200.

Figure 6: Tuning the R-Tree fanout parameter.

5.5 Evaluation of top-k STPSJoin

In the following, we evaluate the proposed algorithms for the top- k STPSJoin query. We vary the result size k in order to study the behaviour of the algorithms. Figure 7 shows the results of the experiments. The baseline TOPK-S-PPJ-F is competitive and is the better performing algorithm in the Flickr dataset. The poor performance of TOPK-S-PPJ-S shows that the simple ordering of the users based exclusively on the size of their object-sets is more efficient than the statistical approach that it follows, compared to the overhead that the additional computation imposes. TOPK-S-PPJ-P exploits an additional pruning step and offers a better performance in the cases of GeoText and Twitter. In the case of Flickr, while it is outperformed by TOPK-S-PPJ-F, it remains competitive. This is due to the fact the the Flickr dataset contains objects with very high similarity, mainly because of the nature of the Flickr service (ie. people describe popular places with nearly the same keywords). The

Figure 7: Results for the top- k STPSJoin algorithms on GeoText, Flickr and Twitter datasets with varying k (GeoText: $\epsilon_{loc} = 0.001$, $\epsilon_{doc} = 0.3$, $\epsilon_u = 0.3$; Flickr: $\epsilon_{loc} = 0.001$, $\epsilon_{doc} = 0.6$, $\epsilon_u = 0.6$; Twitter: $\epsilon_{loc} = 0.001$, $\epsilon_{doc} = 0.4$, $\epsilon_u = 0.4$).

very high textual similarity between objects leads to high user similarities. Therefore, the additional filtering step of TOPK-S-PPJ-P cannot disqualify large numbers of user pairs.

5.6 Parameter Tuning

The STPSJoin query requires ϵ_{loc} , ϵ_{doc} , and ϵ_u to be provided as input. The values of these thresholds define what is “near” in terms of spatial, textual and user similarity, and are determined by the nature of the data and task in hand. In order to tackle situations in which there is no prior knowledge that can be used to determine the values of these thresholds, we present an automated process in order to discover sensible thresholds. In this case, the necessary input is an acceptable result set size.

The tuning algorithm is initialised with relaxed initial thresholds. Our experiments show that these can be predefined values regardless of the dataset. The only requirement is that they are relaxed enough to guarantee a result-set larger than the input value. Threshold steps are calculated as fractions of the initial values.

The algorithm follows a greedy strategy. Initially, it executes S-PPJ-F using the starting thresholds and populates a result-set. Then, the process traverses the parameter combination space in a depth-first manner. At any given step the algorithm selects probabilistically which parameter to tighten (an alternative strategy is to modify the least modified threshold). Tightening the parameters monotonically decreases the results-set that was the outcome of the previous step. As a result, S-PPJ-F is not executed again for the different parameters. Instead, PPJ-C is used to identify which pairs from the previous step adhere to the new thresholds. If the result set size reaches the desired value, the algorithm stops and the current threshold values are returned. If a step brings about thresholds that yield no results, the process backtracks to the previous step, and an alternative threshold is tightened.

	S-PPJ-F		Tuning	
Result size	5	25	25	50
GeoText	2,229	145 (8)	124 (4)	110 (3)
Flickr	24,363	738 (23)	693 (17)	1,066 (10)
Twitter	82,412	1,278 (10)	3,085 (7)	1,439 (2)

Table 3: Parameter tuning including S-PPJ-F time and tuning time in ms (number of iterations) for varying result-sets.

Table 3 shows the time required for parameter tuning after the initial execution of S-PPJ-F. Initial thresholds were the minimum thresholds used in Section 5.3, and the datasets were those with the minimum number of users used in Section 5.2. It is worth noting that the initial running time of S-PPJ-F consumes a significant amount of the overall time.

5.7 Summary

Our experimentation verifies the superiority of the proposed algorithms for the treatment of the STPSJoin query, in terms of execution time for all datasets used. The pruning strategy employed by S-PPJ-F manages to significantly boost the algorithm’s performance. Furthermore, the S-PPJ-D algorithm which induces data partitioning is efficient enough to be considered as a viable choice in cases when the data are already partitioned with an R-tree (or any other data partitioning method). Our experimentation shows that S-PPJ-F can be directly modified to efficiently handle the top- k STPSJoin query variant. Nevertheless, we propose an additional pruning strategy in top- k STPSJoin that performs even better with datasets of lower degrees of similarity. Even in the case of the Flickr dataset, which does not fall into this category, TOPK-S-PPJ-P achieves competitive results. The experimental analysis is conducted on three real datasets of varied size (the two of them are publicly available) and different parameter settings have been examined in order to reach to the optimum configurations. The results show that the algorithms scale well in very large databases and can therefore be used effectively in real-world scenarios.

6. CONCLUSIONS

This paper studies the problem of similarity search on spatio-textual point sets. We formally define this problem as STPSJoin and present its top- k variant. STPSJoin queries identify pairs of similar users, with respect to web documents such as tweets and photographs associated with these users.

In order to efficiently process (top- k) STPSJoin queries, we propose algorithms that leverage different spatio-textual indexes, and integrate early termination pruning mechanisms with filter and refinement approaches. We conducted large-scale experiments on real-world datasets for multiple values on the problem parameters. The better performing algorithm S-PPJ-F is orders of magnitude more efficient in terms of execution time than the baseline methods. Finally, S-PPJ-D shows improvement over the baseline methods for

the case of data-driven partitioned databases, even though it is significantly outperformed by S-PPJ-F. For the case of the top- k STPSJoin query, the TOPK-S-PPJ-P algorithm offers the best results in the majority of the datasets, but also remains competitive in the case of the Flickr dataset, which contains significantly larger amounts of similar spatio-textual objects.

In the future, we plan to focus on distributed architectures in order to further enhance the efficiency of our methods. Furthermore, we intend to integrate additional characteristics in STPSJoin queries, which are often associated with web objects, such as temporal information.

ABSTRACT

In this paper, we study a novel type of spatial queries, namely Nearest Window Cluster (NWC) queries. For a given query location q , NWC (q, l, w, n) retrieves n objects within a window of length l and width w , where the distance between the query location q to these n objects is the shortest. To facilitate efficient NWC query processing, we identify several properties and accordingly develop an NWC algorithm. Moreover, we propose several optimization techniques to further reduce the search cost. To validate our ideas, we conduct a comprehensive performance evaluation using both real and synthetic datasets. Experimental results show that the proposed NWC algorithm, along with the optimization techniques, is very efficient under various datasets and parameter settings.

Keywords: Nearest window cluster query, spatial query processing, location-based service, spatial database.

1. INTRODUCTION

Spatial queries have received tremendous attention from the research community in past decades. In the past several years, owing to the emerging location-based services, a number of new spatial queries have been proposed to meet various application needs [16] [11][7][13][22][9]. However, many interesting/important applications still are not well supported by existing spatial queries. The following is an example.

- Suppose Bob is attending a business meeting in a foreign city. He wishes to buy some souvenirs for his family. With only a rough idea of what to buy (e.g., some local-brand clothes), he would like to search for some, say n , nearby clothes shops which are close to each other in a small area so he can walk around these clothes shops to find the souvenirs.

In this example, Bob aims to find the nearest area with sufficient choices (i.e., n clothes shops) clustered in the area so he can go around to compare products and prices and even have fun doing some bargaining. Figure 1 illustrates the example above where each

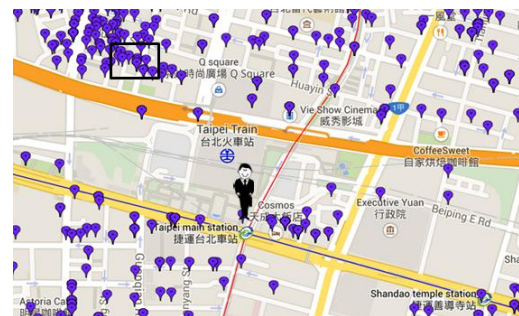

Figure 1: Example of a nearest window cluster query.

bubble indicates a clothes shop. Ideally, a location-based service would be able to suggest the clothes shops within the window back to Bob. Unfortunately, existing spatial queries such as kNN, trip-planning queries [15] and collective spatial keyword queries [2] do not meet Bob's need effectively and efficiently. To the best of our knowledge, no previous work on spatial queries address the query problem arising in the example scenario.

In this paper, we propose a novel type of spatial queries, namely *Nearest Window Cluster (NWC)* queries that finds a clustered of objects located in a spatial window nearest to a query point, e.g., the query issuer's location. Given a query point q , window length l and window width w , and the number of objects to find n , NWC (q, l, w, n) returns n objects located within a window of length l and width w , where the *distance* from these n objects to q is the shortest.¹

Two main challenges arise in processing the NWC queries. First, while the locations of data objects are given, the locations of *qualified* windows are unknown in advance.² Second, the number of qualified windows may be huge. To address these challenges, we identify several properties that allow us to find qualified windows quickly. Accordingly, we develop an NWC algorithm that iteratively finds the nearest qualified window to return the objects within the qualified window. To facilitate efficient visits of data objects, we adopt R-tree to index the data objects.

Observing that the bottleneck of the NWC algorithm lies in finding the nearest qualified window, we propose four optimization techniques, namely *search region reduction (SRR)*, *distance-based pruning (DIP)*, *density-based pruning (DEP)* and *incremental window query processing (IWP)* to accelerate searching the nearest

¹We will discuss distance measures in Section 2.

²A window is considered as qualified if it contains n objects.

qualified window, thereby improving the efficiency of the NWC algorithm. The SRR technique takes advantage of the distance of the best objects found so far to shrink the search regions of qualified windows and prune some objects from further processing. The DIP technique uses the distance of the best objects found so far to safely prune the index nodes distant from the query location q , thereby reducing the I/O cost. Inspired by the *clustering effect* of spatial objects [1] (e.g., certain objects such as clothes shops are usually clustered in some hot areas), the DEP technique maintains a density grid of the whole object space that records the number of objects in each grid cell. With the density grid, the DEP technique is able to prune the index nodes with insufficient objects and to avoid redundant window queries incurred during query processing. Finally, to alleviate the cost of window queries generated by the NWC algorithm, the IWP technique inserts *backward* and *overlapping pointers* into the leaf nodes and some intermediate nodes of the R-tree. With these pointers, fewer index nodes are involved for window queries, thereby achieving better performance.

The rest of this paper is organized as follows. In Section 2, we review related work and present the problem definition. In Section 3, we elaborate the properties of NWC queries and develop the NWC algorithm based on these properties. In addition, four optimization techniques are proposed to accelerate NWC query processing. The performance of the NWC algorithm is analyzed in Section 4, while the experimental results of the NWC algorithm are reported in Section 5. Finally, we conclude this paper in Section 6.

2. PRELIMINARIES

2.1 Problem Formulation and Transformation

Based on the application scenario discussed earlier, we consider a set of static data objects, denoted as P , in two-dimensional Euclidean space.³ The nearest window cluster query is formally defined as below.

Definition 1 (Nearest Window Cluster (NWC) Query) Given a query point q , a spatial window area specified by length l and width w , and the number of data objects n , a nearest window cluster query $NWC(q, l, w, n)$ aims to retrieve n objects satisfying the following criteria:

1. these n objects are clustered within a spatial window of length l and width w , and
2. the *distance* from the window with these n objects reside to q is the shortest among all other windows with n objects satisfying (1).

To facilitate our discussion, we define the notion of qualified window with respect to an NWC query as follows.

Definition 2 (Qualified Window) Given an NWC query (q, l, w, n) , a *qualified window*, denoted as $qwin$, is a window of length l and width w that contains data objects $S_{qwin} = \{p_1, p_2, \dots, p_{|S_{qwin}|}\} \subseteq P$, where $|S_{qwin}| \geq n$.

Let $MINDIST(q, qwin)$ be the distance from q to the closest point in the qualified window $qwin$ covering $\{p_1, p_2, \dots, p_n\}$. As the distance measure mentioned above aims to measure the distance between q and these n objects, denoted as $\{p_1, p_2, \dots, p_n\}$, we consider the following in our algorithm.

³We focus on 2D data objects in accordance with real-world applications. The proposed algorithms could be easily adjusted to three dimensional space.

- Minimum distance:

$$dist_{min}(q, \{p_1, p_2, \dots, p_n\}) = \min_{i=1,2,\dots,n} dist(q, p_i) \quad (1)$$

- Maximum distance:

$$dist_{max}(q, \{p_1, p_2, \dots, p_n\}) = \max_{i=1,2,\dots,n} dist(q, p_i) \quad (2)$$

- Average distance:

$$dist_{avg}(q, \{p_1, p_2, \dots, p_n\}) = \frac{1}{n} \sum_{i=1}^n dist(q, p_i) \quad (3)$$

- Nearest window distance:

$$dist_{nearest}(q, \{p_1, p_2, \dots, p_n\}) = \min_{\forall qwin \in qwins} (MINDIST(q, qwin)), \quad (4)$$

where $qwins$ is a set of all qualified windows containing $\{p_1, p_2, \dots, p_n\}$.

With the above definitions, we can transform the problem of NWC query processing as below.

Problem Transformation. When $MINDIST(q, qwin)$ is always smaller than or equal to $dist(q, \{p_1, p_2, \dots, p_n\})$, the processing of an NWC query can be performed by incrementally finding the next nearest qualified window to q and using the distance of the best objects found so far, denoted as $dist_{best}$, to prune the search space until no better qualified window is found.

Specifically, we can solve the NWC query by the following steps.

Step 1: Set $dist_{best}$ to ∞ and set $objs$ to \emptyset .

Step 2: Find the nearest qualified window $qwin$.

Step 3: If $qwin$ is found and $MINDIST(q, qwin) < dist_{best}$, perform Steps 4-6. Otherwise, go to Step 7.

Step 4: Let $\{p_1, p_2, \dots, p_n\}$ be the n objects in $qwin$ of the shortest distance to q .

Step 5: If $dist(q, \{p_1, p_2, \dots, p_n\}) < dist_{best}$, set $objs$ to $\{p_1, p_2, \dots, p_n\}$ and $dist_{best}$ to $dist(q, \{p_1, p_2, \dots, p_n\})$.

Step 6: Find the next nearest qualified window $qwin$ and go to Step 3.

Step 7: Return $objs$.

Clearly, $MINDIST(q, qwin)$ is always smaller than or equal to minimum, maximum, average and nearest window distances between q and $\{p_1, p_2, \dots, p_n\}$ (see Equations (1), (2), (3) and (4), respectively). As the bottleneck of the above procedure is in finding the nearest qualified window, we will focus on nearest qualified window search for the rest of this paper. The advantages of using nearest qualified window search to process an NWC query are twofold. First, the above procedure can be used for other distance measures as long as $MINDIST(q, qwin)$ can be used as the lower bound of the employed distance measures. Second, the properties of nearest qualified window search can be used to efficiently process NWC queries.

Table 1: List of used symbols

Symbol	Description
P	Data object set
T_P	R-tree on P
q	query location
n	the desired number of data objects
SR_p	search region of object p
$qwin_p$	best qualified window of p
S_{qwin_p}	the set of the data objects inside $qwin_p$
$ S_{qwin_p} $	the cardinality of S_{qwin_p}
$dist(q, \{p_1, p_2, \dots, p_n\})$	the distance between q and $\{p_1, p_2, \dots, p_n\}$
$objs$	the best objects found so far
$dist_{best}$	the distance of the best objects found so far

2.2 Related Work

In the past two decades, a large number of spatial queries have been proposed and studied by researchers in the database community. Here we focus on the variants of NN queries due to their relevance to our work. Constrained NN [8] queries find the nearest neighbor(s) constrained to a specific region instead of the entire data space. Nearest surround (NS) queries [13] consider the object orientation and retrieve the nearest neighbors at different angles with respect to the query location q . A reverse NN (RNN) query [12][21] finds all the data objects with q as their nearest neighbor. RkNN queries [19][3] search for all the data objects that have q as one of their k nearest neighbors. The ranked RNN (RRNN) query [14] allows to identify and rank the t data objects most influenced by q . Different from typical RNN queries, RFN [22] queries find the objects that have q as their *furthest* neighbor. With RFN queries, a plant producing hazardous gas could be constructed at a point with fewest residents being affected.

Group NN (GNN) queries [16] (also known as aggregate NN [17] queries) retrieve the data object(s) with the smallest sum of distance to Q where Q is the set of query points. GNN queries are useful when a group of friends intend to find a meeting restaurant with the minimum distances to them. Group nearest group (GNS) queries [6], a generic version of GNN queries, return more objects for gathering to reduce the traveling costs of users. With data object set P and target object set Q , optimal-location-selection (OLS) queries [9] find $q \in Q$ outside a specific region R with maximal optimality where the optimality metric is determined by the number of data objects in R and the accumulated distances to q . OLS query is useful for applications like optimal lifeguard station selection. Range NN (RangeNN) queries [11][5] search for the NNs for every point in a rectangle. It could be used to offer location privacy and computation saving. Given a specified window size, the maximizing range sum (MaxRS) problem [4] is to find the window win with the largest sum of weights of all objects within win among all candidate windows of the specified window size. Although bearing similarity to the proposed NWC queries, the MaxRS problem does not consider any query location and thus is naturally different from the proposed NWC query.

3. PROCESSING NEAREST WINDOW CLUSTER QUERIES

In this section, we elaborate the NWC query processing based on the procedure of nearest qualified window search mentioned in Section 2.1. First, we identify some unique properties of the nearest qualified windows in Section 3.1. Based on these properties, we develop an NWC algorithm to find the nearest qualified window of

the NWC query in Section 3.2. To improve the efficiency of NWC search, in Section 3.3, we further propose four optimization techniques, including (i) *search region reduction*, (ii) *distance-based pruning*, (iii) *density-based pruning* and (iv) *incremental window query processing* to reduce the search cost. To facilitate better readability, the symbols used throughout this paper are listed in Table 1.

3.1 Properties of the Nearest Qualified Windows

In this section, we introduce the following properties regarding the nearest qualified window to facilitate efficient NWC search.

Lemma 1 The nearest qualified window of an NWC query, or one of its equivalent qualified windows, has at least one object on one vertical edge and at least one object on one horizontal edge.

PROOF. The proof is omitted for the interest of space. \square

A qualified window $qwin$ is said to be *generated* by a data object p when p is on at least one edge of $qwin$. Therefore, we use data objects as the basis to *generate* qualified windows and consider only those qualified windows generated by some data objects for NWC query processing. In other words, we consider only those qualified windows generated by data objects on one vertical or horizontal edge based on the relative position of q and object p . Furthermore, based on Lemma 1, we can utilize the lying quadrant of p (with q as the origin) to determine that we merely need to evaluate the qualified windows with p on the right or left edge (top or bottom edge) by the following two observations.

1. Consider a qualified window, say $qwin$, generated by data object p on one of the vertical edges (denoted by e_R or e_L). When p is in the first or fourth quadrant with respect to the origin q , p must be on the right edge e_R of $qwin$; when p is in the second or third quadrant, p must be on the left edge e_L of $qwin$.
2. Consider a qualified window, say $qwin$, generated by data object p on one of the horizontal edges (denoted by e_T or e_B). When p is in the first or second quadrant with respect to the origin q , p must be on the top edge e_T of $qwin$; when p is in the third or fourth quadrant, p must be on the bottom edge e_B of $qwin$.

3.2 NWC Algorithm

With the above properties and the steps discussed in Section 2.1, we present the NWC algorithm which incrementally finds the next qualified window to q and uses the distance of the best object found so far ($dist_{best}$) to prune the search space until no better qualified window is found. Since the bottleneck of the NWC algorithm lies in finding the nearest qualified window, we focus on nearest qualified window search. The idea of the NWC algorithm is as follows. The NWC algorithm visits all data objects based on their distance to the query location q in ascending order. To facilitate efficient visits of data objects, we adopt R-tree to index the data objects. When visiting an object p , the NWC algorithm creates the *search region* for object p (denoted as SR_p) to cover all qualified windows generated by p , and then find all qualified windows generated by p (i.e., qualified windows within SR_p). When a qualified window, say $qwin_p$, is discovered and $MINDIST(q, qwin_p) < dist_{best}$, the NWC algorithm retrieves the n objects, say $\{p_1, p_2, \dots, p_n\}$, in $qwin_p$ of the shortest distance to q and checks whether $dist(q, \{p_1, p_2, \dots, p_n\}) < dist_{best}$. If so, the NWC algorithm sets $objs$ and $dist_{best}$ to $\{p_1, p_2, \dots, p_n\}$ and $dist(q, \{p_1, p_2, \dots, p_n\})$, respectively. The

NWC algorithm repeats the above steps until no better qualified window is found.

We now discuss how to build SR_p covering all qualified windows generated by p . According to the observations in Section 3.1, p has to be on the vertical and horizontal edges in order to guarantee all potential qualified windows generated by p are contained in SR_p . In fact, we consider p only on either the vertical or the horizontal edge for building SR_p because the other case is handled naturally while processing other objects. Specifically, if SR_p is built on the condition that p is on the vertical edge, the other potential qualified windows on the condition that p is on the horizontal edge will be contained within the search region of another object p' on the vertical edge (i.e., $SR_{p'}$). To avoid redundant computation, when visiting data object p , we consider p only on the vertical edge for SR_p construction. Due to space limitation, we mainly explain the case where p is in the first quadrant with respect to the origin q (i.e., p is on the right edge) since the other cases are able to be addressed similarly.

With p on the right edge, the four vertexes v_1, v_2, v_3 and v_4 of SR_p are defined below, where x_p and y_p are the x and y coordinates of p , respectively.

$$\begin{array}{llll} x_{v_1} = x_p - l & y_{v_1} = y_p - w & x_{v_2} = x_p & y_{v_2} = y_p - w \\ x_{v_3} = x_p & y_{v_3} = y_p + w & x_{v_4} = x_p - l & y_{v_4} = y_p + w \end{array}$$

It is obvious that all windows generated by p are inside SR_p . Therefore, the NWC algorithm is able to evaluate only data objects inside SR_p for identifying the qualified windows generated by p . To do so, the NWC algorithm retrieves all the objects within SR_p by issuing a window query with SR_p as the query window. To efficiently obtain the qualified windows generated by p , the NWC algorithm first reorders the objects in S_{SR_p} based on their y coordinates in ascending order and then skips the objects with y coordinates lower than p . The data objects below p are skipped because their associated qualified windows would not contain p . Finally, the NWC algorithm sequentially visits each object remaining in S_{SR_p} , say p' , to consider the window, say $qwin_{p'}$, with p on the right edge and p' on the top edge for each p' .

When a window $qwin_{p'}$ is considered, the NWC algorithm evaluates whether $qwin_{p'}$ is qualified. If the number of objects within $qwin_{p'}$ is smaller than n (i.e., $|S_{qwin_{p'}}| < n$), $qwin_{p'}$ is not qualified and the NWC algorithm skips $qwin_{p'}$. When $qwin_{p'}$ is qualified, (i.e., $|S_{qwin_{p'}}| \geq n$), the NWC algorithm retrieves the n objects, say $\{p_1, p_2, \dots, p_n\}$, in $qwin_{p'}$ of the shortest distance to q . If $dist(q, \{p_1, p_2, \dots, p_n\}) < dist_{best}$, the NWC algorithm sets $dist_{best}$ and $objs$ to $dist(q, \{p_1, p_2, \dots, p_n\})$ and $\{p_1, p_2, \dots, p_n\}$, respectively. Otherwise, the NWC algorithm skips $qwin_{p'}$ and considers another window generated by p .

We use the example in Figure 2 to illustrate the process of identifying qualified windows in SR_p . Let's consider an intermediate step, where p_5 is the candidate data object under examination. To find $qwin_{p_5}$, the NWC algorithm first builds SR_{p_5} based on the residing quadrant of p_5 to q and retrieves all data objects within SR_{p_5} . Since p_5 is in the first quadrant, the NWC algorithm sorts all data objects within SR_{p_5} based on their y coordinates in ascending order. As shown, the y coordinate of p_4 is smaller than that of p_5 , so the NWC algorithm skips p_4 and sequentially considers p_5, p_6 , and p_7 on the top edge. Suppose that the desired number of objects in a qualified window is three (i.e., $n = 3$). When p_5 is considered, the window with p_5 on the right and top edges is not qualified since this window contains only two objects. When p_6 is evaluated, the window with p_5 on the right edge and p_6 on

Figure 2: Discover $qwin_p$ from SR_p .

the top edge is set to $qwin_{p_5}$ since this window contains three objects. The NWC algorithm retrieves the three objects of the shortest distance to q from $qwin_{p_5}$ (i.e., $\{p_4, p_5, p_6\}$) and checks whether $dist(q, \{p_4, p_5, p_6\}) < dist_{best}$. If so, $dist_{best}$ and $objs$ are set to $dist(q, \{p_4, p_5, p_6\})$ and $\{p_4, p_5, p_6\}$, respectively. Then the NWC algorithm continues to find the next window in SR_p until all windows in SR_p have been evaluated.

3.3 Optimization Techniques

While being able to answer NWC queries, the NWC algorithm suffers from costly and redundant evaluations of objects and index nodes. In light of this, we design the following optimization techniques to mitigate the cost of NWC search.

- **Search region reduction (SRR):** The search region reduction technique exploits the distance between q and the best objects found so far (i.e., $dist_{best}$) to reduce the search regions of the remaining data objects, thereby saving the cost of qualified window discovery. Besides, with $dist_{best}$, SRR tries to exclude those objects that are unlikely to create closer qualified windows to q , eliminating the redundant evaluation of those objects.
- **Distance-based pruning (DIP):** The distance-based pruning technique takes advantage of $dist_{best}$ to save the access to the index nodes that are too distant to create closer qualified windows, thereby achieving reductions in I/O cost.
- **Density-based pruning (DEP):** We propose to build a density grid that maintains the number of objects residing in each grid cell. With the density grid, we propose a density-based pruning technique to prune the index nodes with insufficient objects (compared with the numbers of objects requested by NWC queries) to eliminate unnecessary I/O cost. In addition, DEP is able to prune some redundant window queries which do not produce any qualified window.
- **Incremental window query processing (IWP):** To reduce the I/O cost to process the window queries generated by the NWC algorithm, we propose to enhance the R-tree by inserting *backward pointers* and *overlapping points* into the leaf nodes and some intermediate nodes, respectively. We design the incremental window query processing technique to use these backward pointers and overlapping pointers to efficiently process these window queries with less I/O costs.

The details of these optimization techniques are described in the following subsections.

3.3.1 Search Region Reduction

To identify each qualified window $qwin_p$ generated by object p , the NWC algorithm issues a window query with the search region

Figure 3: Reduced SR_{p_5} with $dist_{best}$.

SR_p of p as the query window. Obviously, the smaller SR_p is, the lower the I/O cost is. Thus, we propose the search region reduction technique (abbreviated as SRR) to 1) avoid evaluations of unnecessary search regions or 2) reduce the sizes of the search regions by exploiting the following two observations.

- Object p may be so distant to q that all qualified windows generated by p having distances greater than $dist_{best}$. For such object p , building SR_p is unnecessary and thus no window query is issued.
- The qualified windows in the specific portions of SR_p may never have a distance smaller than $dist_{best}$. Thus, SR_p can be shrunk, leading to smaller query windows.

With $dist_{best}$, when processing object p , SRR first checks whether the creation of SR_p is necessary based on x_p or y_p . Specifically, let the coordinates of the bottom-left vertex of SR_p , say v_1 , be (x_{v_1}, y_{v_1}) . When the distance from q to v_1 is greater than $dist_{best}$, there is no need to build SR_p since no qualified window generated by p will be closer to q than $dist_{best}$. Thus, the reduced search region of p , denoted as SR'_p , is set to be empty. Otherwise, the building of SR_p is necessary. Then, SRR tries to utilize $dist_{best}$ to shrink SR_p into a smaller search region SR'_p so that the distance of each qualified window in SR'_p is shorter than $dist_{best}$. The coordinates of the four vertices of SR'_p are calculated below.

$$\begin{aligned} x'_{v_1} &= x_p - l & y'_{v_1} &= y_p - w & x'_{v_2} &= x_p & y'_{v_2} &= y_p - w \\ x'_{v_3} &= x_p & y'_{v_3} &= y_p + w' & x'_{v_4} &= x_p - l & y'_{v_4} &= y_p + w' \end{aligned}$$

It is clear that w' is the maximal value making the following two equations satisfied.

$$0 \leq w' \leq w \quad (5)$$

$$(x_p - l - x_q)^2 + (y_p + w' - w - y_q)^2 \leq dist(q, qwin_{best})^2 \quad (6)$$

Equation (5) indicates that p should be within SR'_p , while Equation (6) indicates that the minimum distance from q to each window of length l and width w in SR'_p should be shorter than $dist_{best}$. According to Equations (5) and (6), the value of w' is

$$w' = \min \left(w, \sqrt{dist_{best}^2 - (x_p - l - x_q)^2} - (y_p - w - y_q) \right).$$

In Figure 3, SSR helps to reduce SR_{p_5} with w' being only

$$\sqrt{dist_{best}^2 - (x_{p_5} - l - x_q)^2} - (y_{p_5} - w - y_q).$$

3.3.2 Distance-Based Pruning

Figure 4: Node N_2 can be safely pruned based on $dist_{best}$.

In addition to reducing search regions of objects, $dist_{best}$ is able to be used to safely prune some index nodes as long as all qualified windows created by any object inside these pruned index nodes are guaranteed to be of distances to q greater than $dist_{best}$. For example, index node N_2 in Figure 4 can be safely pruned because any qualified window created by any object inside N_2 is unlikely to have the distance to q smaller than $dist_{best}$. Based on this observation, we propose the distance-based pruning technique (abbreviated as DIP) to facilitate the pruning of unvisited index nodes. DIP defines a *pruning region* (denoted as PR) based on $dist_{best}$, l , and w . If an unvisited index node N is completely inside PR , N is able to be safely pruned without being visited. With $dist_{best}$, PR is defined as below.

$$\begin{aligned} PR_1 &= \{(x, y) | x \geq x_q + dist_{best} + l, y_q \leq y \leq y_q + w\} \\ PR_2 &= \{(x, y) | x_q \leq x \leq x_q + l, y \geq y_q + dist_{best} + w\} \\ PR_3 &= \{(x, y) | x \geq x_q + l, y \geq y_q + w \\ &\quad \wedge (x - (x_q + l))^2 + (y - (y_q + w))^2 \leq dist_{best}^2\} \\ PR &= PR_1 \cup PR_2 \cup PR_3 \end{aligned} \quad (7)$$

As defined in Equation (7), PR is composed of three subregions: PR_1 , PR_2 , and PR_3 . PR_1 guarantees that each qualified window generated by each object in PR_1 has the vertical distance to q greater than $dist_{best}$, while PR_2 ensures that the horizontal distance between q and each qualified window generated by each object in PR_2 is greater than or equal to $dist_{best}$. PR_3 excludes the region where an object can be used to generate a qualified window with the distance to q smaller than $dist_{best}$. Hence, if index node N is totally contained within PR , no closer qualified window can be generated by each object in N and thus N can be safely pruned to reduce I/O cost.

3.3.3 Density-Based Pruning

The spatial clustering effect in practice leads objects like clothes shops to be clustered in certain areas. Thus, an index node may be so sparse that all windows generated by each object in the index node are not qualified. With this observation, we devise the density-based pruning technique (abbreviated as DEP) to save I/O cost by avoiding visits to sparse index nodes. To facilitate DEP, the whole object space is divided into a $g_d \times g_d$ density grid and each grid cell is associated with the number of objects within the cell. When processing an index node, DEP first extends the MBR of the index node and checks whether the summation of the objects in the grid

Figure 5: An illustrative example of backward pointers

cells intersecting the extended MBR is smaller than n . If so, this index node will be pruned. We now describe the method to extend an MBR in the first quadrant with respect to the origin q , and the other cases can be handled in a similar manner. Suppose that the counterclockwise order of the four vertices of the MBR is v_1, v_2, v_3 and v_4 , and v_1 is the bottom-left vertex of the MBR. The MBR can be *extended* as follows to ensure that all windows generated by each object within the MBR must be within the extended MBR.

$$\begin{aligned} x'_{v_1} &= x_{v_1} - l & y'_{v_1} &= y_{v_1} - w & x'_{v_2} &= x_{v_2} & y'_{v_2} &= y_{v_2} - w \\ x'_{v_3} &= x_{v_3} & y'_{v_3} &= y_{v_3} + w' & x'_{v_4} &= x_{v_4} - l & y'_{v_4} &= y_{v_4} + w' \end{aligned}$$

Besides, it is possible that the search region of an object does not contain enough objects to generate any qualified window. DEP also utilizes this observation to eliminate the window queries of such objects with the aid of the density grid. Specifically, before issuing a window query for the currently processing object p , DEP checks whether the summation of the objects in the grid cells intersecting the search region SR_p is smaller than n . If so, DEP cancels the window query since SR_p never contains any qualified window.

3.3.4 Incremental Window Query Processing

As mentioned in Section 3.2, the NWC algorithm issues a window query with query window SR_p (SR'_p when SRR is used) to identify the qualified windows generated by object p . With traditional window query processing, solving a window query requires to access the R-tree from root node to some leaf nodes. However, we observe that some index nodes in the R-tree, especially the index nodes close to the root node, are usually unnecessary to visit when processing the window queries issued by the NWC algorithm. In view of this, we propose to add some *backward pointers* into each leaf node of the R-tree and some *overlapping pointers* into the nodes pointed by backward pointers. Based on backward and overlapping pointers, we design an incremental window query processing technique (abbreviated as IWP) to allow window queries to be processed from intermediate nodes instead of root node, thereby reducing the I/O cost.

Consider an R-tree with height h . Each leaf node is with depth h . Suppose that there are r backward pointers (denoted as $(bp_1, mbr_1^b), (bp_2, mbr_2^b), \dots, (bp_r, mbr_r^b)$) for each leaf node. It is obvious that SR'_p is very likely to be totally covered by the intermediate nodes

Figure 6: An illustrative example of overlapping pointers

close to the leaf node containing p . Thus, inspired by Exponential Index [20], for a leaf node s , the backward pointers are set by the following rules.

1. The first backward pointer bp_1 points to s .
2. bp_i , where $1 < i < r$, points to the ancestor of s with depth $h - 2^{i-2}$.
3. The last backward pointer bp_r points to the root node.
4. mbr_i^b , where $1 \leq i \leq r$, is the MBR of the node pointed by bp_i .

According to the third rule, r is the smallest integer making the following equation true.

$$h - 2^{r-2} \leq 0$$

Thus, we can obtain that $r = \lceil \log_2 h + 2 \rceil$.

Figure 5 shows an illustrative example of backward pointers. Only part of an R-tree with height eight is shown for better readability. Since $h = 8$, each leaf node is of $r = \lceil \log_2 8 + 2 \rceil = 5$ backward pointers (i.e., gray squares in Figure 5). bp_1 points to the leaf node, while bp_2, bp_3, bp_4 and bp_5 point to the ancestors of the leaf node with depth 7, 6, 4 and 0, respectively.

Since most variants of R-tree do not guarantee the MBRs of intermediate nodes in the same depth level to be non-overlapped, using only backward pointers to incrementally process window queries may lead to wrong query results. Therefore, some overlapping pointers are needed for the nodes pointed by backward pointers (except the root node) to facilitate correct incremental window query processing. We use the example in Figure 6 to illustrate the overlapping pointers. Since overlapping with two other nodes with the same depth, the node N_i is of two overlapping pointers $((op_1, mbr_1^o), (op_2, mbr_2^o))$ where op_j is the pointer pointing to the j -th intermediate node with the same depth as N_i and overlapping with N_i , and mbr_j^o is the MBR of the node pointed by op_j .

With backward pointers and overlapping pointers, a window query can be incrementally processed as follows. When an object p is inserted into the priority queue PQ , the backward pointers of the leaf node where p is stored are also inserted into PQ along with p . When processing the window query with SR'_p as the query window, instead of searching from the root node of the R-tree, IWP retrieves the corresponding backward pointers, finds the smallest value of i so that SR'_p is totally covered by mbr_i^b , and searches from the node pointed by bp_i . In addition, for each overlapping pointer op_j of the node pointed by bp_i , IWP also executes the window query from the node pointed by op_j when mbr_j^o overlaps with the query window.

Finally, the NWC algorithm enhanced with optimizations as well as some companion functions are given in Algorithms 1, 2 and 3.

3.4 k Nearest Window Cluster Query Processing

An NWC query is to provide the user with an area with n objects (choices). In practice, it is possible that the user even would like

Algorithm 1: NWC algorithm enhanced with optimizations

Data: NWC query (q, l, w, n) , priority queue PQ
Result: a set of n objects

```

1  $dist_{best} \leftarrow \infty, objs \leftarrow \emptyset, PR \leftarrow \emptyset$ ;
2  $PQ.enqueue(Root\ of\ T_p)$ ;
3 while  $|PQ| > 0$  do
4    $p \leftarrow PQ.dequeue()$ ;
5   if  $p$  is an index node then
6      $MBR_p \leftarrow$  the MBR of  $p$ ;
7     Extend  $MBR_p$  as  $MBR'_p$  based on DEP;
8     if  $MBR_p - PR \neq \emptyset$  and  $isPrunedByDEP(MBR'_p)$  is FALSE then
9       for each child  $c$  of  $p$  do
10         $PQ.enqueue(c)$ ;
11   else
12     //  $p$  is an object
13     determine the lying quadrant of  $p$  with respect to  $q$ ;
14     determine whether  $p$  is on the left or right edge;
15     build  $SR_p$  and reduce  $SR_p$  as  $SR'_p$  by SRR;
16     if  $SR'_p \neq \emptyset$  and  $isPrunedByDEP(SR'_p)$  is FALSE then
17        $S_{SR'_p} \leftarrow IWP(SR'_p)$ ;
18       sort  $S_{SR'_p}$  in ascending/descending order of y coordinates;
19       remove  $p_i$  from  $S_{SR'_p}$  when the y coordinate of  $p_i$  is
20         smaller/larger than the y coordinate of  $p$ ;
21       for  $i = 1$  to  $|S_{SR'_p}|$  do
22         build  $qwin_p$  by setting  $p$  on the right/left edge and  $p_i$  on the
23         top/bottom edge;
24         if  $|S_{qwin_p}| \geq n$  and  $MINDIST(q, qwin_p) < dist_{best}$  then
25           let  $\{p_1, p_2, \dots, p_n\}$  be the  $n$  objects in  $qwin_p$  of the
26           shortest distance to  $q$ ;
27           if  $dist(q, \{p_1, p_2, \dots, p_n\}) < dist_{best}$  then
28              $dist_{best} \leftarrow dist(q, \{p_1, p_2, \dots, p_n\})$ ;
29              $objs \leftarrow \{p_1, p_2, \dots, p_n\}$ ;
30             update  $PR$  accordingly;
31 return  $objs$ ;

```

Algorithm 2: Function $isPrunedByDEP(rect, n)$

Data: a rectangle $rect$
Result: whether $rect$ is pruned by DEP

```

1  $ub \leftarrow 0$ ;
2 for each cell  $cell$  in the density grid do
3   if  $cell$  intersects  $rect$  then
4      $ub \leftarrow ub +$  the number of objects in  $cell$ ;
5 if  $ub < n$  then
6   return TRUE;
7 else
8   return FALSE;

```

Algorithm 3: Function $IWP(rect)$

Data: a rectangle $rect$
Result: the set of objects within $rect$

```

1  $result \leftarrow \emptyset, nodes \leftarrow \emptyset$ ;
2 fetch the backward pointers associated with  $p$ ;
3 for  $i = l$  to  $r$  do
4   if  $rect \subseteq mbr_i^b$  then
5      $N_i \leftarrow$  the index node pointed by  $bp_i$ ;
6     insert  $N_i$  into  $nodes$ ;
7     break;
8 for each overlapping pointer  $op_j$  of  $N_i$  do
9   if  $mbr_j^b \cap rect \neq \emptyset$  then
10    insert the index node pointed by  $op_j$  into  $nodes$ ;
11 for each node  $N$  in  $nodes$  do
12   perform traditional window query processing with query window  $rect$ 
13   starting from  $N$ ;
14   insert the resultant objects into  $result$ ;
15 return  $result$ ;

```

to retrieve multiple areas so that the user is able to pick a proper area from them. To satisfy such needs, we extend NWC queries to k NWC queries that enable users to retrieve k object groups where each group consists of n objects located within a window of length l and width w . It is obvious that the user is not willing to get k object groups and each pair of groups consist of almost the same objects. Thus, we introduce a new parameter m which allows a user to specify the maximal number of identical objects allowed in each pair of groups. The formal definition of a k NWC query is given below.

Definition 3 (k NWC Query) Given a query location q , a spatial window area specified by length l and width w , the number of data objects n , and the maximal number of identical objects, say m , in any two object groups, a k nearest window cluster (k NWC) query (k, q, l, w, n, m) retrieves k object groups, $objs_1, objs_2, \dots, objs_k$, satisfying the following criteria.

- Each object group consists of n objects within a window of length l and width w .
- For each pair of object groups, $objs_1$ and $objs_2$, there are at most m objects in both $objs_1$ and $objs_2$ (i.e., $|objs_1 \cap objs_2| \leq m$).
- The k object groups are ordered by their distances to q in ascending order. That is, $dist(q, objs_i) \leq dist(q, objs_j) \forall i, j$ where $i < j$.
- For each group of n objects, say obj'_j , within a window of length l and width w and $obj'_j \neq obj_i$ where $i = 1, 2, \dots, k$, at least one of the following conditions should be satisfied.
 1. $dist(q, objs_k) \leq dist(q, obj'_j)$.
 2. There exists an integer i ($1 \leq i \leq k$) so that $dist(q, obj_i) \leq dist(q, obj'_j)$ and $|obj_i \cap obj'_j| > m$.

It is obvious that Lemma 1 also holds for k NWC queries. To answer k NWC queries, similar to NWC queries, we are allowed to consider only those qualified windows with objects on their vertical and horizontal edges. Based on Lemma 1, we now design the k NWC algorithm, an extension of the NWC algorithm, to support k NWC queries as below. The k NWC algorithm maintains the k object groups $\{objs_1, objs_2, \dots, objs_k\}$ found so far in *groups* and sorts the k object groups by their distances to query location q in ascending order. The optimization techniques proposed in Section 3.3 can also be used to mitigate the I/O cost of identifying the nearest qualified windows of a given k NWC query. Specifically, when k object groups are obtained, the distance between q and the k -th object group (i.e., $dist(q, objs_k)$) is employed in SRR to reduce the search regions of remaining objects and in DIP to prune remaining index nodes. When finding a qualified window $qwin_p$, the k NWC algorithm performs the following steps to handle $qwin_p$.

- Step 1: Let $objs_p = \{p_1, p_2, \dots, p_n\}$ be the n objects in $qwin_p$ of the shortest distance to q .
- Step 2: Scan *groups* in reverse order to find the first object group, say $objs_i$, which is of distance shorter than $objs_p$. In case that no such i exists, set i to 0 and go to Step 4. If $i = k$, drop $objs_p$ and stop this procedure.
- Step 3: Check whether $|objs_p \cap objs_j| \leq m$ for each $objs_j$, $j = 1, 2, \dots, i$. If not, drop $objs_p$ and stop this procedure.
- Step 4: Remove $objs_k$ from *groups* and insert $objs_p$ into *groups* at position $i + 1$ (i.e., as $objs_{i+1} = objs_p$).

Figure 7: Illustration of analysis

- Step 5: Check whether $|objs_p \cap objs_j| \leq m$ for each $objs_j$, $j = i+2, i+3, \dots, k-1$. Remove $objs_j$ from groups when $|objs_p \cap objs_j| > m$.

4. THEORETICAL ANALYSIS

4.1 Time Complexity Analysis of NWC Algorithm

In this section, we develop a cost model to analyze the I/O cost of the NWC algorithm. To facilitate the following discussion, as shown in Figure 7, the space is divided into multiple disjoint rectangles of height l and width w . Since the NWC algorithm visits the objects according to their distances to q in ascending order [10], it is very likely that the NWC algorithm visits the objects in all level- i rectangles and then visits the objects in all level- $i+1$ rectangles until the best objects are found.

We assume that the objects in an area are Poisson distributed with mean λ . For simplicity, we also assume that the probability that a window is not qualified is independent of the probability of any other window. Thus, the average number of objects in a window of length l and width w is $\lambda \times l \times w$ and the probability that a window is not qualified is

$$\mathbf{P} = P\{X \leq n-1\} = e^{-\lambda \times l \times w} \sum_{i=0}^{n-1} \frac{(\lambda \times l \times w)^i}{i!}. \quad (8)$$

An object in a level- i rectangle is called a level- i object, while a qualified window generated by a level- i object is called a level- i qualified window. Due to the effect of DIP, we also assume that the objects within a level- i qualified window can be verified as the best objects only when 1) there is no level- j qualified window, where $j = 1, 2, \dots, i-1$, and 2) all level- i qualified windows have been checked.

Consider an object p . The NWC algorithm issues a window query to retrieve all objects within the search region of p (i.e., SR_p) and the average number of objects in the upper-half of SR_p is $\lambda \times l \times w$. For each object p' on the upper-half of SR_p , the NWC algorithm then generates one window with p on the right edge and p' on the top edge and checks whether the window is qualified or not. Thus, the average number of windows generated by an object is $\lambda \times l \times w$, and the probability that an object cannot generate a qualified window is $\mathbf{P}^{\lambda \times l \times w}$.

Let $\mathbf{N}(i)$ be the number of level- i rectangles and it is clear that

$$\mathbf{N}(i) = (2i)^2 - (2(i-1))^2 = 8i - 4. \quad (9)$$

We can obtain that the average number of level- i objects is $\mathbf{N}(i) \times \lambda \times l \times w$. Denote the probability that there is no level- i qualified window (that is, all windows generated by all level- i objects are not qualified) to be $\mathbf{Q}(i)$. Since there is no level-0 rectangle, $\mathbf{Q}(0) = 1$.

For each positive integer i , we can derive that

$$\mathbf{Q}(i) = \prod_{j=1}^i \mathbf{P}^{\lambda \times l \times w} = \mathbf{P}^{\mathbf{N}(i) \times (\lambda \times l \times w)^2}.$$

The probability that the qualified window consisting of the best objects is a level- i qualified window is $(1 - \mathbf{Q}(i)) \times \prod_{j=0}^{i-1} \mathbf{Q}(j)$.

Consider the case that the qualified window consisting of the best objects is a level- i qualified window. All level- j objects, where $j = 1, 2, \dots, i$, should be retrieved. Let the average number of objects to be retrieved in this case be $\mathbf{O}(i)$. We can obtain

$$\mathbf{O}(i) = \sum_{j=1}^i \mathbf{N}(j) \times \lambda \times l \times w = 2 \times i^2 \times \lambda \times l \times w. \quad (10)$$

Since these objects are retrieved in accordance with their distances to q , the average I/O cost to retrieve them is close to the average I/O cost of using K nearest neighbor query to retrieve $\mathbf{O}(i)$ objects. For each retrieved object p , the NWC algorithm issues a window query to get the objects within SR_p , and thus, the average number of issued window queries is $\mathbf{O}(i)$. Let the average I/O cost to use K nearest neighbor query to retrieve K objects be $\mathbf{KNN}(K)$, and let the average I/O cost of a window query of length l and width w be $\mathbf{WIN}(l, w)$. The average I/O cost when the qualified window consisting of the best objects is a level- i qualified window is $\mathbf{O}(i) \times \mathbf{WIN}(l, w) + \mathbf{KNN}(\mathbf{O}(i))$.

Suppose that the whole space contains at most level- $MaxLV$ rectangles. The average I/O cost of the NWC algorithm is

$$\sum_{i=1}^{MaxLV} \left\{ \left[(1 - \mathbf{Q}(i)) \times \prod_{j=0}^{i-1} \mathbf{Q}(j) \right] \times \left[\mathbf{O}(i) \times \mathbf{WIN}(l, w) + \mathbf{KNN}(\mathbf{O}(i)) \right] \right\},$$

where $\mathbf{WIN}(l, w)$ can be obtained from [18] and $\mathbf{KNN}(K)$ can be obtained from [10].

4.2 Time Complexity Analysis of k NWC Algorithm

Let the probability that a window is not qualified be \mathbf{P} where \mathbf{P} can be obtained by Equation (8). Let the probability that a qualified window consists of at most m identical objects with each object group in groups be $Pr(m, k)$. Thus, the probability that the objects within a window cannot be inserted into groups be $\mathbf{P}' = 1 - [(1 - \mathbf{P}) \times Pr(m, k)]$. Suppose that the object group within a level- i qualified window will not be removed from groups due to the insertion of any object group within a level- j qualified window where $j > i$. Therefore, when the object group within a level- i qualified window becomes the k -th nearest object group, the k NWC algorithm will terminate when all object groups within level- i qualified windows have been checked.

We now derive the probability that the k -th nearest object group is within a level- i qualified window. Due to the effect of SRR and DIP, we assume that the k -th nearest object group is within a level- i qualified window only when 1) the number of object groups within level- j , where $j = 1, 2, \dots, i-1$, qualified windows inserted into $qwins_{best}$ is smaller than k and 2) the number of object groups within level- j , where $j = 1, 2, \dots, i$, qualified windows inserted into $qwins_{best}$ is larger than or equal to k .

As shown in Equation (10), the average number of all level- j objects, where $j = 1, 2, \dots, i$, is $\mathbf{O}(i)$. Since the average number of windows generated by an object is $\lambda \times l \times w$, the probability that there are a object group within level- j , where $j = 1, 2, \dots, i$, qualified windows inserted into groups is

$$\mathbf{R}(i, a) = C_a^{\mathbf{O}(i) \times \lambda \times l \times w} \times (1 - \mathbf{P}')^a \times \mathbf{P}'^{\mathbf{O}(i) \times \lambda \times l \times w - a}.$$

Figure 8: Distributions of the used datasets

Table 2: Description of datasets

Dataset	Cardinality	Description
CA	62,556	Real places in California
NY	255,259	Real places in New York
Gaussian	250,000	Generated by Gaussian distribution

According to Equation (9), there are $N(i)$ level- i rectangles and the average number of level- i objects is $N(i) \times \lambda \times l \times w$. Therefore, the probability that there are at least b object groups within level- i qualified windows inserted into *groups* is

$$S(i, b) = 1 - \sum_{d=1}^{b-1} \left[C_d^{N(i) \times (\lambda \times l \times w)^2} \times (1 - P^d) \times P^{N(i) \times (\lambda \times l \times w)^2 - d} \right].$$

Therefore, the probability that the k -th nearest object group within a level- i qualified window is

$$\sum_{j=0}^{k-1} [R(i-1, j) \times S(i, k-j)].$$

When the k -th nearest object group is within a level- i qualified window, the k NWC algorithm visits all objects in all level- j rectangles, where $j = 1, 2, \dots, i$. Similar to the derivations in the previous subsection, the average I/O cost when the k -th nearest object group is a level- i qualified window is $O(i) \times \text{WIN}(l, w) + \text{KNN}(O(i))$. Suppose that space contains at most level- MaxLV rectangles. The average I/O cost of the k NWC algorithm is

$$\sum_{i=1}^{\text{MaxLV}} \left\{ \left[\sum_{j=0}^{k-1} [R(i-1, j) \times S(i, k-j)] \right] \times [O(i) \times \text{WIN}(l, w) + \text{KNN}(O(i))] \right\}.$$

5. PERFORMANCE EVALUATION

In this section, we conduct experiments to evaluate the performance of the proposed NWC algorithm and the proposed optimization techniques. All algorithms are implemented in Java. Three datasets, two real and one synthetic, are used in the evaluation. The CA dataset contains 62,556 places in California⁴, while the NY⁵ dataset contains 255,259 places in New York. The data space for these two real datasets are normalized to a square of width 10,000. The synthetic dataset is created based on Gaussian distribution with mean 5000 and standard deviation 2000. The cardinality of the Gaussian dataset is default at 250,000. These datasets are summarized in Table 2, while Figure 8 depicts the object distributions of

Figure 9: Effect of grid size

Figure 10: Effect of object distribution

these datasets.

All datasets are indexed by R^* -trees with the page size set to 4096 bytes. The maximum number of entries in a node is 50. The default value of n is 8 and the window length and width are both 8. The grid cell size is set to 25. Similar to [18][10], we consider I/O cost as the performance metric, which is the number of R^* -tree nodes visited, since I/O cost dominates the total execution time of the NWC algorithm. We run 25 queries for each experiment and report the average as the experimental result. To measure the benefit of each optimization technique, we separately run the experiments of the NWC algorithm augmented with each optimization technique (labelled as SRR, DIP, DEP and IWP, respectively). In addition, we devise a scheme NWC+ by enabling only SRR and DIP (which do not incur extra storage overhead). Finally, we devise a scheme NWC* which enables all optimization techniques proposed in this work. The schemes compared in the experiments are summarized in Table 3. In the following, we show our experimental results by varying various parameter settings, including grid size, object distribution, number of objects and window size.

5.1 Effect of Grid Size

In this experiment, we investigate the effect of the grid size by varying the grid size from 25 to 400. Since only scheme DEP uses the density grid, we present only the experimental results of scheme DEP here. Figure 9 shows that for the CA and Gaussian datasets, the I/O cost increases along with the grid size. With the smaller grid size, the granularity of the density grid gets finer. Thus scheme DEP is able to obtain tighter upper bounds during query processing, thus achieving better pruning effect. For the NY dataset, it is interesting to see that the I/O cost of scheme DEP stays nearly constant regardless of the grid size, as depicted in Figure 9. The reason is that the objects in the NY dataset are highly clustered in certain areas, resulting in less effective pruning even when the grid size is small. This result indicates that scheme DEP could not benefit from the density grid for extremely clustered data distributions.

5.2 Effect of Object Distribution

Figure 11: Effect of the number of search objects

Figure 12: Effect of window size

We study the effect of the object distribution on the performance of all the schemes in this experiment by generating five Gaussian datasets. We fix the same mean 5,000 but varying standard deviations from 2,000 to 1,000. As shown in Figure 10, the I/O cost of scheme NWC increases as the standard deviation decreases. When the standard deviation gets smaller, the data objects are more clustered and more objects are within search regions. Thus, scheme NWC has to access more nodes to process these window queries issued for the search regions. On the contrary, for schemes SRR, DIP, and NWC+, their I/O costs decrease as the standard deviation gets smaller. In our experiment, the I/O cost reduction rates of schemes SRR, DIP and NWC+ over scheme NWC increase from 57% to 93% as the standard deviation decreases from 2000 to 1000. This is because the more clustered object distribution leads these schemes to be able to find *locally best qualified windows* (a qualified window $qwin$ is called locally best if $MINDIST(q, qwin) < dist_{best}$ when $qwin$ is discovered) more easily, achieving better pruning effect. It is not surprising that scheme NWC+ outperforms schemes SRR and DIP by using SRR and DIP together.

On the other hand, the I/O costs of schemes DEP and IWP increase as the standard deviation decreases. As discussed above, scheme DEP performs well in nearly uniformly distributed datasets, but achieves relatively poor performance when the object distribution is highly clustered. In our experiment, the I/O cost reduction rate of scheme DEP over scheme NWC decreases from 54.8% to 14.1% along with the decrease of the standard deviation. Regarding scheme IWP, the performance downgrades owing to that the more highly clustered data objects cause more index nodes to overlap together and thus increases the number of overlapping pointers. The more overlapping pointers are, the more index nodes scheme IWP accesses. In our experiment, the I/O cost reduction rate of scheme IWP over scheme NWC decreases from 59.5% to 55.6% as the standard deviation decreases from 2000 to 1000. From the

experimental result, we can observe that the proposed optimization techniques are complementary with each other. SRR and DIP perform well on highly clustered datasets (i.e., with small standard deviations) while DEP and IWP outperform SRR and DIP on nearly uniformly distributed datasets (i.e., with large standard deviations). By combining the advantages of all the optimization techniques, scheme NWC* performs the best in terms of I/O cost and significantly reduces 98.3% I/O cost compared with scheme NWC. Moreover, the I/O cost reduction of scheme NWC* over scheme NWC+ is ranging from 73.8% to 79.7%, showing that the small storage overhead produced by DEP and IWP really pays off especially on the cases not suitable for SRR and DIP.

We now evaluate the storage overheads of scheme DEP and scheme IWP. When the grid size is set to 25, the density grid is of 160000 grids. As we use short integer to store the number of object in each cell, the storage overhead of DEP (the size of the density grid) is about 312KB. On the other hand, it is obvious that the numbers of backward and overlapping pointers are proportional of object numbers. The numbers of backward and overlapping pointers for the CA, NY and Gaussian datasets are 26473, 6236 and 29037, respectively. Suppose that the size of one pointer is 4 bytes. The storage overheads of IWP (the size of these pointers) in the CA, NY and Gaussian datasets are about 103KB, 24KB and 113KB, respectively. These storage overheads are acceptable.

5.3 Effect of the Number of Searched Objects

This experiment evaluates the effect of the number of searched objects n . In the experiment, we vary the value of n from 8 to 128. Note that we set the y axis in logarithmic scale in this and the following experiments due to the varied scale of I/O cost. Figure 11 shows that the I/O cost of scheme NWC almost stays constant because scheme NWC accesses all the objects in R*-tree regardless of the value of n . The other schemes suffer from higher I/O costs with the value of n increasing, because a larger value of n causes more

index nodes to be accessed in order to find the locally best qualified windows. When the value of n is too large to find any qualified window, schemes SRR, DIP and NWC+ would degenerate to scheme NWC since no pruning is achieved. As shown in Figure 11a, the I/O costs of scheme SRR, DIP, and NWC+ are equal to the I/O cost of scheme NWC when the value of n is larger than or equal to 32. Similarly, Figure 11c shows that schemes SRR, DIR, and NWC+ incur the same I/O cost as scheme NWC when the value of n is 8 or larger. These three schemes degenerate faster in the Gaussian dataset because the data objects are nearly uniformly distributed in the Gaussian dataset. Different from the CA and Gaussian datasets, schemes SRR, DIP, and NWC+ still outperform scheme NWC in the NY dataset even when the value of n is 128. The reason is that the highly clustered objects in the NY dataset allow these schemes to find locally best qualified windows quickly even for large values of n .

On the other hand, schemes DEP and IWP are more resilient to the increase of the value of n . For scheme DEP, it prunes more index nodes and search regions when the value of n gets larger. Thus, scheme DEP remains to perform well in the Gaussian dataset as long as the value of n is large to a certain extent. As shown in Figure 11c, when n increases from 8 to 128, the I/O cost reduction rate of scheme DEP over scheme NWC in the Gaussian dataset increases from 18% to 99.1%, showing the benefit of scheme DEP. For scheme IWP, a larger value of n only affects the performance slightly because IWP mainly focuses on saving the I/O cost of window query processing. As such, scheme IWP is able to reduce the I/O cost in the case that schemes SRR, DIP and DEP performs poorly (e.g., $n = 8$ in the Gaussian dataset). We can observe from Figure 11c that the I/O cost reduction rate of scheme IWP over scheme NWC keeps in 59.6% when n increases from 8 to 128. Due to the complementary advantages of the optimization techniques, scheme NWC* performs the best in all the cases, and compared with scheme NWC, is able to reduce 95.7%~99.4%, 97.6%~99.9% and 88.2%~99.1% I/O costs in the CA, NY and Gaussian datasets, respectively.

5.4 Effect of the Window Size

In this experiment, we explore the effect of the window size on I/O costs for all schemes by increasing the window length and width from 8 to 128. We can see in Figure 12 that the I/O cost of scheme NWC gets larger as the window size increases. This is because the larger window sizes result in larger search regions and more data objects involved in the discovery of qualified windows. On the contrary, as the window size increases, it is easier to find locally best qualified windows. With more locally best qualified windows, schemes SRR and DIP achieve better performance. We can see in Figure 12c that schemes SRR and DIP degenerate to scheme NWC in the Gaussian dataset when window size is set to 8. Setting window size to 8 is too small to find any qualified window in the Gaussian dataset since distribution of the objects in the Gaussian dataset is close to uniform distribution. Except for such an extreme case, the I/O cost reduction rates of schemes SRR and DIP over scheme NWC increase from 93.7% to 99.8% and from 95.5% to 99.9% in the CA and Gaussian datasets, respectively, as the window size gets from 16 to 128. As depicted in Figure 12b, the I/O cost reduction rates of schemes SRR and DIP over scheme NWC in the NY dataset keep in 99.5%~99.9%. The reason is that in the NY dataset, there are a large number of data objects and these data objects are highly clustered. Schemes SRR and DIP are still able to get enough locally best qualified windows even window size is set to 8. Thus, increasing the window size does not significantly increase I/O costs of scheme SRR and DIP. Similar to previous ex-

Figure 13: Effect of k

periments, scheme NWC+ outperforms schemes SRR and DIP in all cases.

On the contrary, schemes DEP and IWP do not benefit from larger window sizes. When the window size gets larger, the number of qualified windows increases, thereby reducing the pruning effect of DEP. As the window size is large to a certain extent, scheme DEP could not achieve any pruning and thus will degenerate to scheme NWC, referring to Figure 12a and Figure 12b. For scheme IWP, the large window size results in more overlapping index nodes when processing window queries, reducing the benefit of scheme IWP. As such, scheme IWP is less effective for large window sizes. Fortunately, DEP and IWP are still able to reduce some I/O costs when SRR and DIP are used. Therefore, scheme NWC* achieves the best performance and the I/O cost reduction rates of scheme NWC* over scheme NWC+ are from 88.1% to 21.4%, 21% to 0.6% and 65.8% to 11.9% in the CA, NY and Gaussian datasets, respectively, when window size gets from 8 to 128.

5.5 Effect of k

We now evaluate the performance of these schemes for k NWC queries. We can observe from the above experiments that scheme NWC+ is of the best performance when extra storage except R-tree is not available. On the other hand, scheme NWC* performs the best when extra storage is available. Thus, we only compare the performance of scheme k NWC+ and scheme k NWC* (extensions of scheme NWC+ and scheme NWC*, respectively, for k NWC queries) in this and the following experiments.

Figure 13 shows the effect of k on the CA and NY datasets. It is obvious that when k gets larger, both schemes need to spend more time in exploring more qualified windows. As shown in Figure 13, the I/O costs for both schemes almost linearly increase. As mentioned in Section 5.4, since the NY dataset is of many highly clustered objects, the I/O costs of both scheme in the CA dataset are higher than the I/O costs in the NY dataset. In addition, due to the effect of DEP and IWP, scheme k NWC* outperforms scheme k NWC+ in both datasets. Since both schemes perform well in the NY dataset, the I/O cost reduction rate of scheme k NWC* over scheme k NWC+ in the CA dataset is higher than that in the NY dataset. In our experiment, the average I/O cost reduction rates of scheme k NWC* over scheme k NWC+ in the CA and NY datasets are around 84.3% and 35.3%, respectively.

5.6 Effect of m

Figure 14 shows the effect of m on the CA and NY datasets. Setting m to a larger value means that users accept more identical objects in the nearest qualified windows. When a nearest qualified window is found, the qualified windows nearby are of high likelihood to be the qualified windows. Thus, it is easier

Figure 14: Effect of m

for both schemes to find k nearest qualified windows when m gets larger. Similarly, both schemes are of higher I/O costs in the CA dataset than in the NY dataset. Fortunately, with the aid of DEP and IWP, scheme $kNWC^*$ outperforms scheme $kNWC^+$ in both datasets. In our experiment, the average I/O cost reduction rates of scheme $kNWC^*$ over scheme $kNWC^+$ in the CA and NY datasets are around 83.8% and 33.9%, respectively.

6. CONCLUSIONS

In this paper, we propose a novel type of spatial queries, namely nearest window cluster (NWC) queries. To process NWC queries, we identify several properties to find qualified windows, leading to the development of the NWC algorithm. To further accelerate NWC search, we present four optimization techniques to reduce I/O cost. We conduct several experiments to evaluate the performance of the NWC algorithm and the proposed optimization techniques. Experimental results show that these optimization techniques are complementary with each other, and the NWC algorithm with these optimization techniques performs the best in terms of I/O cost.

Adaptive query parallelization in multi-core column stores

Mrunal Gawade

ABSTRACT

With the rise of multi-core CPU platforms, their optimal utilization for in-memory OLAP workloads using column store databases has become one of the biggest challenges. Some of the inherent limitations in the achievable query parallelism are due to the degree of parallelism dependency on the data skew, the overheads incurred by thread coordination, and the hardware resource limits. Finding the right balance between the degree of parallelism and the multi-core utilization is even more trickier. It makes parallel plan generation using traditional query optimizers a complex task.

In this paper we introduce *adaptive parallelization*, which exploits execution feedback to gradually increase the level of parallelism until we reach a sweet-spot. After each query has been executed, we replace an expensive operator (or a sequence) by a faster parallel version, i.e. the query plan is morphed into a faster one. A convergence algorithm is designed to reach the optimum as quick as possible.

The approach is evaluated against a full-fledged column-store using micro-benchmarks and a subset of the TPC-H and TPC-DS queries. It confirms the feasibility of the design and proves to be competitive against a statically optimized heuristic plan generator. Adaptively parallelized plans show optimal multi-core utilization and up to five times improvement compared to heuristically parallelized plans on the workload under evaluation.

1. INTRODUCTION

Column store databases are designed with a focus on analytical workloads. Almost all database vendors these days have a column store implementation. A recent study by Microsoft showed that a majority of real world analytic jobs process less than 100 GB of input [3]. This can be accommodated by an in-memory solution on a single high-end server. They come with an abundance of CPU power using tens of cores [27, 23]. Query parallelization is one of the ways to utilize multi-cores. This calls for a renewed look at the traditional query parallelization techniques, such as the *exchange operator* based parallelization [15], since the state of the art column store systems such as IBM BLU accelerator [24], HyPer [30] use work stealing based approach for multi-core scalability.

Figure 1: Response time variations due to varying degree of parallelism under concurrent workload (32 hyper-threaded cores).

An important issue is the degree of parallelism (**DOP**) of a plan which reflects the maximum number of parallel operator executions. With tens of cores on CPUs, finding the optimal degree of parallelism of a query plan using heuristic and cost model based exchange operator approach is difficult [2]. Some of the prominent problems are a huge multi-core aware plan search space, parallelism aware accurate cost model estimations, and the optimal placement of exchange operators in the plan. The degree of parallelism problem becomes even more difficult under a concurrent workload due to competition for shared resources, such as CPU cores, memory, and memory controllers. This forces many systems to take a conservative approach towards plan parallelization decisions, as a sub-optimal parallel plan could often degrade performance. Often a serial plan is preferred as long as it ensures a robust performance [1].

For example, consider Figure 1, which shows execution of three TPC-H heuristically parallelized queries for different DOP under a heavy concurrent CPU bound workload, which ensures 0% CPU core idleness (Scale factor 10 on 256 GB RAM with 32 hyper-threaded cores). The queries show varying performance under different DOP. The traditional plan generation approaches based on heuristic and cost model [10] fall short, as the plans do not reflect runtime resource variations, making them suboptimal under a concurrent workload.

We introduce *adaptive parallelization*, a new mechanism to generate *range partitioned* parallel plans using query execution feedback, while taking into account the run-time resource contention. Adaptive parallelization generates a better plan (P1) from an old plan (P0) in a greedy manner, by parallelizing the most expensive operator from P0, under repeated query invocations. The inspiration is derived from the observation that in real world systems the same query templates get reused multiple times only changing some parameters. Starting with a serial plan, each successive query invocation results in a new parallel plan, until a near minimal execution time parallel plan is detected, which ensures a near optimal DOP. Adaptive parallelization under concurrent workload reflects resource contention, making adaptive parallelized plans resource

contention aware [11]. The success of adaptive parallelization depends on its ability to converge quickly, while ensuring a near minimal execution parallel plan.

Adaptive parallelization also allows to analyze the relation between DOP and multi-core utilization. Multi-core utilization represents the fraction of actual CPU cores used versus the available cores during query processing. Maximum multi-core utilization however need not improve performance, as it might lead to memory bandwidth pressure due to parallel operator executions [22]. Hence, finding the right balance between the DOP and multi-core utilization is important. Since adaptive parallelization generates new parallel plans incrementally, it enables us to analyze the relation between DOP and multi-core utilization. Adaptive parallelized plans have minimal multi-core utilization and a near optimal degree of parallelism, which helps in achieving better response time during concurrent workloads.

We summarize our main contributions as follows.

- We introduce *adaptive parallelization*, a new execution feedback based parallel plan generation technique, that ensures near optimal degree of parallelism.
- We introduce an adaptive parallelization convergence algorithm for different scenarios.
- We analyze the parameters affecting the speedup of the core relational algebra operators.
- A near optimal DOP allows adaptive parallelized plans to show up to five times response time improvement compared to heuristically parallelized plans.

Paper outline: The paper is structured as follows. In Section 2 we describe the architecture of adaptive parallelization. We also provide parallelization heuristics for operators and illustrate the dynamic partitioning scheme and discuss related problems. Section 3 describes the convergence algorithm to find the near minimal execution parallel plan along with various convergence scenarios. In Section 4 we provide a detailed experimental evaluation. Related work is described in Section 5. We conclude citing the major lessons learned in Section 6.

2. ARCHITECTURE

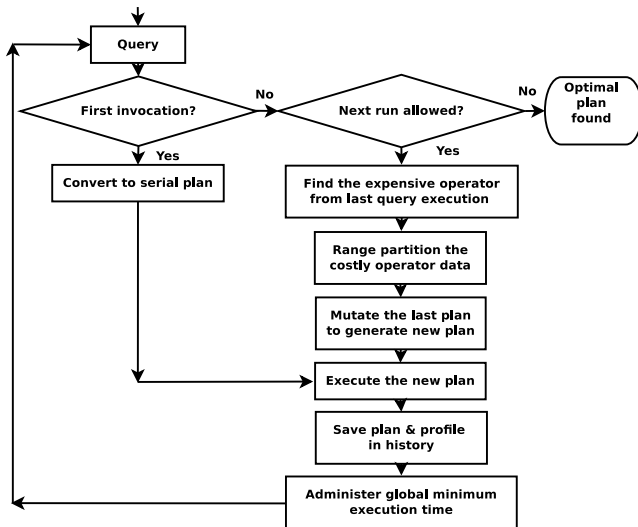

Figure 2: Adaptive parallelization workflow.

Adaptive parallelization could be used by any columnar database system as long as its plan representation allows identification of individual expensive operators.

Run-time environment: It consists of a scheduler, an interpreter, and a profiler. The scheduler uses a data-flow graph based scheduling policy, where an operator is scheduled for execution once all its input sources are available. While an interpreter per CPU core executes the scheduled operators, the profiler gathers performance data on an executed operator basis. The profiling overhead is minimal due to vectorized nature of execution. The profiled data consists of operator’s execution time, memory claims, and thread affiliation id. Cost model based plan generation approaches often suffer from incorrect cardinality estimates. We use a heuristic plan generation approach where parallelization decisions are based on execution time feedback, without a need for operator’s cardinality statistics.

The execution time is a good metric for parallelization decisions as it reflects the system state such as the memory bandwidth pressure and the processor usage. Though the presence of system noise might affect execution time, such disturbances level out during adaptation.

Infrastructure components: The Adaptive Parallelization (AP) infrastructure is implemented using the following components a) operator stubs to morph a plan based on past behavior, b) the plan administration policies to choose a suitable plan from the plan history, and c) the AP convergence algorithm, which we describe in Section 3.

Workflow: The adaptive parallelization work-flow is summarized in Figure 2. The first phase is similar to most systems [16] where an optimal serial plan (Figure 3 Plan 1) is generated. Our approach differs in the second phase where the the query is cached, plan is fed to the framework, executed, and the profiling information such as the query execution time, the operator execution time, the number of invocations, etc. are stored. On the next query invocation a new parallel plan (Figure 3 Plan 2) is derived from the immediate old plan (Plan 1) by parallelizing the most expensive operator (Select on input A). The AP process iterates by invoking the same query again and generating parallel plans in an incremental manner by parallelizing the most expensive operators in successive steps. The number of iterations to find the minimal execution time parallel plan is controlled by a convergence algorithm described in Section 3. As the book keeping and compilation time is minimal we only report the execution time.

Why feedback based approach? Like parallel databases, multi-core CPUs make the parallel plan search difficult [19]. The main problem is finding the *optimal number of partitions* per operator for an *optimal input serial plan*. Finding an optimal input serial plan is out of the scope of this paper. During parallelization when an operator’s data is partitioned, there are combinatorial possible choices for the partition size. For example, in the worst case, each operator’s data could be partitioned in a single tuple, such that the total number of operators equal the number of tuples. In the best case a single operator could work on the entire non-partitioned input. The possible partition size choices for different operators represent multiple parallel plans with different execution times, making this a combinatorial plan search problem. The plan search space exploration is usually done using a combination of both the heuristic and the cost model based approach. It allows to prune the search space for an efficient search. Overall, finding an optimal multi-core aware parallel plan using traditional approaches is difficult. In comparison the feedback based approach we propose is relatively easy, as the assumption is the input serial plan we start with is an *optimal plan*. Since the approach explores the search space in a guided way

by parallelizing only the most expensive operator, we avoid a large space of uninterested plans.

2.1 Plan mutation

We refer to the process described in the workflow as *plan mutation*. Plan mutation could be guided by different policies. In this paper we use parallelization of the *expensive operator* in a plan as the guiding principle. An operator is considered *expensive* if its execution time is the highest amongst all operators. Based on the complexity, we categorize mutation in three types as Basic, Medium, and Advanced.

Basic: Basic mutation involves parallelization of an expensive operator by introducing two new operators of the same type, called expensive operator's **cloned operators**. The cloned operators work on the expensive operator's partitioned data. Partitioning is cheap when it involves no data copy, but introducing range partitioned sliced view of the columnar data. (Value / hash based partitioning needs the presence of a partition operator, about which we discuss in Section 5.) An *exchange union* operator (either a newly introduced or an existing one) combines the result of the cloned operators. In Figure 3 we see one such example for select operator parallelization.

Figure 3: **Basic mutation.**

The two most popular algorithms for the join operator are the hash join and the sort merge join. We analyze the hash join implementation as it suits most workloads due to the omnipresence of non-sorted data. We consider adaptive

Figure 4: **Join parallelization.**

parallelization of the join operator plan (Figure 4 Plan 1) when only the larger (outer) input is split into equi-range partitions on consecutive runs. Figure 4 Plan 2 shows the parallelized plan with the two new join cloned operators. An exchange union operator combines the output of the cloned operators.

Medium: Medium mutation handles plan parallelization when the *exchange union* operator (U) itself turns out to be expensive, as a result of intermediate data copying due to low selectivity input. This mutation stage arises, when the exchange union operator is introduced as a result of the basic mutation.

Figure 5 shows one such example where Plan 1 with an expensive exchange union operator is mutated into Plan 2. The mutation process involves propagating the inputs to the exchange union operator, to its data flow dependent operators. The data flow dependent operators are cloned to match the exchange union operator's input. Finally a newly introduced exchange union operator combines the result of the cloned operator's output.

Advanced: Advanced mutation involves parallelization of operators such as group-by and sort, that do not exhibit the filtering property (selectivity = 0).

Figure 6 shows parallelization of a group-by operator with the advanced mutation. The expensive operator (group-by) is parallelized by introduc-

Figure 6: **Advanced mutation.**

Figure 7: **Complex operator dependencies in TPC-H Q14 parallel plan.** Rectangles represent operators, and edges between them represent the dependencies. The graph is only meant to give a high level perspective of the plan's complexity, abstracting individual operator details. [12] shows graphs where operators are visible.

ing two cloned operators on its equi-range partitioned data. Next the aggregation operators such as sum and average are parallelized by introducing two aggregation cloned operators. The cloned operators (group-by) result is propagated to the aggregation cloned operators (sum). Finally, an exchange union operator combines the parallelized aggregation operators result. Since the aggregation cloned operators always show very high filtering property, the exchange union operator combining their result is cheap.

Summary: A relational operator gets parallelized in two cases. In the first case, the operator itself might be expensive and gets parallelized using either the basic or the advanced mutation. In the second case, operator parallelization occurs as a result of using the medium mutation, where the operator is in the data flow dependent path of the expensive exchange union operator. In both cases identifying and resolving the parallelizable operator's output propagation dependency across the entire plan is an essential step.

The three mutation schemes we described cover all possible mutations as an operator could either get parallelized due to its own expensiveness or as a result of its presence in the data flow path of another parallelizable operator.

2.2 Making plans simpler to mutate

Most columnar systems [1, 4, 7, 18] use a simple representation of plan with operators represented using physical algebra. The operators use standardized interfaces for individual columnar data and related argument passing. Column store specific functionality such as operations on multiple columns and tuple reconstruction are mostly hidden away as the internal logic in the execution engine framework. Some column stores like the open-source system MonetDB, however use an abstract language to represent plans [6], where column store specific functionality such as the tuple reconstruction and other columnar operations is exposed in the plan representation itself. Use of operators with different semantics and specialized operators such as the tuple reconstruction operators is common. Figure 7 shows one such plan with complex data flow dependencies.

Plan mutations using either the medium or advanced mutation involves resolving parallelized operator's propagation dependencies. Hence, care has to be taken to resolve parallelized operator's propagation dependencies. To make plan mutations simpler, modification of some of the operator's semantic representation is needed. We describe the related aspects in the rest of the section.

Adaptive parallelization and operator semantics: Operators can have different semantics depending on primitives being used. Adaptive parallelization could further add more information such as the partition under use, total number of partitions, etc. Plan mutations thus generate combination of different operator semantics.

Figure 8: **Column A dynamically partitioned with iterations.**

For example, consider the case of the filter operator which can have two representations. One which accepts normal columnar input and the other which accepts column and also a bit vector from another selection operator's output. Hence, the filter operator could be represented using two primitives depending on the number and the type of inputs. Depending on the data flow dependency, a suitable filter operator gets parallelized during plan mutations.

Adaptive parallelization uses different parallelization rules catered to different operator semantics. Since any operator could be expensive, resulting in its parallelization, the challenge for different mutation schemes lies in how well they are able to resolve the data flow dependencies across different operator semantics.

Plan rewriting: One of the techniques to ease the mutation process is to modify the original input serial plan from the SQL compiler using a query rewriter. The rewriter substitutes original operators (for example, aggregation operators and tuple reconstruction operators) with new adaptively parallelization aware operators. These new operators use modified implementation of operators such as group-by, aggregation operators (sum, avg), and sort, by keeping their original semantics, but with changed arguments ordering, to resolve possible operator propagation dependencies. For systems with simple plan representations the operator propagation dependencies due to multiple columns could be handled in the execution engine framework logic.

2.3 Adaptive parallelization aware partitioning

In a column store the operators operate on an array or vector representation of the data. For readability, we consider the array representation with range partitioning. It involves creating read only slices on the base or the intermediate column. Creating slices involves marking the boundary ranges for the base or intermediate columnar data and is cheap, as there is no data copying involved. This technique could be also used during vectorized execution where the vectors are derived from the partitioned range of the base and intermediate input. We briefly describe a value based partitioning approach use case in Section 5.

Dynamic partitioning: Adaptive parallelization generates dynamically sized partitions on the base or intermediate column, as any operator could be parallelized during successive iterations. In contrast a heuristically parallelized plan often uses a fixed number of partitions based on the available CPU cores. To explain dynamic partitioning of a column using a select operator, we use Figure 8.

When the select operator on the column in 8A turns expensive, the column is sliced in two partitions represented by 8B. When the select operator on partition 1 in 8B turns expensive, two new partitions are introduced, represented by 2nd and 3rd in 8C. Now there are three select operators, one on 0th partition of 8B and two on 2nd and 3rd partition of 8C. When the select operator on 2nd partition in 8C becomes expensive, it is divided further and two new partitions 4th and 5th in 8D are introduced. So now there are total 4 select operators working on 0th partition of 8B, 3rd partition of 8C and 4th, 5th partition of 8D. Please note that the partitions are of different sizes and their boundaries are aligned on the base column in 8A. Maintaining the alignment during dynamic partitioning is important, as misalignment could lead to problems such as a) repetition of data b) omission of the data across different operator

Figure 9: **Different alignment scenarios between columns during tuple reconstruction due to dynamic partitioning.**

partitions. Thus, dynamic partitioning allows the operators to work on different sized partitions of the same column in parallel.

Dynamic partitioning and tuple reconstruction: Tuple reconstruction is a well known problem in column stores [17] and is implemented as join lookup. Column stores use either early or late materialization strategies for column projection using tuple reconstruction, which involves using row-ids to fetch values from the column that needs projection. For example, consider the columnar representations in Figure 10, which shows head (H) and tail (T) columns grouped as Left (L) and Right (R). The head column (LH / RH) contains row-ids, whereas the tail column contains either row-ids (LT) or actual values (RT). The @ indicates a row-id. When the head column (LH / RH) contains consecutive row-ids, it is not materialized and used as a virtual column. During tuple reconstruction, the row-ids in the left tail (LT) are used as an index in (RH) to fetch the corresponding values from the right tail (RT). For example, row-ids 2, 4, 5, 7 from LT are probed in the RH, whose corresponding values in RT are 12, 11, 20, and 13.

One important aspect is the effect dynamic partitioning has on the tuple reconstruction due to possible misalignment between LT and RH. When row-ids from LT are used as an index to fetch values from RT, the row-ids in LT should be a subset of row-ids in RH. If not, then a lookup using row-id in LT, for the row-id index in RH does not exist, resulting in an invalid access.

LH	LT	RH	RT
1@	2@	1@	15
2@	4@	2@	12
3@	5@	3@	44
4@	7@	4@	11
5@	8@	5@	20
		6@	16
		7@	13

Figure 10: **Tuple reconstruction between two columns.**

Since adaptive parallelization generates variable sized partitions, it gives rise to different alignment scenarios as shown in Figure 9 (B,C,...F). Consider the mis-alignment example in Figure 10. Here LT start row-id=2, which is greater than RH start row-id=1, and LT end row-id=8, which is greater than RH end row-id=7. Hence, LT's upper boundary starts after RH's upper boundary, whereas LT's lower boundary extends beyond RH's lower boundary as represented in Figure 9D. In Figure 9 the lengths of columns provide just a logical representation of over and undershooting of boundaries, and do not represent the actual content. To maintain the alignment the lower boundary of LT is adjusted by removing row-id=8, to match the lower boundary of RH. The correct boundary alignment is represented by dashed lines in Figure 9D. Adaptive parallelization depending on the operator semantics uses one of the alignment scenarios, to make sure that the partitions align correctly. Fixed size partitions always lead to correct alignment (See Figure 9A), resulting in a valid access.

Another important aspect arises when the output of operators working on the dynamically partitioned data is packed together. Here the exchange union operator must maintain the correct ordering to avoid the incorrect results. The correct ordering is maintained, as the operators whose results are packed follow the mutation sequence order, hence the results being packed together fol-

low the same order. Adaptive parallelized plans could become very large due to successive partitioning and operator propagation, which could make partition misalignment related problems, if any, hard to identify and resolve.

Plan explosion: As adaptive parallelization involves propagating the parallelized operator’s output on its dependent operators, the plans could quickly grow large. Plan explosion results as a side effect of the exchange union operator removal during the *medium* mutation. For example, when a descendant of the same type of operator stays expensive during successive invocations, it gets parallelized and a single exchange union operator combines the output of all such parallelized operators. As a result the number of input parameters to the exchange union operator could become very large. Eventually if the exchange union operator itself turns expensive, it is removed using the *medium* mutation. This leads to a plan explosion, as the medium mutation propagates inputs of the exchange union operator on its data flow dependent operators. For each operator in the data flow path, new instructions (operators) which equals the number of the exchange union operator inputs are added in the plan. Hence, if the number of input parameters to the exchange union operator is large, the plans could grow very large.

The growth of large plans is suppressed by not removing the exchange union operator if its input parameters cross a certain threshold. The threshold in the current implementation is 15 parameters, chosen on the basis of empirical observations from different parallelization cases. Suppressing the exchange union operator removal however stops further plan parallelization, as the exchange union operator stays the most expensive operator in all further query invocations.

We have described adaptive parallelization aware infrastructure changes so far. Obtaining a minimal execution parallel plan however depends on how fast the adaptive parallelization process converges. In the next section we describe a new algorithm that ensures convergence in different scenarios.

3. ALGORITHM

In this section we introduce the heuristics for the global minimum execution identification from the set of available plans and the corresponding convergence algorithm. The algorithm is loosely inspired by the hill climbing approach [26]. Figure 11 shows different cases of the presence of minima, plateaus, and up-hills in the execution times, during adaptive parallelized runs of a join operator plan. We refer to the minimal execution time amongst them as the *global minimum execution (GME)*. Like most systems that generate parallel plans, our base assumption is an optimal input serial plan. Hence, the focus of parallelization is to identify the optimal number of partitions for operator’s data in the input plan. Problems such as sub-optimal parallel plans due to poor join ordering which might require backtracking are not considered, as the input is an optimal serial plan.

The convergence algorithm should be able to find the GME in all cases of minima, plateaus, and up-hills in the execution time, and converge in minimal number of runs. Next we formally define the GME first, the convergence algorithm next, and then illustrate different convergence scenarios.

3.1 Global minimum execution (GME)

As the runs progress, the GME is the minimal execution time amongst so far observed runs, and keeps on changing, during an active adaptive parallelization instance.

We denote the current run’s execution time as *CurExec*. The *execution time improvement (CurExecImprv)* at the current run is calculated with respect to 0th run’s (*SerialExec*) execution time.

Figure 11: Adaptive parallelization convergence algorithm scenarios for join operator parallelization.

$$CurExecImprv = |(SerialExec - CurExec)| / SerialExec.$$

To calculate the first GME improvement, we initialize GME to the first run’s execution time after the serial execution (0th run).

$$GMEimprv = |(SerialExec - GME)| / SerialExec.$$

As the runs progress, new GME needs to be identified. A new run’s execution time becomes the new GME, if the run’s execution time improvement is better than the current GME’s execution time improvement by a certain threshold.

$$GME = CurExec \\ \{if (CurExecImprv - GMEimprv) > threshold\}.$$

As the runs progress, the new execution times could be slightly lower than the existing GME, hence, selecting the correct threshold is important in discarding such new execution times, which otherwise could become the new GME. For example, consider a hypothetical adaptive parallelization instance. Let *CurExecImprv* at the 8th run be 96%, *GMEimprv* at the 3rd run = 90%, and *threshold* = 5%, then $(CurExecImprv - GMEimprv) > 5$. Hence, the Current run Execution time at the 8th run is considered the new Global Minimum Execution (GME). Correct tuning of the *threshold* parameter is thus crucial as it helps to discard multiple possible GMEs and to choose the optimal execution time amongst them, as the new GME.

Finding GME could be also difficult due to the presence of many local minima, about which we illustrate next.

The global minimum detection problem: The problem could be formally stated as finding the global minimum execution from many local minima that occur as the runs progress. When the execution time of a run is more than its previous run, a local minimum results at the previous run. For example, a local minimum occurs at the 4th run in Figure 11. The convergence algorithm has to overcome many such local minima during its exploration of the global minimum. We use the rate of improvement in the execution time of the runs as a heuristic, to avoid the local minimas.

The execution time of consecutive runs could improve or worsen depending on the run-time conditions (execution skew, operating system interference), giving rise to positive or negative *rate of execution time improvement (ROI)*. The ROI of a run is defined with respect to its previous run’s execution time (*PrevExec*). We define ROI as follows.

$$ROI = (PrevExec - CurExec) / MAX(CurExec, PrevExec).$$

In Section 3.2 while describing the core convergence algorithm, we illustrate how to use ROI to avoid local minimas. Finding GME is difficult, however, another equally difficult task is to find it in the minimal convergence runs, about which we illustrate next.

The minimal run convergence problem: The problem could be formally stated as finding GME in a minimal number of runs, dur-

ing consecutive query invocations. Too few runs have a risk of non-occurrence of the global minimum and the algorithm converging on a local minimum. Too many runs might ensure a global minimum at the cost of a slow convergence. Hence, finding the right balance between the minimum convergence runs and the GME is of prime importance for the convergence algorithm.

3.2 Convergence algorithm

We describe the convergence algorithm using the context described so far in Section 3. The aim is to find the GME in minimal number of convergence runs. We model the number of convergence runs (*Convergence_Runs*) using the parameters *credit* and *debit*. A credit reflects the number of runs accumulated at each run due to a positive ROI. A debit reflects the number of runs accumulated at each run due to a negative ROI.

$$\begin{aligned} \text{Credit} &= \text{Credit} + (\text{ROI} * \text{Number_Of_Cores}). \\ \text{Debit} &= \text{Debit} + (|(\text{ROI})| * \text{Number_Of_Cores}). \end{aligned}$$

The value of (*credit - debit*) at each run reflects the balance (*Convergence_Runs*) available for the system to converge. Hence, the next run is allowed only if the balance is positive i.e. (*(credit - debit) > 0*).

$$\text{Convergence_Runs} = \text{Credit} - \text{Debit} = f(\text{ROI}).$$

The algorithm starts with the value of *credit* = 1 and *debit* = 0. When parallelism reduces the execution time, the ROI of the first run is positive and very high (Figure 11 - The algorithm starts with the 0th run). With an increase in runs, the ROI decreases. During the initial few runs the algorithm should ensure availability of sufficient runs as a balance, to avoid premature convergence. During the later runs, as the ROI slows down, the algorithm should ensure as few balance runs as possible, to ensure fast convergence. From the formula above, as both *credit* and *debit* are dependent on ROI, they are a function of ROI, which makes the *Convergence_Runs* also a function of ROI. The algorithm convergence is hence guaranteed, since the heuristic *Credit - Debit > 0*, which decides the available *Convergence_Runs* becomes invalid eventually. Next we describe various convergence scenarios and how the heuristic *Credit - Debit > 0* becomes invalid, which guarantees the algorithm's convergence.

3.3 Convergence scenarios

We identify three scenarios during which the algorithm should ensure the convergence, 1. No premature convergence in a local minimum before identifying a global minimum. 2. No extended convergence, and 3. The convergence in a noisy environment. We expect these scenarios to cover the entire spectrum as the aim is to find the global minimum, and the possible problems for the convergence algorithms could be its early termination, late termination, and termination during noisy environment. We describe these scenarios next.

3.3.1 No premature convergence

When parallelism improves the execution time, the first run always has a very high ROI (Figure 11 - The algorithm starts with the 0th run). Hence, the *credit* accumulated after the first run is very high with an upper limit of (*Number_Of_Cores + 1*). This ensures that there are sufficient runs available as a balance in the system during the initial stages to overcome plateaus and up-hills. Each run after the first run contributes more *credit*, ensuring more runs. This is also analogous to the concept of accumulation of the *potential energy* by a body when it falls from great heights. The greater the height, the higher the potential energy. The energy allows the body to keep moving in plateaus and climb high hills, as long as

there is a balance energy.

3.3.2 No extended convergence

Accumulation of high *credit* in the few initial runs on a stable system could result in a state where the algorithm *never* converges. In a stable system the execution time variations are minimal, leading to fewer *debts* being made. In such a system, the proportion of accumulated *credit* will always be much higher than the accumulated *debit* after a few initial runs. For example, consider Figure 11. After 15 runs the ROI is minimal, ensuring that no new significant *credit* or *debit* is introduced. However, the accumulated *credit* till 7 runs is very high, as the ROI till 7 runs is very high. This situation leads to non-convergence as there are always balance runs available i.e. (*credit - debit <= 0*) is never true.

Leaking debit: To ensure the algorithm converges in a finite number of runs we introduce the concept of *leaking debit*. In this scheme after a *threshold* on the number of runs is crossed, a constant *debit* gets deducted from the available *credit* at each run. *It ensures the available credit is drained to 0, so that the algorithm converges in a finite number of runs.* Hence, *leaking debit* is a function of the available *credit* at the threshold run. The threshold run value is calibrated to be the *Number_Of_Cores* on the CPU. It ensures at least those many runs are used to find the optimal execution time. The *Leaking_Debit* is calculated by dividing the available *credit* at the threshold run amongst the possible remaining number of runs during the global minimum search.

$$\begin{aligned} \text{Remaining_Runs} &= \text{Extra_Runs} * \text{Number_Of_Cores}. \\ \text{Leaking_Debit} &= \text{Credit} / \text{Remaining_Runs}. \end{aligned}$$

Based on plan complexity, some queries converge early, while some take longer after crossing the *threshold run* reference. To avoid premature convergence, the system specific tunable parameter *Extra_Runs* is used, which ensures that the *remaining number of runs* to search the global minimum are sufficient. Note that *Remaining_Runs* is just an approximate bound. Plan representations vary considerably across systems. Hence, based on empirical observations from different parallelization cases, and multiple experimental runs (five), for the current platform, *Extra_Runs*=eight is considered a safe boundary value to avoid the premature convergence. Higher values result in an extended convergence.

3.3.3 Convergence in a noisy environment

Depending on the stability of the run-time environment (operating system process interference, memory flushes, etc.) the execution time of an individual run could vary considerably. The execution time of some of the runs in a noisy environment is often greater than the serial plan execution time. One such peak is visible in Figure 11 at the 30th run. Most peak executions are followed and preceded by a normal execution. If care is not taken such peaks will make the algorithm halt *immediately* as the *debit* due to peak ascent will be higher than the accumulated *credit*. Hence, the algorithm should converge gracefully in such a noisy environment.

Our solution is to mark all such unique peaks as outliers, and ignore their presence. The algorithm incorporates this by allowing the immediate next run to execute. This ensures the balance runs stay unaffected, as the *debit* made during the peak *ascent* is compensated by an equivalent *credit* during the peak *descent*, during the next run. Concurrent workload could also affect the convergence, however, tuning the *Extra_Runs* parameter to find the leaking debit should take care of it.

3.3.4 Global minimum plan identification proof

The convergence algorithm should ensure a global minimum plan while converging in a reasonable number of runs. The lower bound

Table 1: System configuration

CPU	Sockets	Threads	L1 cache	L2 cache	Shared L3 cache	Memory	OS
Intel Xeon E5-2650@ 2.00GHz	2	32	32KB	256 KB	20MB	256GB	Fedora 20
Intel Xeon E5-4657Lv2@ 2.40GHz	4	96	32KB	256KB	30MB	1TB	Fedora 20

on the convergence runs is $Number_Of_Cores + 1$, while the upper bound approximates between $(Number_Of_Cores + 1 + Remaining_Runs)$ and extra runs added to the previous upper bound, if any, due to a large credit accumulation. The convergence runs are directly influenced by the *Leaking_Debit*, and credit / debit accumulation.

The global minimum plan’s existence beyond the upper bound of the convergence runs is not possible. We provide a proof by contradiction. If such a plan exists then its execution should be significantly better. In that case the corresponding expensive operator should have been identified much earlier, even before the first upper bound on the convergence runs is reached. If multiple such plans exists, then that indicates improved execution with each run. Such improvement should then add extra runs (more credit) to the first upper bound on the convergence runs, which would prolong the global minimum search further, to find a more optimal plan. Hence, no matter the situation, a near global minimum plan is identified in the available convergence runs. In all the convergence scenarios when the heuristic *Credit - Debit* > 0 , that decides available *Convergence_Runs*, turns invalid, the algorithm converges.

4. EXPERIMENTS

Adaptive parallelization is implemented in MonetDB, being the only full fledged open-source columnar system, with memory mapped columnar representation for the base and the intermediate data. The operators are represented in an intermediate language called MonetDB Assembly Language (MAL) [6], with their implementation in C. The operators have variable number of arguments depending on their semantics, and form complex data flow patterns in MAL plans, as shown in Figure 7.

Table 1 summarizes our experimental hardware platform, which consists of two types of machines, with two and four socket CPUs each. All experiments, unless mentioned, use in-memory data (without disk IO) on the two socket machine. Heuristic parallelization unless mentioned uses 32 threads. Each graph plots an average of four runs of the same experiment. We use the four socket machine to test one of the workload’s scalability from NUMA perspective.

The experimental section is divided into two broad categories. In the first we analyze how parallelization gets affected by various operator level parameters. In the second we analyze it at the SQL query level. We use a mix of micro-benchmarks, simple, and complex SQL queries to gain parallelization behavior insights.

We use TPC-H and TPC-DS workload for SQL query level performance comparison. We observe the TPC-H isolated execution of both the adaptive and the heuristic parallelization shows similar performance. However, adaptive plans are better as they use fewer number of cores, which helps during concurrent workload. Adaptive plans show better performance than the heuristic plans for the TPC-DS workload isolated execution, due to optimal number of partitions, and the presence of the skewed data. In the rest of the section we describe the experimental details.

4.1 Operator level analysis

Adaptive parallelization helps to analyze the role of individual operators in influencing parallelized execution, as it uses expensive operator parallelization as a heuristic. Getting insights into the issues such as the execution skew becomes easier. An operator’s execution time varies on the basis of type of computation, data distribution, amount of data being read / written, type of data access (serial / random), and memory hierarchy of the access (cache / main

Figure 12: **Parallelized select operator execution on skewed data using static and dynamic (adaptive) sized partitioning. The second bar indicates a work stealing based approach.**

memory / disk IO). We analyze some of these factors next.

4.1.1 Data skew

This experiment highlights the role of *dynamic* sized partitions to avoid execution skew during parallelized execution, when the data distribution is *non-uniform* (skewed). The execution skew occurs when at least one of the parallelized operators takes longer to execute than the rest.

Static partitioning (equi-range partitioning) of skewed data leads to execution skew as some partitions have more matches than the rest. Adaptive parallelization performs well in skewed data scenario as the operator with the skewed partition turns expensive, and gets parallelized until expensiveness balances out.

Figure 12 shows the execution time when parallel select operators work on statically or dynamically (adaptively) partitioned skewed column of type *long* (8 bytes). The number of tuples in the input column are 1000 million (M) (size = 8GB). Figure 13 shows the column’s data distribution with 500 million random tuples in the first half. The second half contains skewed data with 5 sequential clusters of 100 million identical tuples. We vary the select operator’s condition to generate the execution skew.

500M Random Numbers	100M Same	100M Same	100M Same	100M Same	100M Same
---------------------	-----------	-----------	-----------	-----------	-----------

Figure 13: **Data distribution for a skewed column.**

Figure 12 shows execution with 8 threads on 8 dynamically sized partitions (blue) is up to 60% better than the execution with 8 threads on 8 static partitions (khaki). One may argue that the work stealing approach [5] could solve the problem of execution skew due to the static partitions. We analyze it by creating a large number of smaller partitions (128) operated upon by 8 threads. Large number of smaller partitions allows those threads that finish work early to operate on remaining partitions, while threads on skewed partitions stay busy. Identifying the optimal combination of static partitions and threads is however non trivial, as in some cases more partitions might lead to plan blow-up resulting in scheduling overheads. In contrast we observe that the dynamic sized (adaptive) partitioning approach with 8 threads and just 8 partitions fares competitively with static 8 threads, 128 partitioned approach.

Summary: Skew handling is a natural property of adaptive parallelization. It is a result of dynamically sized range partition creation, and a side effect of the expensive operator parallelization heuristic.

4.1.2 Selectivity, Input size and Exchange union operation

This experiment analyzes the effect of selectivity, input size, and the exchange union operation on the parallelized execution of select and join operators, in terms of their speed-up. *Speedup* is defined as the ratio of serial to parallel plan execution time. The experiment also allows to analyze the speed-up effect when the number of threads varies from 1 to 32. This is possible since with each it-

Figure 14: Effect of variations of data size and selectivity on the speedup of the adaptively parallelized *Select* operator plan.

Table 2: *Select* operator plan speedup (compared to serial execution) using adaptive and heuristic parallelization.

	AP = Adaptive, HP = Heuristic parallelization					
	Selectivity					
	0%		50%		100%	
Size (GB)	AP	HP	AP	HP	AP	HP
100	10	10	8.5	10	7	9
20	10.5	12	8.5	12	8	12
10	16	11	14.5	11	12	9.5

eration one more partition gets added and is available for one more execution thread (from a pool of 32 threads) to operate in parallel.

Exchange union operation: Many systems use the *exchange operator* based parallelism [15], where one of the concerns is to identify the correct placement of the exchange operator in a plan to minimize its overhead [2]. Most systems use a cost model based approach for this decision. A good example is [30], where Vectorwise is shown to have a limited speed-up due to the exchange operator overheads.

As the exchange union operator combines parallelized operator’s result, its expensiveness varies depending on the size of the data being packed. Low selectivity reflects more matching data, hence more data to be packed. The packing overhead is minimized by pushing the exchange union operator as high as possible. It ensures the final data to be packed is relatively small, as it gets filtered by the intermediate operators.

Adaptive parallelization (AP) enables to analyze the exchange union operator’s placement with successive iterations of parallelized plans, as it directly affects the speed-up. In the next two experiments we observe that the AP plan’s speed-up is comparable to the speed-up of the heuristically parallelized (HP) plans. The speed-up gets hindered due to operator dependencies that form critical paths, which can not be parallelized. However, the AP plans benefit by their optimal multi-core utilization due to less partitions, which ensures improved *concurrent* execution performance, as described in Section 4.2.5.

Select operator adaptive parallelization: We use query 6 from the TPC-H benchmark to analyze the speedup of the select operator (See Table 2). Query 6 is a simple query with only selection predicates on the *Lineitem* table. We vary the selectivity by varying the parameter *l_quantity* from the selection predicate. Figure 14 plots the execution time of AP plans on the Y axis with respect to iterations (X axis), when selectivity is varied from 0% (all output) to 100% (no output), and scale factor is varied from 10 GB to 20 GB. We do not plot the graph for 100GB for readability purpose, and only list its speedup in Table 2.

From Table 2 as the selectivity increases the speedup decreases. During low selectivity a single select operator in a serial plan writes a large number of output tuples, as compared to its parallel plan counterparts. This results in the large speedup as serial execution time is much higher, whereas parallel execution time is much lower. During highest selectivity (100%) since there is no output the serial execution is less expensive as compared to 0% selectivity serial execution. This results in lower speedup. The speedup increases with a decrease in the input size. This is a result of lower minimum time

Figure 15: Effect of variations of data size on the speedup of the adaptively parallelized *Join* operator plan. Outer input partitioned and inner input used to build hash table.

during parallel execution, due to less input data. With increased selectivity the speedup for AP is less compared to HP. This is due to the presence of less expensive exchange union operators, which do not get pushed higher in the plan.

Table 3: *Join* operator plan speedup (compared to serial execution) using adaptive and heuristic parallelization.

	AP = Adaptive, HP = Heuristic parallelization			
Size (MB)	64		16 (Smaller Input)	
(Larger Input)	AP	HP	AP	HP
3200	15.75	14	18.5	18
2000	15	13.5	17.75	17.75
640	13.75	13	17	15

Join operator adaptive parallelization: For the join operator (hash) plan parallelization analysis, we partition the outer input and build up the hash table on the inner input. We use a micro-benchmark for a fine grained control, where the outer input has 400 M, 250 M, and 80 M (M = Millions) random tuples of type *long* (8 bytes), and the inner input has 8 M and 2 M tuples. The outer inputs stay larger than the inner input of size 16 MB (2 M tuples) even after 32 partitions (threads on CPU). The 16 MB input fits in the shared L3 cache (20 MB).

Figure 15 shows the join operator plan speedup and Table 3 quantifies it. The speedup of 16 MB input join is more than the 64 MB input join, as the 16 MB input join’s hash table fits partially in the L3 cache (20 MB), which improves the probe phase, due to reduced cache thrashing. Speedup also decreases as the outer table size decreases, as the serial execution time is directly proportional to the outer table size. For all sizes the best speedup is obtained when the number of partitions are 32, with 32 threads (hyper-threading enabled). Maximum speed-up observed is around the number of physical cores (16). Both AP and HP show a similar performance unlike the previous select operator plan analysis case, as the join plan contains only join and union operators.

Summary: Adaptive parallelization works for both the select and the join operator and these operators scale linearly with the number of physical cores. Input size, selectivity, and properties such as cache consciousness affects the speedup.

Having analyzed how individual operators affect parallel execution, in the next section we focus on holistic SQL query level analysis, from execution performance and convergence perspective.

4.2 SQL query level analysis

4.2.1 TPC-H queries

Since the TPC-H benchmark is considered the de-facto workload for performance comparison, in this section we use a subset of queries (see Table 4) from TPC-H (scale factor 10). TPC-H has uniformly distributed data. The adaptively parallelized group-by operator implementation at present supports single attribute group-by queries. Hence, we modify some queries so that they have a single attribute group-by representation. Since we use the same set of queries to evaluate multiple parallelization approaches, the

Figure 16: **Heuristic vs adaptive parallelization performance in isolated and concurrent environment for MonetDB and Vectorwise.**

comparison is fair. We plot an average of four executions using the experimental set-up described towards beginning of Section 4.

Table 4: TPC-H queries.

Simple	Q6	Q14			
Complex	Q4	Q8	Q9	Q19	Q22

We compare adaptive parallelization (AP) with heuristic parallelization (HP), the default parallelization technique in MonetDB, under isolated execution setting. HP uses parameters such as the number of threads, physical memory size, and the largest table size to identify the number of partitions for the largest table in the serial plan. A plan re-writer generates a parallel plan from a serial plan by propagating the partitions to data flow dependent operators. Though both HP and AP start with the same serial plan, the final parallel plan is different for both techniques as in AP only the most expensive operator gets parallelized unlike in HP, where all possible parallelizable operators are parallelized. In Figure 16 the first two bars show HP vs AP performance when queries execute in isolation. All AP queries except Q9 and Q19 show similar performance as HP. Q9 and Q19 show a degraded performance due to the presence of some non-parallelizable operators, which prolong the query execution. The robustness of individual query execution could be observed in Figure 18C, where queries show minimal execution time variations. Though the execution performance of adaptive plans is similar to the heuristic plans, the adaptive plans are better as they use much fewer number of partitions (See Table 5). It helps during concurrent workload execution, where adaptive plans exhibit better execution performance due to better resource utilization. Table 5: AP and HP Q14 plan statistics.

	AP	HP
# Select operators	10	65
# Join operators	16	32
% Multi-core Utilization	35	75

4.2.2 TPC-DS queries

TPC-DS benchmark has 25 tables, out of which 6 tables are relatively large (above 1GB in size), in a scale factor 100 dataset. The benchmark supports 99 query templates. We use a few modified queries. These queries are a subset of the original TPC-DS queries and are chosen such that they contain the large tables and a few smaller dimension tables. Since we compare both the adaptive and the heuristic parallelization technique with the same queries, the comparison gives a perspective of their respective performance.

We experiment on both the two socket and the four socket machine (See Table 1 for configuration) with 100GB dataset, to get a perspective of the NUMA effects. Graphs in Figures 17a and 17b show the comparison. Adaptive plans exhibit a maximum of 5 times better performance compared to heuristic plans, which could be attributed to *correct partitioning by adaptive parallelization compared to heuristic parallelization and the skewed data distribution*. The execution time for both two and four socket machine shows similar time, which indicates minimal NUMA effects. As authors in [14] observe, since MonetDB uses a memory mapped representation for the buffer data, as the number of partitions increase, we expect them to get assigned to the memory modules of

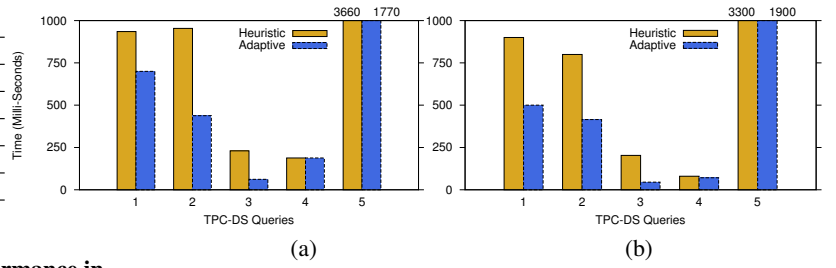

Figure 17: **Isolated execution performance of TPS-DS queries on a) 2 socket machine with 2.00 GHz CPU b) 4 socket machine with 2.40 GHz CPU, on 100GB data.**

the sockets on which operator execution gets scheduled. We also observe a limit on the execution improvement, even though a higher number of cores are used, which indicates increased parallelism need not improve performance beyond a threshold.

4.2.3 Concurrent workload execution

This experiment highlights the effectiveness of adaptively parallelized plans compared to heuristically parallelized plans in a concurrent workload setting. Concurrent query executions in batch workload leads to resource contention, which in turn affects the degree of parallelism of individual queries under execution. Resource contention varies with random workload, however for the current set-up we consider a homogeneous concurrent workload. In Figure 16 the 4th and 5th bar shows HP vs AP execution under a concurrent workload. The workload consists of random simple and complex queries from the TPC-H benchmark (10GB), where 32 clients invoke queries repeatedly. AP Q8 shows 50% improved execution compared to HP Q8. Simple queries such as Q6 and Q14 show around 90% execution improvement in AP. HP plans have too many partitions compared to the AP plans as shown in Table 5. AP plans also reflect the resource contention through execution feedback. Hence, AP plans are more robust and better performing under a concurrent workload, compared to statically generated HP plans. In [11] authors discuss HP vs AP plans comparison under different concurrent workload resource contention scenarios in a detailed manner.

4.2.4 Comparison with Vectorwise

We compare the concurrent workload performance of Vectorwise (version 3.5.1 with histogram build feature enabled to generate optimized plans), a leading analytical columnar database using pipelined vectorized execution [7], with adaptive parallelization in MonetDB. Vectorwise uses cost model based exchange operator dependent parallel plans. The resources are allocated based on the number of connected clients and the system load. During a heavy concurrent workload (32 clients invoking random TPC-H queries repeatedly on 10GB data), the first client's query gets all the resources, while the queries from the remaining clients get less resources based on an admission control scheme. Figure 16 shows MonetDB adaptive parallelized query execution performance is better than the Vectorwise execution performance, during the concurrent workload. MonetDB does not have explicit resource control based plan generation scheme, which helps in the current case. We hypothesize that as workload queries are invoked repeatedly, Vectorwise queries under analysis execute serially due to lack of resources.

4.2.5 Multi-core utilization

This experiment highlights that an AP plan is better than a HP plan from the multi-core utilization perspective. Multi-core utilization represents the fraction of actual CPU cores used versus the available cores during query processing. AP ensures minimal multi-core utilization as each operator is parallelized with a different degree of parallelism unlike HP. Figures 19 and 20 visualize AP vs HP plan execution of TPC-H Q14, in an isolated execution

Figure 18: Convergence algorithm shows minimal variations across multiple invocations in the graphs A, B, and C for adaptively parallelized query execution. Graph D shows most queries converge quickly after detection of the global minimum.

Figure 19: Adaptive parallelization multi-core utilization (35%) during isolated execution of TPC-H Q14. Green- Select, Blue-Join, Brown- Exchange union operator.

setting. The length of a colored box represents an operator's execution interval (In an operator-at-a-time execution model an operator executes completely. Blue- join, Green-select, Brown- exchange union operator.) A whitespace indicates no execution. The amount of whitespace in Figure 19 is much more than in Figure 20, indicating lower multi-core utilization for AP. In the HP execution (Figure 20) the length of the join operators is much longer than the corresponding operators in the AP execution (Figure 19), which hints at the memory bandwidth pressure. In [13] authors analyze parallel plans in detail using this visual scheme.

The degree of parallelism per operator thus influences the overall multi-core utilization. For example, while only ten select operators execute in AP, many more execute in HP (See Table 5). Since AP shows lower multi-core utilization (35%) during isolated execution, the spare resources ensure better response time during concurrent workload, as further elaborated in [11].

4.3 Convergence algorithm robustness

Adaptive parallelization not only should converge in minimal number of runs, but also should exhibit robustness. The robustness implies during *multiple* adaptive parallelization invocations of a query a) the total number of convergence runs b) the run at which the global minimum occurs, and c) the global minimum execution time should not show much variations. In this experiment we test the robustness of the convergence algorithm in an isolated execution setting. Graphs in Figure 18 (A,B,C) show these three cases.

Graph 18(A) shows the number of convergence runs to find the optimal execution time for three invocations. Except for Q6 and Q22 all other queries show minimal variations for convergence runs. Q6 is the most simple query in the given set of queries. It shows the most speed-up amongst all queries, but that also makes it vulnerable to external factors such as operating system noise interference, etc. Since the global minimum time is very low, even small inter-

Figure 20: Heuristic parallelization multi-core utilization (75%) during isolated execution of TPC-H Q14. Green- Select, Blue-Join, Brown- Exchange union operator.

ference affects its performance. Q22 is a complex query where join operator is always the most expensive operator.

Graph 18(B) shows the run where the global minimum time occurs during three invocations of the query set under evaluation. Depending on the resource contention and the run-time interference from the operating system we get small variations across different runs for all queries. The highest difference is observed between the first and the third run for Q19. However, overall the number of runs do not show much deviations.

Graph 18(C) shows the global minimum time for adaptively parallelized queries for three invocations. The global minimum time for all queries is almost stable across multiple invocations. This indicates the robustness of the generated plans.

Graph 18(D) shows that the queries 4, 6, 9, 19 converge quickly after detection of the global minimum. Different types of queries show different convergence properties and the algorithm gets tuned to converge in the least possible number of runs. For example, Q8, Q14, and Q22 show the global minimum with fewer than 40 runs, while the total convergence runs are around 100. The slow convergence is a result of the *Leaking_Debit* being too low, which leads to the *credit* getting drained slowly. The convergence runs are close to 60 for the same global minimum, when the *Leaking_Debit* is high.

How to lower number of convergence runs? At present plan parallelization introduces only a single new operator per invocation, which results into a higher number of convergence runs, as the execution skew introduced by a single new operator needs to level out. The number of runs could be made much lower if more and even number of operators are introduced per invocation. We avoid it at present to analyze the parallel plan evolution with each new operator addition.

5. RELATED WORK AND APPLICABILITY TO OTHER SYSTEMS

The basic optimizer approach of “optimize once and execute many” as proposed by System R has reached its limits [28]. Hence, adaptive query processing techniques are being proposed to address query optimization problems due to unreliable cardinality estimates, data skew, parameterized query execution, changing workload, complex queries with many tables, etc. [9]. In this section we describe some state of the art adaptive techniques.

Adaptive aggregation is used by the authors in [8] to handle different group-by based parallelization cases. The operator performs a lightweight sampling of the input to choose the best aggregation strategy with high accuracy, at runtime. Algorithmic approaches are based on using independent and shared hash tables with locking and atomic primitives to minimize hash table access contention. Three cases are identified that affect performance based on the average run-length of identical group-by values, locality of references to the aggregation hash table, and frequency of repeated access to the same hash table location. This work targets adaptivity from a single operator’s perspective, whereas our work targets it at the plan level. The approach used here could be combined with our adaptive approach to improve per operator performance.

Vectorwise uses micro-adaptivity to improve query execution time by using run-time execution feedback [25]. Micro-adaptivity is defined as the ability to choose the most promising execution primitive at run-time, based on real time statistics. Most methods, like adaptive parallelization, use plan level modification, whereas micro-adaptivity uses the available execution primitives at run time. It chooses primitives based on the platform, instance, and call adaptivity using parameters such as compiler, branch prediction, selectivity, loop unrolling, etc.

The Learning Optimizer (LEO) in DB2 uses query execution feedback for cardinality estimation corrections [29]. It uses learning and feedback based infrastructure to monitor query execution and generates feedback for correction in the cardinality estimation and related statistics. More learning helps in better cost model predictions. LEO has improved query execution performance by orders of magnitude. MonetDB does not use cardinality related statistics, however if used with the statistics correction methods, the selection of operator’s to parallelize could be improved further.

In [4] authors illustrate adaptive parallel execution in Oracle for big data analytics. In Oracle problems such as reliance on query optimizer estimates are handled by changing the data distribution decisions adaptively, during query execution.

Column store architectures differ in various aspects such as plan representation, partitioning strategy, scale out support, etc. Encompassing all the requirements in a single architecture is not possible due to their architectural confinements. While describing the related state of the art column stores, we also describe the possibility of adaptive parallelization’s application to them.

Vertica uses a value based partitioning approach [18]. It uses a Read Optimized Store (ROS), where the data is stored in multiple ROS containers on a standard file system. Two files per column within a ROS container are stored, one with the actual column data and the other with position index. This representation is very similar to the representation in Figure 10, where RH is the index, while RT is the actual value. Vertica also supports grouping multiple columns together in a file, however this hybrid row-column storage is rarely used in practice because of the performance and compression penalty it incurs.

Vertica execution engine uses a multi-threaded pipelined vector-

ized execution where the execution plan consists of standard relational algebra operators. Operators such as StorageUnion are used for partitioning data across operators. Hence, StorageUnion is equivalent to a partition operator. Operators such as ParallelUnion are used for directing execution to multiple threads and to combine the parallelized operator’s results. Hence, ParallelUnion is equivalent to an exchange union operator.

To understand the feasibility of applying adaptive parallelization in Vertica, let’s assume that the execution starts with a serial plan and incrementally introduces value based partitions to partition the expensive operator’s data. For example, when a select operator becomes expensive and needs to be parallelized, a partition operator is introduced which creates two value based partitions, which would be consumed by two new select operators. The two new select operator’s output is combined using an exchange union operator. This is similar to the basic mutation scheme with the addition of a partition operator that feeds two newly introduced select operators.

When one of the newly introduced select operators itself becomes expensive, we further partition that operator’s data into two more value based partitions, by introducing a new partition operator in the data flow path after the previous partition operator, and before the input of the expensive select operator. Thus in a hypothetical case when one of the select operators stays expensive during consecutive invocations, new partition operators would keep on getting added to the existing plan. We expect the cost of the partitioning operator to be small considering its presence in the existing Vertica execution plans. Quantifying the exact cost is difficult due to lack of sufficient references. Similar logic could be applied for other operator’s parallelization.

Apollo creates column store indexes in a traditional row store database like SQL server [20]. It is the first database which uses the existing row store to create new column store indexes. The method involves creation of batches of rows to create segments from which individual columns are stored in individual column representations. The column segments information is stored in the directory structure, with a catalog.

The columns are compressed and encoded using different types of encoding. New operators called batch operators are introduced which get called if there is bulk data to be processed. The valid rows to process are noted down in bitvector formats.

Apollo uses range partitioning of data. Since traditional SQL server uses cost model based exchange operator induced parallelization, Apollo leverages the existing SQL server parallelization technique using the exchange operator based parallelization.

To understand how adaptive parallelization might be applied in Apollo type of column store, we need to find similarities between adaptive parallelization and Apollo architecture. Both do range partitioning of data, hence the fundamental assumption of range partitioned access stays the same, and could change in the way individual operators are implemented. For example, the operations like the join operator consists of separate build and probe operators, where build uses a shared hash table, where all threads build a hash table, and then probe operator probes it in parallel. As Apollo extends the exchange operator based parallelization as used in SQL server, we expect adaptive parallelization to be useful, due to its dependence on the exchange operator based parallelization.

Hyper uses LLVM [21] generated Just In Time (JIT) compiled plans. The longest pipeline in a plan is identified, by looking for a pipeline breaker operator. The operators in the longest pipeline are fused using JIT compilation such that their highly efficient machine language code represents a single task. The fusing allows tuples to be kept in registers to process them without generating intermedi-

ate results. Hyper's morsel driven parallelism uses work stealing based approach to assign the fused pipeline tasks to a fixed number of pre-created threads. The task allocation based approach allows controlling the number of tasks executing in parallel dynamically, at run-time, and allows better control over resource allocation during concurrent execution of queries.

Adaptive parallelization technique is based on the fundamental assumption that an expensive operator is always identifiable in an execution plan. This is a basic requirement since plan parallelization is a result of incrementally parallelizing the expensive operator during successive query invocations, until a global minimum plan is identified.

Identification of a single expensive operator is not feasible in Hyper's execution plans due to the JIT compiled fused nature of operator's pipeline, which prevents a direct application of adaptive parallelization. However, in a broader sense if the entire task is considered to be expensive and treated as an expensive operator, application of the adaptive parallelization logic could be possible. Hence, the feasibility of adaptive parallelization technique in Hyper depends on how to categorize the expensiveness metric.

DB2 BLU accelerator [24] uses evaluator chains, which comprises DB2 BLU operators working on columnar data. The data is accessed in strides. It uses novel data structures that minimize latching allowing seamless scaling with multi-cores. Parallelism involves cloning of evaluator chains once per thread, where the number of threads is decided by cardinality estimates, system resources and system load. Each thread requests strides for its evaluator chains until no more strides are available. DB2 BLU also uses work stealing based approach where worker threads operate on tasks comprising of evaluator chain based work.

6. CONCLUSION

Adaptive parallelization uses query execution feedback to generate resource contention and skew aware range partitioned multi-core parallel plans. It helps in finding the right balance between the multi-core utilization and the degree of parallelism for the exchange operator based parallel plans. We observe a near linear speedup with the number of cores while analyzing the parallel plan evolution using parameters such as the input size and selectivity. During TPC-DS isolated workload execution, the adaptively parallelized plans show up to five times better performance compared to heuristically parallelized plans. During TPC-H concurrent workload, they show minimal multi-core utilization, allowing better resource utilization. They also fare competitively with work stealing based scheduling approach.

Using different convergence scenarios we show that the adaptive parallelization convergence algorithm behaves robustly, and converges in a reasonable number of runs.

ABSTRACT

With the explosion of large, dynamic graph datasets from various fields, graph partitioning and repartitioning are becoming more and more critical to the performance of many graph-based Big Data applications, such as social analysis, web search, and recommender systems. However, well-studied graph (re)partitioners usually assume a homogeneous and contention-free computing environment, which contradicts the increasing communication heterogeneity and shared resource contention in modern, multicore high performance computing clusters. To bridge this gap, we introduce PARAGON, a *parallel architecture-aware* graph partition refinement algorithm, which mitigates the mismatch by modifying a given decomposition according to the nonuniform network communication costs and the contentiousness of the underlying hardware topology. To further reduce the overhead of the refinement, we also make PARAGON itself architecture-aware.

Our experiments with a diverse collection of datasets showed that on average PARAGON improved the quality of graph decompositions computed by the de-facto standard (hashing partitioning) and two state-of-the-art streaming graph partitioning heuristics (deterministic greedy and linear deterministic greedy) by 43%, 17%, and 36%, respectively. Furthermore, our experiments with an MPI implementation of Breadth First Search and Single Source Shortest Path showed that, in comparison to the state-of-the-art streaming and multi-level graph (re)partitioners, PARAGON achieved up to 5.9x speedups. Finally, we demonstrated the scalability of PARAGON by scaling it up to a graph with 3.6 billion edges using only 3 machines (60 physical cores).

1. INTRODUCTION

It is well-known that graph (re)partitioning has been extensively studied in the area of scientific simulations [14, 34]. Yet, its importance is continuously increasing due to the explosion of large graph datasets from various fields, such as the World Wide Web, Pro-

tein Interaction Networks, Social Networks, Financial Networks, and Transportation Networks. This has led to the development of graph-specialized parallel computing frameworks, e.g., Pregel [21], GraphLab [19], and PowerGraph [13].

Pregel, as a representative of these computing frameworks, embraces a vertex-centric approach where the graph is partitioned across multiple servers for parallel computation. Computations are often divided into a sequence of *supersteps* separated by a global synchronization barrier. During each superstep, a user-defined function is computed against each vertex based on the messages it received from its neighbors in the previous step. The function can change the state and outgoing edges of the vertex, send messages to the neighbors of the vertex, or even add or remove vertices/edges to the graph.

Traditional Graph Partitioners Clearly, the distribution of the graph data across servers may impact the performance of target applications significantly. *Graph partitioning* has been studied for decades [14, 34], attempting to provide a good partitioning of the graph data, whereby both the skewness and the communication (edge-cut) among partitions are minimized as much as possible, in order to minimize the total response time for the entire computation. However, classic graph partitioners such as METIS [23] and Chaco [7] do not scale well with large graphs.

Streaming Graph Partitioners Streaming graph partitioners (e.g., DG/LDG [39], arXiv'13 [11], and Fennel [42]) have been proposed in order to overcome the scalability challenges of classic graph partitioners, by examining the graph incrementally. One of the main shortcomings of these approaches is that they also assume uniform network communication costs among partitions as classic graph partitioners do. That is, they all assume that the communication cost is proportional only to the amount of data communicated among partitions. *This assumption is no longer valid in modern parallel architectures due to the increasing communication heterogeneity* [47, 8]. For example, on a $4 * 4 * 4$ 3D-torus interconnect, the distance to different nodes starting from a single node varies from 0 to 6 hops.

Architecture-Aware Graph Partitioners Architecture-aware graph partitioners [24, 8, 46] have been proposed to improve the mapping of the application's communication patterns to the underlying hardware topology. Chen et al. [8] (SoCC'12) took architecture-awareness a step further, by making the partitioning algorithm itself partially aware of the communication heterogeneity. However, both [8] and [24] (ICA3PP'08) are built on top of existing heavyweight graph partitioners, namely, METIS [23] and PARMETIS [30], which

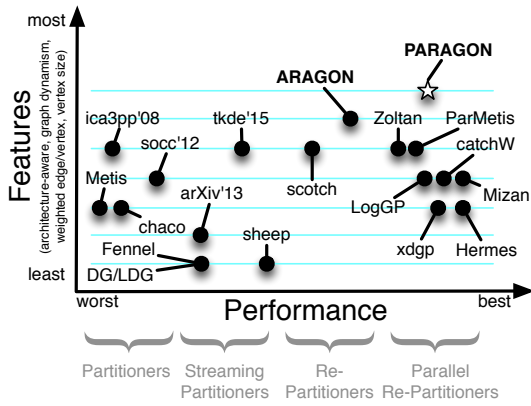

Figure 1: Classification of all graph partitioners/re-partitioners according to their features vs performance profile.

are known to be the best graph partitioners and repartitioners in terms of partitioning quality but have poor scalability. Finally, although Xu et al. [46] (TKDE’15) proposed a lightweight architecture-aware streaming graph partitioner, the partitioner may lead to sub-optimal performance for dynamic graphs [43].

Traditional Graph Repartitioners Most real-world graphs are often non-static, and continue to evolve over time. Because of this *graph dynamism*, both the quality of the initial partitioning and the mapping of the application communication pattern to the underlying hardware topology will continuously degrade over time, leading to (a potentially significant) load imbalance and additional communication overhead. Considering the sheer scale of real-world graphs, repartitioning the entire graph from scratch using [46, 8, 24], even in parallel, is often impractical, either because of the long partitioning time or the huge volume of data migration the repartitioning may introduce. To address this, several graph repartitioning algorithms have been proposed, such as Zoltan [1, 6] and PARMETIS [30, 33]. Although they are able to greatly reduce the data migration cost, they are all architecture-agnostic and do not scale well with massive graphs.

Parallel/Lightweight Graph Repartitioners Parallel lightweight graph repartitioners (e.g., CatchW [37], xdgp [43], Hermes [26], Mizan [17], arXiv’13 [11], and LogGP [45]) have been proposed to improve the performance and scalability of graph repartitioning. Instead of seeking an optimal partitioning at once, these algorithms adapt the graph decomposition to changes efficiently by incrementally migrating vertices from one partition to another based on some local heuristics. However, they are all oblivious of the nonuniform network communication costs among partitions.

Limitations of the State-of-the-Art Despite the plethora of graph partitioners and repartitioners (Figure 1), the current state-of-the-art is suffering from two main problems:

- Graph (re)partitioners either consider architecture-awareness (for CPU/network heterogeneity) or consider performance (i.e., parallel/lightweight implementation), but never both. This is illustrated in Figure 1, where the top-right corner is empty (except for PARAGON, which is presented in this paper).
- No existing graph (re)partitioner considers the issue of *shared resource contention* in modern multicore high performance computing (HPC) clusters. Shared resource contention is a well-known issue in multicore systems and has received a lot of attention in system-level research [15, 41].

Our prior work We have previously presented an architecture-aware graph repartitioner, ARAGONLB [48]. Although ARAGONLB considers the communication heterogeneity for target applications, it disregards the issue of shared resource contention, and the repartitioning itself is not architecture-aware. Moreover, the refinement algorithm that ARAGONLB uses to improve the mapping of the application communication pattern to the underlying hardware topology requires the entire graph to be stored in memory by a single server, which is infeasible for large graphs. Furthermore, the refinement algorithm is performed sequentially, which may become a performance bottleneck. Finally, ARAGONLB assumes that compute nodes used for parallel computation have the same number of cores and memory hierarchies, which may not always be true.

Contributions In this paper, we present PARAGON, which overcomes both limitations of the current state-of-the-art graph repartitioners by extending ARAGONLB in the following aspects.

1. We separate the refinement algorithm, ARAGON, from ARAGONLB as an independent component, and develop a parallelized version of ARAGON, PARAGON, for large graphs (Section 3, 4, 5). We further reduce the overhead of PARAGON by making it aware of the nonuniform network communication costs (explained in Section 2.1).
2. We identify and consider the issue of shared resource contention in modern HPC clusters for graph partitioning (Section 2.2 & 6).
3. We perform an extensive experimental study of PARAGON with a diverse set of 13 datasets and two real-world applications, demonstrating the effectiveness and scalability of PARAGON (Section 7).

2. MOTIVATION

In this section we explain the importance of architecture-awareness (i.e., communication heterogeneity and shared resource contention) for efficient graph (re)partitioners.

2.1 Communication Heterogeneity

For distributed graph computations on multicore systems, communication can be either *inter-node* (i.e., among cores of different compute nodes) or *intra-node* (i.e., among cores of the same compute node). In general, intra-node communication is an order of magnitude faster than inter-node communication. This is because in many modern parallel programming models like MPI [27, 25], a predominant messaging standard for HPC applications, intra-node communication is implemented via shared memory/cache [16, 5], while inter-node communication needs to go through the network interface. Additionally, both inter-node and intra-node communication are themselves nonuniform.

Nonuniform Inter-Node Network Communication Modern parallel architectures, like supercomputers, usually consist of a large number of compute nodes linked via a network. Consequently, the communication costs among compute nodes vary a lot because of their varying locations. For example, in the Gordon supercomputer [28], the network topology is a 4x4x4 3D torus of switches with 16 compute nodes attached to each switch. As a result, the distance to different compute nodes starting from a single node varies from 0 to 6 hops. Also, supercomputers often allow multiple jobs to concurrently run on different compute nodes and contend for the shared network links, limiting the effective network bandwidth available for each job and thus amplifying the heterogeneity.

Nonuniform Intra-Node Network Communication Communication among cores of the same compute node is also nonuniform because of the complex memory hierarchy. Communication among

(a) Uniform Memory Access (UMA) Architecture

(b) Nonuniform Memory Access (NUMA) Architecture

Figure 2: Example Architectures of Modern Compute Nodes

cores sharing more cache-levels can achieve lower latency and higher effective bandwidth than cores sharing fewer cache-levels. For example, in the architecture described by Figure 2a, communication among cores sharing L2 caches (e.g., between the first and second core of Socket 0) offers the highest performance, while communication among cores of the same socket but not sharing any L2 cache (e.g., between the first and third core of Socket 0) delivers the next highest performance. Communication among cores of different sockets performs the worst. Similarly, in Figure 2b, cores of the same socket (intra-socket communication) usually communicate faster than cores residing on different sockets (inter-socket communication). This is because intra-socket communication can be achieved via the shared caches, while inter-socket communication has to go through the front-side bus and the off-chip memory controller (Figure 2a) or the inter-socket link controller (Figure 2b).

Take-away *To improve the performance of graph-based big-data applications, we should not only minimize the number of edges across different partitions (edge-cut), but also the number of edge-cuts among partitions having higher network communication costs (hop-cut). This is the major difference between architecture-agnostic solutions (that only minimize edge-cut) and architecture-aware ones (that try to minimize both edge-cut and hop-cut).*

2.2 Intra-Node Shared Resource Contention

As mentioned above, MPI intra-node communication is implemented via shared memory, which can either be user-space or kernel-based [16, 5]. Current MPI implementations often use the former for small messages and the latter for large messages. The user-space approach requires two memory copies. The sender first needs to load the send buffer into its cache and then write the data to the shared buffer (which may require loading the shared buffer block into the sender’s cache first). Then, the receiver reads the data from the shared memory (which may demand loading the shared memory block and receiving buffer into the receiver’s cache first). For kernel-based approaches, the receiver first loads the send buffer directly to its cache with the help of the OS kernel. Then, the receiver writes the data to the receiving buffer (which may require loading the receiving buffer into its cache first). Clearly, kernel-based approaches reduce the number of memory copies to be one, mitigating the traffic on the memory subsystem. However, it demands a trap to the kernel on both the sender and receiver, making it inefficient for small messages. As can be seen, intra-node communication generates lots of memory traffic and cache pollution, which may saturate the memory subsystem if we put too much communication within each compute node. This issue is further amplified by the increasing contentiousness of the shared resources in modern multicore systems. Table 1 summarizes the resources that different cores may have to compete for when they are communicating with each other for the architectures presented in Figures 2a and 2b. The

Table 1: Intra-Node Shared Resource Contention

Cores/Resources	Core Groups	Sharing		Contention		
		Socket	LLC	LLC	FSB/QPI(HT)	Memory Controller
UMA Fig. 2a	G1	✓	✓	✓	✓	✓
	G2	✓			✓	✓
	G3					✓
NUMA Fig. 2b	G1	✓	✓	✓		✓
	G2				✓	

summary is based on whether the cores are on the same socket and whether they share the last level cache (LLC).

Take-away *Focusing solely on placing neighboring vertices as close as possible is not sufficient to achieve superior performance. In fact, putting too much communication within each compute node may even hurt the performance due to the traffic congestion on memory subsystems.* Counter-intuitively, offloading a certain amount of intra-node communication across compute nodes may sometimes achieve better performance. This is because inter-node communication is often implemented using Remote Direct Memory Access (RDMA) and rendezvous protocols [40], which allow a compute node to read data from the memory of another compute node without involving the processor, cache, or operating system of either node, thus alleviating the traffic on memory subsystems and cache pollution. Additionally, it is reported in [3] that modern RDMA-enabled networks can deliver comparable network bandwidth as that of memory channels. This requires us to examine the impact of multi-core architecture on graph partitionings more carefully, especially for small HPC clusters, since the network may no longer be the bottleneck.

3. PROBLEM STATEMENT

Let $G = (V, E)$ be a graph, where V is the vertex set and E is the edges set, and P be a partitioning of G with n partitions, where

$$P = \{P_i : \cup_{i=1}^n P_i = V \text{ and } P_i \cap P_j = \emptyset \text{ for any } i \neq j\} \quad (1)$$

and let M be the current assignment of partitions to servers, where P_i is assigned to server $M[i]$. The server can be either a hardware thread, a core, a socket, or a machine.

Architecture-aware graph partition refinement aims to improve the mapping of the application communication pattern to the underlying hardware topology by modifying the current partitioning of the graph, such that the communication cost of the target application, given the specific hardware topology, is minimized. The modification usually involves migrating vertices from one partition to another partition. Hence, in addition to the communication cost, the refinement should also minimize the data migration cost among partitions. Also, to ensure balanced load distribution in terms of the computation requirement, the refinement should keep the skewness of the partitioning as small as possible.

Figure 5: Best Decomposition

	N_1	N_2	N_3
N_1		1	6
N_2	1		1
N_3	6	1	

Figure 6: Relative Network Communication Costs

We define the *communication cost* of a partitioning P as:

$$comm(G, P) = \alpha * \sum_{\substack{e=(u,v) \in E \\ \text{and } u \in P_i \text{ and } v \in P_j \text{ and } i \neq j}} w(e) * c(P_i, P_j) \quad (2)$$

where α specifies the relative importance between communication and migration cost, which is usually set to be the number of supersteps carried out between two consecutive refinement/repartitioning steps, $w(e)$ is the edge weight, indicating the amount of data communicated along the edge per superstep, and $c(P_i, P_j)$ can be either the relative network communication cost, the degree of shared resource contentiousness between P_i and P_j or a hybrid of both. Existing architecture-agnostic graph (re)partitioners usually assume $c(P_i, P_j) = 1$.

The *migration cost* of the refinement is defined as:

$$mig(G, P, P') = \sum_{\substack{v \in V \\ \text{and } v \in P_i \text{ and } v \in P'_j \text{ and } i \neq j}} vs(v) * c(P_i, P'_j) \quad (3)$$

where $vs(v)$ is the vertex size, reflecting the amount of application data represented by v , and P' denotes the partitioning after being refined/repartitioned.

The *skewness* of a partitioning, P , is defined as:

$$skewness(G, P) = \frac{\max\{w(P_1), w(P_2), \dots, w(P_n)\}}{\frac{\sum_{i=1}^n w(P_i)}{n}} \quad (4)$$

where $w(P_i) = \sum_{v \in P_i} w(v)$ with $w(v)$ denoting the vertex weight (i.e., the computation requirement of the vertex).

Self Architecture-Awareness In fact, the refinement algorithm itself should be architecture-aware (during its execution), since the refinement may also result in a lot of communication.

4. OUR PRIOR WORK: ARAGON

ARAGON is a serial, architecture-aware graph partition refinement algorithm proposed by us in [48]. It is a variant of the Fiduccia-Mattheyses (FM) algorithm [12]. It tries to reduce the application communication cost by modifying the current decomposition according to the nonuniform network communication costs of the underlying hardware topology. Each time it takes as input two partitions of the n -way decomposition and the relative network communication costs among partitions. For each input partition pair, it attempts to improve the mapping of the application communication pattern to the underlying hardware topology by iteratively moving vertices between them. During each iteration, it tries to find a single vertex such that moving it from its current partition to the alternative partition would lead to a maximal gain, where the gain is defined as the reduction in the communication and migration cost. Upon each movement of a vertex, v , it also updates the gain of v 's neighbors of the partition pair. This process is repeated until all vertices are moved once or the decomposition cannot be further improved after a certain number of vertex movements. Since

ARAGON can only refine one partition pair at a time, it is repeatedly applied to all partition pairs sequentially.

The gain of moving vertex v from its current partition, P_i , to its refinement partner, P_j , is defined as:

$$g^{i,j}(v) = g_{std}^{i,j}(v) + g_{topo}^{i,j}(v) + g_{mig}^{i,j}(v) \quad (5)$$

Here, $g_{std}^{i,j}(v)$ considers the impact of the movement on the communication between P_i and P_j , defined as:

$$g_{std}^{i,j}(v) = \alpha * (d_{ext}(v, P_j) - d_{ext}(v, P_i)) * c(P_i, P_j) \quad (6)$$

where $d_{ext}(v, P_i)$ denotes the amount of data v communicates with vertices of partition P_i , formally defined as

$$d_{ext}(v, P_i) = \sum_{\substack{e=(v,u) \in E \\ \text{and } v \in P_i \text{ and } u \in P_j \text{ and } i \neq j}} w(e) \quad (7)$$

The second term of Equation 5, $g_{topo}^{i,j}(v)$, considers the impact of the movement on the communication between v and its neighbors in other partitions in addition to P_i and P_j . We define it as:

$$g_{topo}^{i,j}(v) = \alpha * \sum_{\substack{k=1 \\ \text{and } k \neq i \text{ and } k \neq j}}^n d_{ext}(v, P_k) * (c(P_i, P_k) - c(P_j, P_k)) \quad (8)$$

The third term of Equation 5, $g_{mig}^{i,j}(v)$, considers the impact of the movement on migration cost, which is defined as:

$$g_{mig}^{i,j}(v) = vs(v) * (c(P_i, P_k) - c(P_j, P_k)) \quad (9)$$

where P_k is the owner of v in the original decomposition. The current owner of v , P_i , may be different from its original owner, P_k , due to the refinement.

Example In the decomposition shown in Figure 3, we have a graph with unit weights and sizes and is initially distributed across 3 machines: N_1 , N_2 , and N_3 . The relative network communication costs among partitions are shown in Figure 6. Clearly, the number of edges among partitions goes from 4 in Figure 3, to 3 in Figure 4. In fact, if we assume uniform network communication costs among partitions, Figure 4 would be the optimal decomposition of the graph. However, if we consider the case where all network costs are not equal (as in Figure 6), then the decomposition in Figure 4 can be further improved by moving vertex a to P_2 (Figure 5). Even though moving vertex a from P_1 to P_2 increases the communication cost between P_1 and P_2 by 1, it actually reduces the communication cost between a and j by 5, since the relative network communication cost between P_1 and P_3 is 6, while that of P_2 and P_3 is 1. For the same reason, moving a to P_2 also decreases the migration cost of a by 5, since vertex a was originally in P_3 .

5. PARAGON

Motivation Clearly, one naive implementation of ARAGON could be as follows: server $M[i]$ is responsible for the refinement of P_i with all its partners $P_{i+1}, P_{i+2}, \dots, P_n$, and server $M[i+1]$ can

not start its refinement for P_{i+1} until server $M[i]$ finishes its refinement. One major issue of this approach is that it requires the entire graph to be sent across network $\frac{n-1}{2}$ times. An advantage of this approach is that each server only needs to hold two partitions in memory at a time (one for its local partition and the other one for the refinement partner). In our prior work [48], ARAGON goes for another extreme, where all servers send their local partitions to a single server that is responsible for the refinement of all partition pairs. By doing this, ARAGON only needs to send the entire graph over network once, significantly reducing the communication traffic. One drawback of this approach is that it requires the server to store the entire graph in memory. Another issue is that the server can easily become a performance and scalability bottleneck.

Overview Based on the observation above, PARAGON takes a middle point of the two extremes, where it allows multiple servers to do the refinement in parallel, each of which is responsible for the refinement of a group of partitions. In this way, we can enjoy the benefits of both extremes without worrying about their drawbacks. Algorithm 1 describes the main idea of PARAGON. During refinement, each server runs an instance of the algorithm with its local partition P_i and the relative network communication cost matrix c as its input. The algorithm first selects a server as master node (Line 1), and then computes everything needed by the master node to make the parallization decision (Line 2). The master node decides how to split partitions into groups such that each group can be refined independently on different servers and the selection of group servers (Line 4–6). The group servers take responsibility of the refinement of each group. Once the decision has been made, each server will send their vertices to the corresponding group servers (Line 7). Upon receiving all the vertices from their group members, group servers will start to do the refinement of each group independently (Line 8–13). After finishing the refinement of its group, group servers will notify their group members about the new locations of their vertices (Line 15). Then, each server will physically migrate vertices to their new owners accordingly (Line 16).

Partition Grouping To assign a partition to a group, we consider three factors: (1) to minimize the refinement time, each group should have roughly equal number of partitions; (2) members of each group should be carefully selected, since the gain of refining each partition pair may vary a lot. Thus, to maximize the effectiveness of refinement, we should group together partitions leading to high refinement gain; and (3) we should minimize the cross-group refinement interference, because the gain of refining one partition pair heavily relies on the amount of data they communicate with other partitions. This is different from the standard FM algorithms, which solely compute the gain of migrating each vertex based on the data it communicates with vertices of the partition pair. For example, in the decomposition of Figure 4, the communication between vertex a and j contributes most to the gain of moving a from P_1 to P_2 for PARAGON. However, for standard FM algorithms, the gain of migrating a to P_2 will be -1, since a has two neighbors in P_1 and 1 in P_2 . Unfortunately, there is no clear way to do the grouping, since we could not use the state-of-the-art graph partitioners (i.e., METIS) to compute a high-quality initial decomposition, due to their poor scalability. As a result, the input decomposition to PARAGON will probably have edge-cuts across all partitions. Fortunately, we find that random grouping along with the *shuffle refinement* (the remedy technique presented below) works quite well.

Shuffle Refinement To mitigate the impact of cross-group refinement interference and increase the gain of the refinement, we perform an additional round of refinement once all the group servers finish the refinement of their own groups. We call this *shuffle refine-*

Algorithm 1: PARAGON

Data: P_i, c

Result: new locations of vertices of P_i

```

1  masterNodeSelection(c)
2  partitionStat( $P_i, ps$ )
3  if server  $M[l]$  is master node then
4       $pg = \text{partitionGrouping}()$ 
5       $gs = \text{optGroupServerSelection}(pg, ps, c)$ 
6      partitionGroupServerBcast( $gs$ );
7  sendPartitionToGroupServers( $P_i, gs$ )
8  if server  $M[l]$  is a group server then
9       $pg = \text{recvPartitionsFromMyGroupMembers}(gs)$ 
10     foreach  $P_i \in pg$  do
11         foreach  $P_j \in pg$  do
12             if  $i \neq j$  then
13                 AragonRefinement( $P_i, P_j, c$ )
14     shuffleRefinement( $pg$ )
15     vertexLocationUpdate( $pg$ )
16  physicalDataMigraton( $P_i$ )

```

ment. In this round, each group server first exchanges the changes it made to the decompositions such that each group server has the up-to-date load information of each partition and the up-to-date locations of the neighbors of each vertex. Then, each group server swaps some of its partitions randomly with other group servers. Subsequently, each group server starts another round of refinement with the new grouping.

The reason why shuffle refinement is a remedy to the above issue is because it increases the number of partition pairs refined by PARAGON and thus the solution space that PARAGON explores. For example, for a graph with 4 partitions and 2 groups, PARAGON originally only refines 2 out of the 6 partition pairs. However, if the group servers swap one of their partitions, PARAGON will refine 4 partition pairs instead of 2. In fact, we can repeat this shuffle refinement multiple times to further expand the solution space PARAGON explores, thus further alleviating the impact of cross-group refinement interference and increasing the gain we can obtain.

The idea of shuffle refinement is very straightforward, but it is not easy to efficiently implement, especially the propagation of the changes that each group server made. One easy way to achieve this is to use a distributed data directory, like the one provided by Zoltan [1]. In this scheme, each group server only needs to make an update to the data directory first, and then all the group servers can pull the up-to-date locations for the neighbors of their vertices. We found that this approach is very inefficient for really big graphs in terms of both memory footprint and execution time. It requires around $O(|V|+|E|)$ data communication.

Another way to achieve this is to maintain an array at each group server, forming a mapping from vertex global identifiers¹ to their locations. In this way, the exchange can easily be achieved via a single (MPI) reduce operation, requiring only $O(|V|)$ data communication. This approach is much more efficient than the distributed data directory approach in terms of execution time, but it is not memory scalable for large graphs.

In our implementation, we adopt a variant of the second approach. That is, we first chunk the entire global vertex identifier space into multiple smaller equal sized regions. Each region contains vertices within a contiguous range. By default, the region size

¹In distributed graph computation, each vertex has a unique global identifier across all partitions and a unique local identifier within each partition.

equals $k = \min\{2^{26}, |V|\}$, where V is the vertex set of the entire graph. Correspondingly, the exchange is split into multiple rounds. Each round only exchanges the locations of vertices of one region. With this scheme, we only need to maintain a smaller array at each group sever and thus the amount of data communication remains unchanged. Although this scheme requires scanning the edge lists of each partition multiple times, it is much more efficient than the distributed data directory approach.

Degree of Refinement Parallelism Theoretically, the number of groups we can have can be any integer between 1 and $\frac{n}{2}$, where n is the number of partitions of the graph. Clearly, if the number of groups equals 1, PARAGON degrades to ARAGON, in which all servers will send their local partitions to a single group server for sequential refinement. The reason why there is an upper bound is because each group needs to have at least 2 partitions for the refinement to proceed. Typically, the higher the number is, the faster the refinement will finish. However, there is a tradeoff between the degree of parallelism and the quality of the resulting decomposition we can have. This is because the higher the number is, the fewer partitions each group will have and thus the fewer partition pairs will be refined. Given a graph with n partitions and m groups, PARAGON only refines $\frac{n(n-m)}{2m}$ partition pairs, while ARAGON refines all $\frac{n(n-1)}{2}$ partition pairs. In other words, ARAGON will eventually select an optimal migration destination among all partitions for each vertex, whereas PARAGON only considers a subset of the partitions for each vertex. This also explains the reason why the resulting decompositions computed by PARAGON are usually poorer than those of ARAGON. Fortunately, the shuffle refinement technique we proposed helps to address the issue.

Group Server Selection Once the master node finishes the grouping process, it will select an optimal server for each group, such that the cost of sending partitions of the group to the group server is minimized. For example, in case of Figure 4, where we assume that P_1, P_2 , and P_3 are of one group, we should select server $M[2]$ as the group server intuitively since $c(P_1, P_2) = c(P_2, P_3) = 1$ while $c(P_1, P_3) = 6$. To achieve this, we define the cost of selecting server $M[s]$ as the group server for group g as:

$$\sum_{P_i \in g} ps[i] * c(P_i, P_s) * (1 + \frac{\sigma(s)}{drp}) \quad (10)$$

Here, $ps[i]$ denotes the number of edges associated with vertices of P_i , which is a good approximation for the amount of data each server needs to send to their group servers. $\sigma(s)$ is the number of group servers that have been designated on the compute node that server $M[s]$ belongs to. It should be noticed that server $M[s]$ can be a hardware thread, a core, a socket, or a machine. drp is the degree of refinement parallelism (number of group servers). The last term $(1 + \frac{\sigma(s)}{drp})$ is the penalty that is added to avoid the concentration of multiple group servers into a single compute node, reducing the chance of memory exhaustion. Once all group servers are selected, the master node will broadcast the group servers of all groups to all slave nodes. Then, each server will send its vertices (as well as their edge lists) to their corresponding group servers, after which the group servers will start to refine partitions of their own groups independently.

Reducing Communication Volume Clearly, PARAGON with the shuffle refinement disabled requires the entire graph to be sent over the network once, and PARAGON with the shuffle refinement enabled demands more data communication. For really big graphs, the communication volume may get very high. Thus, we follow the same approach proposed in [35] to reduce the communication

volume. Specifically, instead of sending the entire partition to their group servers, each server only needs to send vertices that can be reached by a breadth-first search from boundary vertices of each partition within k -hop traversal. Boundary vertices are vertices that have neighbors in other partitions. The rationale behind this is that if a vertex is very far from the boundary vertex, the chance that it get moved by PARAGON to another partition to improve the decomposition is very small. Surprisingly, we find that PARAGON is not sensitive to k in terms of the partitioning quality, and that a larger k does not always lead to partitionings of higher quality. However, it may increase the refinement time greatly. Thus, in our implementation, we set $k = 0$ by default. In other words, we only send boundary vertices of each partition to the group servers.

In fact, [35] has presented a solution to parallelize the standard FM algorithms [12]. However, it may require a graph with n partitions to be sent over the network $n - 1$ times in case the initial decomposition has edge-cuts across all partition pairs. Furthermore, the presence of communication heterogeneity complicates things greatly. First, ARAGON has to be applied to all partition pairs, whereas standard FM algorithms, which assume uniform network communication costs, only need to refine partition pairs that have edge-cuts between them. Second, during each refinement iteration of a single partition pair, standard FM algorithms only need to consider migrating vertices of both partitions that have neighbors in the alternative partition. On the other hand, PARAGON has to consider migrating all boundary vertices.

Master Node Selection As presented so far, each server (slave node) needs to send some auxiliary data (i.e., the number of vertices/neighbors) of their local partitions to the master node for the parallelization decision, and the master needs to broadcast the decision it made to all slave nodes. To reduce the communication cost between the master node and the slave nodes, we also select the master node in an intelligent way using the following heuristic:

$$\min_{m \in [1, n]} \sum_{i=1 \text{ and } i \neq m}^n c(P_i, P_m) \quad (11)$$

The heuristic tries to find a server $M[m]$ that will result in minimal network communication cost as the master node. For example, in case of Figure 4, we should select server $M[2]$ as the master node. Clearly, the selection of master node can be made locally by each server without synchronizing with each other.

Physical Data Migration To support efficient distributed computation, we also provide a basic migration service for graph workloads. Considering that physical data migration is highly application-dependent, the migration service only takes responsibility for the redistribution of the graph data itself. It is the users who are responsible for the migration of any application data associated with each vertex. That is, the users should save the application context before using our migration service and restore the context afterwards. For example, in breadth first search, each vertex is usually associated with a value indicating its current distance to the source vertex. Users need to keep track of the distance value of each vertex while migrating. For complicated workloads, users can exploit the migration service provided by Zoltan [1] to simplify the migration.

6. CONTENTION AWARENESS

So far, we have presented how we parallelize ARAGON. In this section, we will cover how we make PARAGON aware of the issue of shared resource contention in multicore systems. We know that, guided by a given network communication cost matrix, PARAGON is able to gather neighboring vertices as close as possible, and that

the contention is caused by the fact that we put too much communication within the compute nodes. Hence, to avoid serious intra-node shared resource contention, we can simply penalize intra-node network communication costs by a score. The score is computed based on the degree of contentiousness between the communication peers. By doing this, the amount of intra-node communication will decrease accordingly. In our implementation, we refine the intra-node communication costs as follows:

$$c(P_i, P_j) = c(P_i, P_j) + \lambda * (s_1 + s_2) \quad (12)$$

where P_i and P_j are two partitions collocated in a single compute node; λ is a value between 0 and 1, denoting the degree of contention; and s_1 denotes the maximal inter-node network communication cost, while s_2 equals 0 if P_i and P_j reside on different sockets and equals the maximal inter-socket network communication cost otherwise. Clearly, if $\lambda = 0$, PARAGON will only consider the communication heterogeneity, and $\lambda = 1$ means that intra-node shared resource contention is the biggest performance bottleneck, which should be prioritized over the communication heterogeneity. It should be noticed that PARAGON with any $\lambda \in (0, 1]$ considers both the contention and the communication heterogeneity. Considering the impact of both resource contention and communication heterogeneity is highly application- and hardware-dependent, users will need to do simple profiling of the target applications on the actual computing environment to determine the ideal λ for them.

7. EVALUATION

In this section, we first evaluate the sensitivity of PARAGON to varying input decompositions computed by different initial partitioners and the impact of its two important parameters: the degree of parallelism and the number of shuffle refinement times (Section 7.1). We then validate the effectiveness of PARAGON using two real-world graph workloads: Breadth-First Search (BFS) [4] and Single-Source Shortest Path (SSSP) [20], which we implemented using MPI (Section 7.2). Finally, we demonstrate the scalability of PARAGON via a billion-edge graph (Section 7.3).

Datasets Table 2 describes the datasets used. By default, the graphs were (re)partitioned with vertex weights (i.e., computational requirement) set to be their vertex degree, with vertex sizes (i.e., amount of the data of the vertex) set to be their vertex degree, and with edge weights (i.e., amount of data communicated) set to 1. The degree of each vertex is often a good approximation of the computational requirement and the migration cost of each vertex, while a uniform edge weight of 1 is a close estimation of the communication pattern of many graph algorithms, like BFS and SSSP. Given the fact that communication cost is usually more important than migration cost, all the experiments were performed with $\alpha = 10$ (Eq. 2). Unless explicitly specified, all the graphs were initially partitioned by DG (deterministic greedy heuristic), a state-of-the-art streaming graph partitioner [39], across cores of the compute node used (one partition per core). The partitionings were then improved by PARAGON. During the (re)partitioning, we allowed up to 2% load imbalance among partitions. For fairness, DG/LDG were extended to support vertex- and edge-weighted graphs.

Platforms We evaluated PARAGON on two clusters: PittMPIcluster [32] and Gordon supercomputer [28]. PittMPIcluster had a flat network topology, with all 32 compute nodes connected to a single switch via 56GB/s FDR Infiniband. On the other hand, the Gordon network topology was a 4x4x4 3D torus of switches connected via 8GB/s QDR Infiniband with 16 compute nodes attached to each switch. Table 3 depicts the compute node configuration of both clusters. The results presented were the means of 5 runs, except the

execution of SSSP on Gordon (Section 7.2) and the scalability test (Section 7.3).

Network Communication Cost Modelling The relative network communication costs among partitions (cores) were approximated using a variant of the `osu_latency` benchmark [29]. To ensure the correctness of the cost matrix, each MPI rank (process) was bound to a core using the mechanism provided by MVAPICH2 1.9 [25] on Gordon and OpenMPI 1.8.6 [27] on PittMPIcluster. MVAPICH2 and OpenMPI were two different MPI implementations available on the clusters.

7.1 MicroBenchmarks

7.1.1 Varying Degree of Parallelism

Configuration In this experiment, we examined the impact of the degree of parallelism in terms of both the refinement time (i.e., the time that the refinement took) and the refinement quality (i.e., the communication cost of the resulting decomposition). Towards this, we first partitioned the `com-lj` dataset into 40 partitions using DG across 2 compute nodes of PittMPIcluster, and then applied PARAGON to the decompositions with varying degree of refinement parallelism but with shuffle refinement disabled.

Results (Figures 7a & 7b) Figure 7a plots the runtime of PARAGON on the `com-lj` dataset for various degrees of parallelism. As expected, the higher the degree of parallelism, the faster the refinement would finish, and PARAGON significantly reduced the refinement time of ARAGON (PARAGON with degree of parallelism of 1). However, the speedup was achieved at the cost of higher communication cost of the resulting decompositions (Figure 7b). The communication costs presented were normalized to that of the initial decomposition computed by DG. However, in the end, PARAGON still resulted in lower communication cost in all cases when compared to the initial decompositions.

7.1.2 Impact of Shuffle Refinement

Configuration In our second experiment, we were interested to see whether the shuffle refinement technique could address the issue we identified in the previous experiment. Towards this, we repeated the same experiment but with a fixed degree of refinement parallelism (8) and varying number of shuffle refinement times (from 8 to 15).

Figure 7: Refinement time and communication costs of the com-lj decompositions after being refined with varying degree of refinement parallelism on two 20-core compute nodes. The communication costs presented were normalized to that of the initial decomposition.

Figure 8: Y-axis corresponds to the communication costs of the com-lj decompositions after being refined with varying number of shuffle refinement times on two 20-core compute nodes when they were normalized to that of the decompositions refined by ARAGON; X-axis denotes the corresponding refinement time; the labels on each data point were the number of refinement times.

Results (Figure 8) Figure 8 shows the corresponding refinement time and the normalized communication costs of resulting decompositions with the decompositions computed by ARAGON as the baseline. As shown, PARAGON (with shuffle refinement enabled) not only produced decompositions of lower communication costs than ARAGON (when the number of shuffle refinement times was greater than 11), but also completed the refinement faster (ARAGON took around 33s to finish the refinement vs 8.12s by PARAGON with 11 shuffle refinement times).

7.1.3 Impact of Initial Partitioners

Configuration This experiment examined the refinement overhead and the quality of the resulting decompositions, when PARAGON was provided with decompositions computed by four different partitioners: (a) HP, the default graph partitioner of many parallel graph computing engines; (b) DG and LDG, two state-of-the-art streaming graph partitioning heuristics [39]; and (c) METIS, a state-of-the-art multi-level graph partitioner [23]. The graphs were initially partitioned across the same two machines used in our prior experiments but with both the degree of refinement parallelism and the number of shuffle refinement times set to 8.

Quality of the Initial Decompositions (Figure 9) Figure 9 denotes the communication cost of the initial decompositions computed by HP, DG, LDG, and METIS for a variety of graphs. As anticipated, METIS performed the best and HP the worst. However, METIS is a heavyweight serial graph partitioner, making it infeasible for large-scale distributed graph computation either as an initial partitioner or as an online repartitioner (repartitioning from

Figure 9: Communication cost of the initial decompositions computed by HP, DG, LDG, and METIS across cores of two 20-core compute nodes for a variety of graphs.

scratch). It was reported in prior work [42] that METIS took up to 8.5 hours to partition a graph with 1.46 billion edges. Unexpectedly, DG outperformed LDG, the best streaming partitioning heuristic among the ones presented in [39]. This was probably because the order in which the vertices were presented to the partitioner favored DG over LDG (the results of DG and LDG rely on the order in which vertices are presented). This was also the reason why we picked DG as the default initial partitioner for PARAGON.

Quality of the Resulting Decompositions (Figures 10a & 10b) Figures 10a and 10b show the corresponding communication cost of the resulting decompositions and the improvement achieved by PARAGON in terms of the communication cost when compared to the initial decompositions. As shown, the better the initial decomposition was, the better the resulting decomposition would be. In comparison with the initial decompositions computed by HP, DG, and LDG, PARAGON reduced the communication cost of the decompositions by up to 58% (43% on average), 29% (17% on average), and 53% (36% on average), respectively. Although PARAGON did not improve significantly the decompositions computed by METIS for easily partitioned FEM and road networks (left 7 datasets), it achieved an improvement of up to 4.5% for complex networks (right 5 datasets). Given the size of the dataset, the improvement was still non-negligible. Fortunately, we found that PARAGON with DG as its initial partitioner can achieve even better performance than METIS on real-world workloads (Section 7.2).

Refinement Overhead (Figures 11a & 11b) We also noticed that the quality of the initial decomposition impacted the refinement overhead greatly. Figures 11a and 11b plot the migration cost (Eq. 3) and the refinement time. Clearly, the poorer the initial decomposition was, the higher the migration cost and the longer the refinement time would be. Finally, for decompositions, which PARAGON failed to make much improvement, PARAGON only led to a very small amount of overhead.

(a) Communication cost of the decompositions after being refined.

(b) Improvement achieved by PARAGON against the initial decomposition.

7.2 Real-World Applications (BFS & SSSP)

Configuration This experiment evaluated PARAGON using BFS and SSSP on the YouTube, as-skitter, and com-lj datasets. Initially, the graphs were partitioned across cores of three compute nodes of two clusters using DG. Then, the decomposition was improved by PARAGON with the degree of refinement parallelism and the number of shuffle refinement times both set to 8. During the execution of BFS/SSSP, we grouped multiple (8 for YouTube and as-skitter dataset and 16 for com-lj dataset) messages sent by each MPI rank to the same destination into a single one.

Resource Contention Modeling To capture the impact of resource contention, we carried out a profiling experiment for BFS and SSSP with the 3 datasets on both clusters by increasing λ gradually from 0 to 1. Interestingly, we found that intra-node shared resource contention was more critical to the performance on PittMPIcluster, while inter-node communication was the bottleneck on Gordon. This was probably caused by the differences in network topologies (flat vs hierarchical), core count per node (20 vs 16), memory bandwidth (65GB vs 85GB), and network bandwidth (56GB vs 8GB) between the two clusters, and that BFS/SSSP had to compete with other jobs running on Gordon for the network resource, while there was no contention on the network communication links on PittMPIcluster. Hence, we fixed λ to be 1 on PittMPIcluster and 0 on Gordon for the experiment.

Job Execution Time (Tables 4 & 5) Tables 4 and 5 show the overall execution time of BFS and SSSP with 15 randomly selected source vertices on the three datasets and the overhead of PARAGON. The execution time of a distributed graph computation is defined as: $JET = \sum_{i=1}^n SET(i)$, where n is the number of supersteps the job has, while $SET(i)$ denotes the execution time of the i th super-

step and is defined as the i th superstep execution time of the slowest MPI rank. In the table, DG and METIS mean that BFS/SSSP was performed on the datasets without any repartitioning/refinement, PARMETIS is a state-of-the-art multi-level graph repartitioner [30], UNIPARAGON was a variant of PARAGON that assumes homogeneous and contention-free computing environment, and the numbers within the parentheses were the overhead of repartitioning/refining the decomposition computed by DG.

As expected, PARAGON beat DG, PARMETIS, and UNIPARAGON in all cases. Compared to DG, PARAGON reduced the execution time of BFS and SSSP on Gordon by up to 60% and 62%, respectively, and up to 83% and 78% on PittMPIcluster, respectively. If we time the improvements by the number of MPI ranks (48 for Gordon and 64 for PittMPIcluster), the improvements were more remarkable. Yet, the overhead PARAGON exerted (the sum refinement time and physical data migration time) was very small in comparison to the improvement it achieved and the job execution time. By comparing the results of UNIPARAGON with DG, we can conclude that PARAGON not only improved the mapping of the application communication pattern to the underlying hardware, but also the quality of the initial decomposition (edge-cut). Also, if we compare the execution time of BFS/SSSP on both clusters, we would find that the speedup PARAGON achieved by increasing the number of cores from 48 to 60 was much higher than that of DG. What we did not expect was that PARAGON with DG as its initial partitioner outperformed the gold standard, METIS, in 4 out of the 6 cases and was comparable to METIS in other cases.

Communication Volume Breakdown (Figures 12 & 13) To further confirm our observations, we also collected the total amount of data remotely exchanged per superstep by BFS and SSSP among cores of the same socket (intra-socket communication volume),

Table 4: BFS Job Execution Time (s)

Algorithm/Dataset	YouTube	as-skitter	com-lj
PittMPICluster			
DG	30	59	218
METIS	8.50	67	27
PARMETIS	29 (21.00)	59 (9.65)	185 (4.71)
UNIPARAGON	25 (2.70)	27 (2.26)	159 (7.54)
PARAGON	8 (4.00)	10 (3.31)	40 (10.00)
Gordon			
DG	322	577	4319
UNIPARAGON	264 (2.70)	350 (2.07)	3310 (6.98)
PARAGON	220 (3.83)	228 (2.96)	2586 (9.08)

Figure 12: The breakdown of the accumulated communication volume across all supersteps for BFS on PittMPICluster.

among cores of the same compute node but belonging to different sockets (inter-socket communication volume), and among cores of different compute nodes (inter-node communication volume). Since we observed similar patterns for BFS and SSSP in all the cases, we only present the breakdown of the accumulated communication volume across all supersteps for BFS here.

As shown in Figures 12 (for PittMPICluster) and 13 (for Gordon), PARAGON and UNIPARAGON have much lower remote communication volume than DG in all cases, and PARAGON has the lowest inter-node communication volume and highest intra-node (inter-socket & intra-socket) communication volume on Gordon (vice versa on PittMPICluster), which was expected given our choice for λ . It is worth mentioning that on PittMPICluster, intra-node data communication was the bottleneck. Another interesting thing was that in spite of its higher total communication volume when compared to METIS, PARMETIS, and UNIPARAGON, PARAGON still outperformed them in most cases due to the reduced communication on critical components.

Graph Dynamism (Figure 14) To further validate the effectiveness of PARAGON in the presence of graph dynamism, we split the YouTube dataset (a collection of YouTube users and their friendship connections over a period of 225 days) into 5 snapshots with an interval of 45 days. Thus, snapshot S_i denotes the collection of YouTube users and their friendship connections appearing during the first $45 * i$ days. We then ran BFS on snapshot S_1 across three 20-core machines and injected vertices newly appeared in each snapshot to the system using DG whenever BFS finished its computation for every 15 randomly selected vertices. The injection also triggered the execution of PARAGON, UNIPARAGON, and PARMETIS on the decomposition.

Figure 14 plots the BFS execution time for 15 randomly selected source vertices on each snapshot. As shown, both architecture-awareness and the capability to cope with graph dynamism were critical to achieve superior performance. This is especially true as the graph changes a lot from its original version: at snapshot S_5 , PARAGON performed 90% better than DG, 85% better than METIS, 73% better than PARMETIS, and 89% better than UNIPARAGON.

Table 5: SSSP Job Execution Time (s)

Algorithm/Dataset	YouTube	as-skitter	com-lj
PittMPICluster			
DG	2136	1823	5196

Figure 13: The breakdown of the accumulated communication volume across all supersteps for BFS on Gordon.

7.3 Billion-Edge Graph Scaling

Configuration In this experiment, we investigated the scalability of PARAGON as the graph scale increased. Towards this, we generated three additional datasets by sampling the edge list of the friendster dataset (3.6 billion edges). We denote the datasets generated as friendster- p , where p was the probability that each edge was kept while sampling. Hence, friendster- p would have around $3.6 * p$ billion edges. Interestingly, the number of vertices remained almost unchanged in spite of the sampling. We ran the experiment on three compute nodes of PittMPICluster with the degree of refinement parallelism, the number of shuffle refinement times, and the message grouping size set to 10, 10, and 256, respectively.

Results (Figures 15 & 16) Figures 15 and 16 present the execution time of BFS with 15 randomly selected source vertices and the overhead of PARAGON at different graph scales. As shown, PARAGON not only led to lower job execution times, but also to lower speed in which the job execution time increased as the graph size increased. It should be noticed that PARAGON reduced the execution time of all machines (3*20 cores) not just one. Also, the refinement time increased at a much slower rate (from 140s, to 236s, to 312s, and to 410s) than that of the graph size. The reason why we did not present the results of METIS or PARMETIS here was because they failed to (re)partition the graphs (even for the first dataset, of 0.9 billion edges).

8. RELATED WORK

Graph partitioning and repartitioning are receiving more and more attention in recent years due to the proliferation of large graph datasets. In this section, we categorize existing approaches of graph (re)partitioners into three types: (a) heavyweight, (b) lightweight, and (c) streaming, which are presented next.

Heavyweight Graph (Re)Partitioning Graph partitioning and repartitioning has been studied for decades (e.g., METIS [23], PARMETIS [30], Scotch [36], Chaco [7], and Zoltan [1]). These graph (re)partitioners are well-known for their capability of producing high-quality graph decompositions. However, they usually require full knowledge of the entire graph for (re)partitioning, making them scale poorly against

Figure 14: BFS JET with Graph Dynamism

Figure 15: BFS JET vs Graph Size

Figure 16: Refinement Time vs Graph Size

large graphs even if performed in parallel. Furthermore, they are all architecture-agnostic. Although [24], a METIS variant, considers the communication heterogeneity, it is a *sequential static graph partitioner*, which is inapplicable for massive graphs or dynamic graphs. Several recent works [48, 8] have been proposed to cope with the heterogeneity and dynamism. However, they are also too heavyweight for massive graphs because of the high communication volume they generate. As a consequence, they are not appropriate for online graph repartitioning in large-scale distributed graph computation. Furthermore, they disregard the issue of resource contention in multicore systems.

Lightweight Graph Repartitioning As a result of the shortcomings of heavyweight graph (re)partitioners, many lightweight graph repartitioners [37, 43, 26, 17, 45] have been proposed. They efficiently adapt the partitioning to changes by incrementally migrating vertices among partitions based on some heuristics (rather than repartitioning the entire graph). Nevertheless, they are not architecture-aware. Also, many of them assume uniform vertex weights and sizes, and some [43, 26] even assume uniform edge weights, which may not always be true.

In fact, work [17] is a Pregel-like graph computing engine, which migrates vertices based on runtime characteristics of the workload (i.e., # of message sent/received by each vertex and response time) instead of the graph structure (i.e., the distribution of vertex neighbors, edge weights, and vertex sizes). Paper [45] also presents a repartitioning system that migrates vertices on-the-fly based on some runtime statistics (i.e., the average compute and communication time of each superstep and the probability of a vertex becoming active in the next superstep).

Recently, a novel distributed graph partitioner, Sheep [22], has been proposed for large graphs. It is similar in spirit to METIS. That is, they both first reduce the original graph to a smaller tree or a sequence of smaller graphs, then do a partition of the tree or the smallest graph, and finally map the partitioning back to the original graph. In terms of partitioning time, Sheep outperforms both METIS and streaming partitioners. For partitioning quality, Sheep is competitive with METIS for a small number of partitions and is competitive with streaming graph partitioners for larger numbers of partitions. However, Sheep is unable to deal with both weighted and dynamic graphs, and it is architecture-agnostic.

Streaming Graph Partitioning Recently, a new family of graph partitioning heuristics, streaming graph partitioning [39, 11, 42], has been proposed for online graph partitioning. They are able to produce partitionings comparable to the heavyweight graph partitioner, METIS, within a relative short time. However, they are architecture-agnostic. Although [46] has presented a streaming graph partitioner with awareness of both compute and communication heterogeneity, it may lead to suboptimal performance in the presence of graph dynamism.

Vertex-Cut Graph Partitioning Several vertex-cut graph partitioners [44, 31, 13] were also proposed to improve the performance of distributed graph computation. Vertex-cut solutions partition

the graph by assigning edges of the graph across partitions instead of vertices. It has been shown that vertex-cut solutions reduce the communications with respect to edge-cut ones, especially on power-law graphs. However, it also has to deal with the issue of communication heterogeneity and the issue of shared-resource contention, since vertices appearing in multiple partitions need to communicate with each other during the computation. Nevertheless, its discussion is beyond the scope of this paper.

Overview of Related Work Table 6 visually classifies the state-of-the-art graph (re)partitioners according to algorithm and graph properties. In terms of *algorithm properties*, we characterize each approach as to whether it (a) runs in parallel and (b) is architecture-aware (i.e., CPU heterogeneity, network cost non-uniformity, and resource contention). In terms of *graph properties*, we characterize each approach as to whether it can handle graphs with (a) dynamism, (b) weighted vertices (i.e., nonuniform computation), (c) weighted edges (i.e., nonuniform data communication), and (d) vertex sizes (i.e., nonuniform data sizes on each vertex).

9. CONCLUSIONS

In this paper, we presented PARAGON, a *parallel architecture-aware* graph partition refinement algorithm that bridges the mismatch between the application communication pattern and the underlying hardware topology. PARAGON achieves this by modifying a given decomposition according to the nonuniform network communication costs and consideration of the contentiousness of the underlying hardware. To further reduce its overhead, we made PARAGON itself architecture-aware. Compared to the state-of-the-art, PARAGON improved the quality of graph decompositions by up to 53%, achieved up to 5.9x speedups on real workloads, and successfully scaled up to a 3.6 billion-edge graph.

10. ACKNOWLEDGMENTS

We would like to thank Jack Lange, Albert DeFusco, Kim Wong, Mark Silvis, and the anonymous reviewers for their valuable help on the paper. This work was funded in part by NSF awards CBET-1250171 and OIA-1028162.

ABSTRACT

As the volume of the RDF data becomes increasingly large, it is essential for us to design a distributed database system to manage it. For distributed RDF data design, it is quite common to partition the RDF data into some parts, called *fragments*, which are then distributed. Thus, the distribution design consists of two steps: fragmentation and allocation. In this paper, we propose a method to explore the intrinsic similarities among the structures of queries in a workload for fragmentation and allocation, which aims to reduce the number of crossing matches and the communication cost during SPARQL query processing. Specifically, we mine and select some *frequent access patterns* to reflect the characteristics of the workload. Based on the selected frequent access patterns, we propose two fragmentation strategies, vertical and horizontal fragmentation strategies, to divide RDF graphs while meeting different kinds of query processing objectives. Vertical fragmentation is for better throughput and horizontal fragmentation is for better performance. After fragmentation, we discuss how to allocate these fragments to various sites. Finally, we discuss how to process a query based on the results of fragmentation and allocation. Extensive experiments confirm the superior performance of our proposed solutions.

1. INTRODUCTION

As a standard model for publishing and exchanging data on the Web, Resource Description Framework (RDF) has been widely used in various applications to expose, share, and connect pieces of data on the Web. In RDF, data is represented as triples of the form (subject, property, object). An RDF dataset can be naturally seen as a graph, where subjects and objects are vertices connected by named relationships (i.e., properties). SPARQL is a structured query language proposed by W3C to access RDF repository. As we know, answering a SPARQL query Q is equivalent to finding subgraph matches of query graph Q over an RDF graph G [31]. Figures 1 and 2 show an RDF graph and a set of SPARQL query graphs used as the running example in this paper.

As RDF repositories increase in size, evaluating SPARQL queries

is beyond the capacity of a single machine. For example, DBpedia, a project aiming to extract structured content from Wikipedia, consists of 2.46 billion RDF triples [4]; according to the W3C, the numbers of triples in some commercial RDF datasets have been more than 1 trillion [6]. The large-scale of RDF data volume increases the demand of designing the high performance distributed RDF database system.

In distributed database design, the first issue is “data fragmentation and allocation” [18]. We need to divide an RDF graph into several parts, called *fragments*, and then distribute them among sites. One important issue during data fragmentation and allocation in a distributed system is how to reduce the communication cost between different fragments during distributed query evaluation (assuming different fragments are resident at different sites). To minimize the communication cost, many existing graph fragmentation strategies maximize the global goal (such as min-cut [12]). However, evaluating a SPARQL query is a subgraph (homomorphism) match problem. The subgraph match computation often does not involve all vertices in graph G , and the communication cost of subgraph match computation depends on not only the RDF graph but also the query graph. In other words, subgraph match computation exhibits strong locality. There is no direct relation between minimizing the communication cost (in subgraph match computation) and maximizing the global goal. Hence, we propose a *local pattern-based fragmentation* strategy in this paper, which can reduce the communication cost of subgraph match computation.

The intuition behind the local pattern-based fragmentation is as follows: if a query “satisfies” a local pattern and all its matches are in a single fragment, then the query can be evaluated on the single fragment and no communication cost is needed to answering the query. The key issue in local pattern-based fragmentation is how to define the “local patterns”. Different from the existing methods, we consider the query workload-driven “local pattern” definition.

1.1 Why Query Workload Matters ?

The workload-driven distributed data fragmentation has been well studied in relational databases [18]. However, few RDF data fragmentation proposals consider the query workload except for [8, 6]. We will review these related papers in Section 9. Here, we discuss why the query workloads is important for RDF data fragmentation.

We study one real SPARQL query workload, the DBpedia query workload, which records 8,151,238 SPARQL queries issued in 14 days of 2012¹. For this workload, if we set the minimum support threshold as 0.1% of the total number of queries, we mine 163 frequent subgraph patterns. The most surprising is that 97% query graphs are isomorphic to one of the 163 frequent subgraph pat-

*corresponding author: zoulei@pku.edu.cn

¹<http://aksw.org/Projects/DBPSB.html>

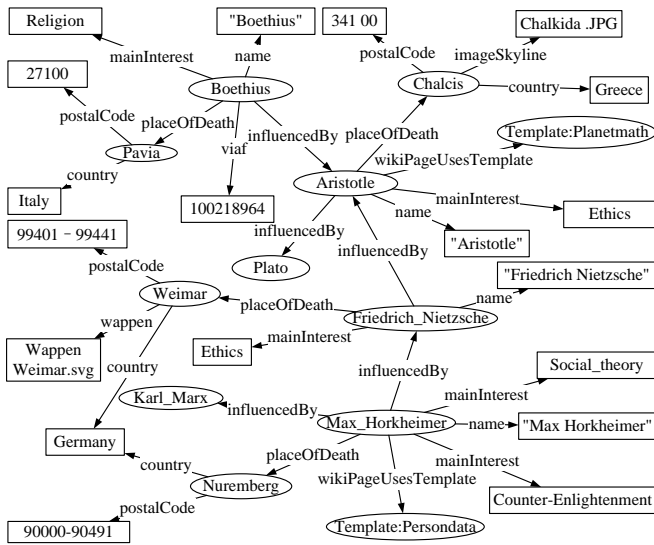

Figure 1: Example RDF Graph

Figure 2: Example SPARQL Query Graphs

terns. Thus, if we use these frequent subgraph patterns as the basic fragmentation units, 97% SPARQL queries do not lead to communication cost, since their matches are resident at one fragment.

1.2 Our Solution

According to the above motivation, we propose a workload-driven data fragmentation for distributed RDF graph systems. Specifically, we first mine frequent subgraph patterns, named *frequent access patterns*, in the query workload. We treat these frequent access patterns as the *implicit* schemas for the underlying RDF data. Then, we propose two fragmentation strategies based on these implicit schemas. We study the following technical issues in this paper.

Frequent Access Pattern Selection. Given a frequent access pattern, we build a fragment by collecting all its matches in the RDF graph. In this way, we can reduce the communication cost (i.e. improve query performance) if a SPARQL query satisfies the frequent access pattern. However, if we simply select all frequent access patterns as the implicit schemas, it may lead to expensive space cost due to the data replication, since different frequent access patterns may involve share the same edges. In other words, we have a tradeoff between performance gain and space cost during selecting frequent access patterns. We formalize the frequent access pattern selection problem (Section 4.1) and prove that it is a NP-hard problem (Theorem 1). Thus, we propose a heuristic algorithm which can guarantee the data integrity and the approximation ratio (Theorem 2). This algorithm also achieves the good performance (See experiments in Section 8).

Vertical and Horizontal Fragmentation. Based on the selected frequent access patterns (i.e., implicit schemas), we design two

fragmentation strategies, i.e. vertical and horizontal fragmentation. These two fragmentation strategies are adaptive to different query processing objectives. The objective of vertical fragmentation strategy is to improve the query throughput, and requires that all structures involved by one frequent access pattern should be placed to the same fragment. Instead, the horizontal fragmentation strategy distributes the structures involved by one frequent access pattern among different fragments to maximize the parallelism of query evaluation, namely, reducing the query response time for a single query. To perform the horizontal fragmentation over RDF graphs, we extend the concept of “minterm predicate” in [18] to “structural minterm predicate” (see Section 5.2), which consider the structures of both RDF graphs and workloads. Different applications have different requirements, so we provide customizable options that can be used for different RDF graphs and SPARQL query workloads.

Query Decomposition. As we know, the query decomposition always depends on the fragmentation. In traditional vertical and horizontal fragmentation in RDBMS and XML, the query decomposition is unique, since there is no overlap between different fragments. As mentioned before, there are some data replications in our fragmentation strategies for RDF graphs. Thus, we may have multiple decomposition results for a query. A cost model driven selection is proposed in this paper.

The contributions of this paper can be summarized as follows:

- We analyze the characteristics of the real SPARQL query workload and use the intrinsic similarities of queries in the workload to mine and select some frequent access patterns for distributed RDF data design. Although we prove that the problem of frequent access pattern selection is NP-hard, we propose a heuristic method to achieve the good performance.
- Based on the above scheme, we propose two fragmentation strategies, vertical and horizontal fragmentation, to divide the RDF graph into many fragments and a cost-aware allocation algorithm to distribute fragments among sites. The two fragmentation strategies provide customizable options that are adaptive to different applications.
- We propose a cost-aware query optimization method to decompose a SPARQL query and generate a distributed execution plan. With the decomposition results and execution plan, we can efficiently evaluate the SPARQL query.
- We do experiments over both real and synthetic RDF datasets and SPARQL query workloads to verify our methods.

2. PRELIMINARIES

In this section, we review the terminologies used in this paper and formally define the problem to be addressed.

2.1 RDF and SPARQL

RDF data can be represented as a graph according to the following definition.

DEFINITION 1. (RDF Graph) An RDF graph is denoted as $G = \{V(G), E(G), L\}$, where (1) $V(G)$ is a set of vertices that correspond to all subjects and objects in RDF data; (2) $E(G) \subseteq V(G) \times V(G)$ is a set of directed edges that correspond to all triples in RDF data; and (3) L is a set of edge labels. For each edge $e \in E(G)$, its edge label is its corresponding property.

Similarly, a SPARQL query can also be represented as a query graph Q . For simplicity, we ignore FILTER statements in SPARQL syntax in this paper.

DEFINITION 2. (SPARQL Query) A SPARQL query is denoted as $Q = \{V(Q), E(Q), L'\}$, where (1) $V(Q) \subseteq V(G) \cup V_{var}$ is a set of vertices, where $V(G)$ denotes vertices in RDF graph G and V_{var} is a set of variables; (2) $E(Q) \subseteq V(Q) \times V(Q)$ is a set of edges in Q ; and (3) L' is also a set of edge labels, and each edge e in $E(Q)$ either has an edge label in L (i.e., property) or the edge label is a variable.

In this paper, we assume that Q is a connected graph; otherwise, all connected components of Q are considered separately. Given a SPARQL query Q over RDF graph G , a SPARQL match is a subgraph of G that is homomorphic to Q [31]. Thus, answering a SPARQL query is equivalent to finding all subgraph matches of Q over RDF graph G . The set of all matches for Q over G is denoted as $\llbracket Q \rrbracket_G$.

In this work, we study a query workload-driven fragmentation. A query workload $Q = \{Q_1, Q_2, \dots, Q_q\}$ is a set of queries that users input in a given period.

2.2 Fragmentation & Allocation

In this paper, we study an efficient distributed SPARQL query engine. There are many issues related to distributed database system design, but, the focus of this work is “data fragmentation and allocation” for RDF repository. We formalize two important problems as follows.

DEFINITION 3. (Fragmentation) Given an RDF graph G , a fragmentation \mathcal{F} of G is a set of graphs $\mathcal{F} = \{F_1, \dots, F_n\}$ such that: (1) each F_i is a subgraph of G and called as a fragment of RDF graph G ; (2) $E(F_1) \cup \dots \cup E(F_n) = E(G)$; and (3) $V(F_1) \cup \dots \cup V(F_n) = V(G)$, where $E(F_i)$ and $V(F_i)$ denote the edges and vertices in F_i ($i = 1, \dots, n$).

In our work, we allow the overlaps between different fragments. Given a fragmentation \mathcal{F} , the next issue is how to distribute these fragments among different sites (i.e., computing nodes). This is called *allocation*.

DEFINITION 4. (Allocation) Given a fragmentation $\mathcal{F} = \{F_1, \dots, F_n\}$ over an RDF graph G and a set of sites $\mathcal{S} = \{S_1, S_2, \dots, S_m\}$ (usually $m < n$), an allocation $\mathcal{A} = \{A_1, \dots, A_m\}$ of fragments in \mathcal{F} to \mathcal{S} is a partitioning of \mathcal{F} such that (1) $A_j \subseteq \mathcal{F}$, where $1 \leq j \leq m$; (2) $A_{j_1} \cap A_{j_2} = \emptyset$, where $1 \leq j_1 \neq j_2 \leq m$; (3) $A_1 \cup \dots \cup A_m = \mathcal{F}$; and (4) All fragments in A_j are stored at site S_j , where $1 \leq j \leq m$.

Given an RDF graph G , a query workload Q and a distributed system consisting of sites \mathcal{S} , the goal of this paper is to first decompose G into a fragmentation \mathcal{F} and then finding the allocation \mathcal{A} of \mathcal{F} to \mathcal{S} .

3. OVERVIEW

This paper studies a SPARQL query workload-driven data fragmentation and allocation problem. Some observations on the real query workload tell us that some RDF properties have few access frequencies. For example, few users input queries contain the properties like *imageSkyline* and *wikiPageUsesTemplate* in Figure 1. As well, the classical distributed database design suggests a “80/20” rule, meaning the active “20%” of query patterns account for “80%” of the total query input [24]. Therefore, we divide the whole RDF repository into two parts: “hot graph” and “cold graph” as follows.

DEFINITION 5. (Infrequent and Frequent Property) Given a query workload $Q = \{Q_1, \dots, Q_n\}$, if a property p occurs in less than θ queries in Q , where θ is an user specified parameter; p is an infrequent property; otherwise, p is a frequent property.

Figure 3: System Architecture

DEFINITION 6. (Hot and Cold Graphs) Given an edge $e = \overrightarrow{u_i u_j} \in E(G)$ with property p , if property p is a frequent property, e is a hot edge; otherwise, e is a cold edge.

Given an RDF graph G , it is divided into two parts: hot graph H and cold graph C , where H consists of all hot edges and C consists of all cold edges.

The goal of this work is how to partition “hot graph” to achieve performance improvement. We regard the cold graph as a “black block”. The cold graph does not overlap to the hot graph, since the cold graph contains different edges with different kinds of properties from the hot graph. Any existing approach can be utilized for the cold graph. We only consider the cold graph in the SPARQL query processing (Section 7), since some queries may involve “infrequent” properties. Moreover, both the cold graph and the hot graph may be disconnected.

Figure 3 illustrates our system architecture. In the offline phase, we mine the *frequent access patterns* (see Section 4) in the workload. Each frequent access pattern can correspond to one or more fragments. Generating a fragment from all matches of a frequent access pattern make many queries be answered efficiently without cross-fragments joins, while it may also replicate some hot edges and increase the space cost. Thus, we should select an appropriate subset of frequent access patterns to balance the efficiency and the space cost. Since we find out that selecting an appropriate set of patterns is a NP-hard problem (Section 4.1), we propose a heuristic pattern selection solution while guaranteeing both the data integrity and the approximation ratio. Based on these selected frequent access patterns, we study two different data fragmentation strategies, i.e., vertical and horizontal fragmentation (Section 5). The vertical fragmentation is to improve the query throughput, and the horizontal fragmentation is to reduce a single query’s response time. Fragments are distributed among different sites. Meanwhile, we maintain the metadata in a data dictionary.

In the online phase, we study how to decompose a query into several subqueries on different fragments and generate an efficient execution plan. A cost model for guiding decomposition is proposed (Section 7.2). Finally, we execute the plan and return the matches of the query.

4. FREQUENT ACCESS PATTERNS

As mentioned before, we believe that a query often contains some patterns in the previously issued queries, so we mine some patterns with high access frequencies and use these patterns as the fragmentation units. Then, if a query Q can be decomposed to some subgraphs isomorphic to the frequent access patterns, Q can be answered while avoiding some joins across multiple fragments.

Before we mine frequent access patterns, we first normalize the query graphs in the workload to avoid overfitting. For each SPARQL query, we remove all constants (strings and URIs) at subjects and

Figure 4: Example Frequent Access Patterns

objects and replace them with variables. The FILTER expressions are also removed. By doing this, we extract a general representation of a SPARQL query from the workload. Figure 4 shows the generalized query graphs of query graphs in Figure 2. We assume that the generalized query in Figure 4 graphs are also frequent access patterns.

To mine patterns with high access frequencies, we need to first count the number of queries in the workload where a pattern p is a subgraph. We define the *frequent access pattern usage value* to record the access frequencies of the frequent access patterns.

DEFINITION 7. (Frequent Access Pattern Usage Value) Given a SPARQL query Q and a frequent access pattern p , we associate a frequent access pattern usage value, denoted as $use(Q, p)$, and defined as follows:

$$use(Q, p) = \begin{cases} 1 & \text{if pattern } p \text{ is a subgraph of } Q \\ 0 & \text{otherwise} \end{cases}$$

Then, given a workload $Q = \{Q_1, Q_2, \dots, Q_q\}$ and a pattern p , we define the *access frequency*, $acc(p)$, as the number of queries in Q where a pattern p is a subgraph.

$$acc(p) = \sum_{k=1}^q use(Q_k, p)$$

A pattern p is *frequent access pattern* if its access frequency is no less than a threshold, $minSup$.

The frequent access patterns can be easily generated by existing frequent graph mining algorithms [17]. Given a workload of SPARQL queries $Q = \{Q_1, Q_2, \dots, Q_q\}$ in a given period, we denote the set of frequent access patterns that we find as $P = \{p_1, p_2, \dots, p_x\}$. In practice, the size of P is often limited. For example, if we set $minSup$ as 0.1% of the total access frequency, there are only 163 frequent access patterns for DBPedia.

4.1 Frequent Access Pattern Selection

Obviously, it is not necessary to generate fragments from all frequent access patterns due to high space cost. For two similar frequent access patterns p and p' , if they are contained by similar queries of the workload, then selecting both p and p' for building fragments will not be able to provide more information than selecting one of p and p' . Hence, it is often sufficient to only select a subset of all frequent access patterns to generate fragments.

To select a subset of all frequent access patterns, there are two factors that we should consider.

1. (*Hitting the Whole Workload*) We should select frequent access patterns to hit the query workload as much as possible. This is because that when we select a frequent access pattern to generate a fragment, all queries isomorphic to this pattern can be answered directly, which improve the efficiency.
2. (*Satisfying the Storage Constraint*) The total storage of the system in real applications is limited, so selecting too many frequent access patterns is not desirable.

The above two factors contradict each other. Hitting the whole workload requires to select as many frequent access patterns as possible, while the storage constraint requires to select not too many frequent access patterns. There should be a tradeoff between the two factors.

In the following, we propose a cost model to combine these two factors for selecting a subset of all frequent access patterns.

4.1.1 Hitting the Whole Workload

If a fragment is generated from the graph induced by matches of a frequent access pattern, then evaluating all queries containing the pattern can be speeded up by using this fragment. The more queries a frequent access pattern hits, the more gains we obtain during query processing. Therefore, the *benefit* of selecting a frequent access pattern to generate its corresponding fragment should be defined based on the number of queries that the frequent access pattern hits.

In addition, if two similar frequent access patterns are contained by the same set of queries in the workload, it is probably wise to include only one of them. Generally speaking, among similar frequent access patterns contained by the same number of queries, it is often sufficient to materialize only the largest frequent access pattern. That is to say, if p' , a subgraph of p , is contained by the same set of queries as p , p is more beneficial than p' to be selected as building fragments. This is because that if we select the larger pattern, a query is more probable to be decomposed to fewer number of subqueries during query processing. Fewer subqueries can avoid some distributed joins, which can improve the efficiency of query processing.

The above observation implies that larger frequent access patterns are more beneficial to be selected as building fragments. This above criterion on the selection of frequent access patterns is formally defined as *size-increasing benefit*.

DEFINITION 8. (Size-increasing Benefit) Given a frequent access pattern p , the benefit of selecting p for hitting the query Q , $Benefit(p, Q)$, is denoted as follows.

$$Benefit(p, Q) = |E(p)| \times use(Q, p)$$

Furthermore, a query in the workload may contain multiple selected frequent access patterns. This means that the query can be decomposed into multiple sets of subqueries if we evaluate the query. Each set of subqueries can map to an execution plan. Since only one execution plan is finally selected to evaluate the query, a query in the workload should only be limited to contribute to the benefits of some particular frequent access patterns once. Based on this observation, we limit a query to only contribute the largest frequent access pattern that the query contains.

DEFINITION 9. (Benefit of a Frequent Access Pattern Set) Given a set of frequent access patterns $P' \subseteq P$, the benefit of selection of P' over the workload Q is the sum of the maximum benefit of its frequent access patterns over Q .

$$Benefit(P', Q) = \sum_{Q \in Q} \max_{p \in P'} \{Benefit(p, Q)\}$$

4.1.2 Satisfying the Storage Constraint

Furthermore, the total storage of the system in real applications is limited, so selecting too many frequent access patterns is not desirable. The selection of frequent access patterns should meet some constraints. When the size of all fragments is larger than the storage constraint, we cannot further select any more frequent

access patterns. We normalize the storage capacity of the system to a value SC . Then, we have the constraint as:

$$\sum_{p \in P'} |E(\llbracket p \rrbracket_G)| \leq SC$$

Here, we assume that SC is larger than the number of edges in the hot graph, so each hot edge can have at least one copy. This assumption guarantees the completeness of the RDF graph.

4.1.3 Combining the Two Factors

Then, our optimization objective is to maximize the benefit subject to the storage constraint. We can prove that this benefit function (Definition 9) is submodular as follows, so this problem is NP-hard.

THEOREM 1. *Finding a set of frequent access patterns with the largest benefit while subject to the storage constraint is NP-hard.*

PROOF. Here, we prove that the benefit function $Benefit(P', Q) = \sum_{Q \in Q} \max_{p \in P'} \{|E(p)| \times use(Q, p)\}$ is submodular. In other words, for every $P_1 \subseteq P_2$ and a frequent access pattern $p \notin P_2$, we need to prove that $\Delta_{Benefit}(p|P_1) \geq \Delta_{Benefit}(p|P_2)$.

For pattern p , we assume that Q' is the set of queries containing p in the workload. There are three kinds of queries in Q' : the set Q_1 of queries not containing any patterns in P_2 , the set Q_2 of queries containing patterns in $(P_2 - P_1)$, and the set Q_3 of queries only containing patterns in P_1 .

Since any query in Q_1 and Q_3 does not concern patterns in $(P_2 - P_1)$, $Benefit(\{p\} \cup P_1, Q_1 \cup Q_3) = Benefit(\{p\} \cup P_2, Q_1 \cup Q_3)$. Hence, the marginal gains of p for P_1 and P_2 over Q_1 and Q_3 are the same.

For Q_2 , $\Delta_{Benefit}(p|P_1) > \Delta_{Benefit}(p|P_2)$, if there exist at least one query Q^* meeting all the two following conditions: 1) the largest pattern contained by Q^* over P_2 is in $(P_2 - P_1)$ and has larger size than p ; 2) the largest pattern contained by Q^* over P_1 has smaller size than p . The above two conditions mean that p can only increase the benefit of P_1 over Q_2 but not the benefit of P_2 over Q_2 . Otherwise, for Q_2 , $\Delta_{Benefit}(p|P_1) = \Delta_{Benefit}(p|P_2)$.

In conclusion, $\Delta_{Benefit}(p|P_1) \geq \Delta_{Benefit}(p|P_2)$ and the function $Benefit(P', Q)$ is submodular. Since the problem of maximizing submodular functions is NP-hard [3], the problem is NP-hard. \square

4.1.4 Our Solution

As proved in Theorem 1, frequent access pattern selection is NP-complete problem. We propose a greedy algorithm as outlined in Algorithm 1. Note that, to guarantee data integrity of distributed RDF data fragmentation, each hot edge should be contained in at least one fragment. Hence, we initialize a pattern of one edge for each frequent property and compute out its corresponding fragment (Line 3-6).

After we select all patterns with one edge, we enumerate all feasible frequent access pattern sets containing one pattern of more than one edge. Let P_1 be a feasible set of cardinality one that has the largest benefit (Line 7). Then, we iteratively select one of the remaining frequent access patterns p' to maximize the value of $\frac{Benefit(\{p'\} \cup P', Q) - Benefit(P', Q)}{|E(\llbracket p' \rrbracket_G)|}$ until we meet the storage constraint or cannot find a frequent access pattern to increase the benefit (Line 8-14). Let P_2 be the solution obtained in the iterative phase. Finally, the algorithm outputs $P' \cup P_1$ if $Benefit(P' \cup P_1, Q) \geq Benefit(P' \cup P_2, Q)$ and $P' \cup P_2$ otherwise (Line 15-17).

THEOREM 2. *Algorithm 1 obtains a set of frequent access patterns of benefit at least $\min\{\frac{1}{(\max_{p \in P} |E(p)|)}, \frac{1}{2}(1 - \frac{1}{e})\}$ times the value of an optimal solution.*

PROOF. There are two parts in Algorithm 1: initialization and greedy selection of frequent access patterns.

Algorithm 1: Frequent Access Pattern Selection Algorithm

Input: A set of frequent access patterns $P = \{p_1, p_2, \dots, p_x\}$
Output: A set $P' \subseteq P$ to generate fragments

```

1  $P' \leftarrow \emptyset$ ;
2  $TotalSize \leftarrow 0$ ;
3 for each  $p \in P$  and  $p$  has only one edge do
4    $P' \leftarrow P' \cup \{p\}$ ;
5    $P \leftarrow P - \{p\}$ ;
6    $TotalSize \leftarrow TotalSize + |E(\llbracket p \rrbracket_G)|$ ;
7  $P_1 \leftarrow \operatorname{argmax}\{\frac{Benefit(\{p_i\}, Q)}{|E(\llbracket p_i \rrbracket_G)|} : p_i \in P, |E(\llbracket p_i \rrbracket_G)| + TotalSize \leq SC \wedge |E(p_i)| > 1\}$ ;
8  $P_2 \leftarrow \emptyset$ ;
9  $TotalSize' \leftarrow 0$ ;
10 while  $TotalSize' \leq SC - TotalSize$  do
11   Find the frequent access pattern  $p' \in P - P'$  with the largest additional value of  $\frac{Benefit(\{p'\} \cup P', Q) - Benefit(P', Q)}{|E(\llbracket p' \rrbracket_G)|}$ ;
12    $P_2 \leftarrow P_2 \cup \{p'\}$ ;
13    $P \leftarrow P - \{p'\}$ ;
14    $TotalSize' \leftarrow TotalSize' + |E(\llbracket p' \rrbracket_G)|$ ;
15 if  $Benefit(P' \cup P_1, Q) \geq Benefit(P' \cup P_2, Q)$  then
16   Return  $P' \cup P_1$ ;
17 Return  $P' \cup P_2$ ;
```

For initialization (Line 3-6 in Algorithm 1), all selected patterns only contain one edge, so $|E(p)| = 1$. Therefore, the benefit of patterns only having one edge of a frequent property is $\sum_{Q \in Q} \max_{p \in P'} \{1 \times use(Q, p)\}$. Since the hot edges hit almost all queries in the workload, $\sum_{Q \in Q} \max_{p \in P'} \{1 \times use(Q, p)\}$ is approximately equal to the size of the workload, $|Q|$. On the other hand, in the worst case, the optimal solution is that all queries in the workload contain the largest frequent access pattern. Then, the benefit of the optimal solution is $\sum_{Q \in Q} \{|E(p_{max})| \times use(Q, p)\}$, where p_{max} is the frequent pattern with the largest size. Hence, the benefit of the selected patterns in the initial phase is at least $\frac{1}{(\max_{p \in P} |E(p)|)}$ of the optimal benefit.

For the phase of greedily selecting frequent access patterns (Line 7-14 in Algorithm 1), since the problem of selecting the optimal set of frequent access patterns is a problem of maximizing a submodular set function subject to a knapsack constraint as discussed in Theorem 1, we directly apply the greedy algorithm in [11] to iteratively select frequent access patterns. [11] proves that the worst-case performance guarantee of the greedy algorithm is $\frac{1}{2}(1 - \frac{1}{e})$, so the benefit of the selected patterns in this phase is at least $\frac{1}{2}(1 - \frac{1}{e})$ of the optimal benefit.

In summary, the final performance guarantee of our algorithm is $\min\{\frac{1}{(\max_{p \in P} |E(p)|)}, \frac{1}{2}(1 - \frac{1}{e})\}$. \square

5. FRAGMENTATION

In this section, we present two fragmentation strategies: vertical and horizontal.

5.1 Vertical Fragmentation

For vertical fragmentation, we put matches homomorphic to the same frequent access pattern into the same fragment. Because a query graph often only contains a few frequent access patterns and matches of one frequent access pattern are put together, other irrelevant fragments can be filtered out during query evaluation and only sites stored relevant fragments need to be accessed to find matches. Filtering out irrelevant fragments can improve the query performance. Furthermore, sites not storing relevant fragments can be used to evaluate other queries in parallel, which improves the total throughput of the system. In summary, the vertical fragmentation strategy utilizes the locality of SPARQL queries to improve

both query response time and throughput. Experimental results in Section 8 also confirm the above argument.

Given a frequent access pattern p , it can then be transformed into a SPARQL query, resulting in a vertical fragment of the RDF graph. We use the results $\llbracket p \rrbracket_G$ of a selection operation based on p to generate a vertical fragment. All vertical fragments generated from our selected frequent access patterns construct a vertical fragmentation. Given a set of frequent access patterns P , we formally define its corresponding vertical fragmentation over an RDF graph G as follows.

DEFINITION 10. (Vertical Fragmentation) Given an RDF graph G and a frequent access pattern p , a vertical fragment F generated from p is defined as $F = \{V(F), E(F), L'\}$, where (1) $V(F) \subseteq V(G)$ is the set of vertices occurring in $\llbracket p \rrbracket_G$; (2) $E(F) \subseteq E(G)$ is the set of edges occurring in $\llbracket p \rrbracket_G$; and (3) $L' \subseteq L$ is the set of edge labels occurring in $\llbracket p \rrbracket_G$.

Then, given a set of frequent access patterns $P = \{p_1, p_2, \dots, p_x\}$, the corresponding vertical fragmentation is $\mathcal{F} = \{F_i | 0 \leq i \leq x \text{ and } F_i \text{ is the vertical fragment generated from } p_i.\}$

EXAMPLE 1. Given the frequent access pattern p_3 in Figure 4, Figure 5 shows the corresponding vertical fragment.

Figure 5: Example Vertical Fragment

5.2 Horizontal Fragmentation

For horizontal fragmentation, we put matches of one frequent access pattern into the different fragments and distribute them among different sites. Then, a query may involve many fragments and each fragment has a few matches. The size of a fragment is often much smaller than the size of the whole data, so finding matches of a query over a fragment explores smaller search space than finding matches over the whole data. If the fragments involved by a query are allocated to different sites, then each site finds a few matches over some fragments with the smaller size than the whole data. This strategy is to utilize the parallelism of clusters of sites to reduce the query response time. The above argument is also confirmed by the experimental results in Section 8.

In this section, we extend the concepts of *simple predicate* and *minterm predicate* originally developed for relational systems [18] to divide the RDF graph horizontally.

5.2.1 Structural Minterm Predicate

First, we define the structural simple predicate. Each structural simple predicate corresponds to a frequent access pattern with a single (in)equality. Given a frequent access pattern p with variables set $\{var_1, var_2, \dots, var_n\}$, a structural simple predicate sp defined on D has the following form.

$$sp : p(var_i) \theta Value$$

where $\theta \in \{=, \neq\}$ and $Value$ is a constant constraint for var_i chosen from a query containing p in Q .

EXAMPLE 2. Let us consider the query graph Q_3 in Figure 2 and its corresponding frequent access pattern p_3 in Figure 4. We can generate four structural simple predicates: (1). $sp_1 : p_3(?x1) = Aristotle$; (2). $sp_2 : p_3(?x1) \neq Aristotle$; (3). $sp_3 : p_3(?x2) = Ethics$; (4). $sp_4 : p_3(?x2) \neq Ethics$.

Then, we define the structural minterm predicate as the conjunction of structural simple predicates of the same frequent access pattern. We can obtain all structural minterm predicates by enumerating all possible combinations of structural simple predicates. Given a set of structural simple predicates $SP = \{sp_1, sp_2, \dots, sp_y\}$ for frequent access pattern p , the set of structural minterm predicates $M = \{mp_1, mp_2, \dots, mp_z\}$ for p is defined as follows.

$$M = \{mp_i | \bigwedge_{sp_k \in SP} sp_k^*, 1 \leq k \leq y\}$$

where $sp_k^* = sp_k$ or $sp_k^* = \neg sp_k$. So each structural simple predicate can occur in a structural minterm predicate either in its natural form or its negated form.

Similar to the frequent access pattern, we can also define the *structural minterm predicate usage value* and *access frequency* to record the access frequency of a structural minterm predicate. We can prune the minterm predicates with small access frequencies.

DEFINITION 11. (Structural Minterm Predicate Usage Value) Given a SPARQL query Q and a structural minterm predicate mp , we associate a structural minterm predicate usage value, denoted as $use(Q, mp)$, and defined as follows:

$$use(Q, mp) = \begin{cases} 1 & \text{if predicate } mp \text{ is a subgraph of } Q \\ 0 & \text{otherwise} \end{cases}$$

Then, given a set of SPARQL queries $Q = \{Q_1, Q_2, \dots, Q_q\}$, we define the *access frequency* of a structural minterm predicate mp as follows.

$$acc(mp) = \sum_{k=1}^{k=q} use(Q_k, mp)$$

In practice, there may exist many minterm predicates. It is too expensive to enumerate all minterm predicates. Therefore, we prune some minterm predicates with too small access frequencies.

Given a structural minterm predicate mp , it can then be transformed into SPARQL queries, resulting in a horizontal fragment of the RDF graph. We use the results $\llbracket mp \rrbracket_G$ of a selection operation based on mp to generate a horizontal fragment. All horizontal fragments generated from the structural minterm predicates that we obtain construct a horizontal fragmentation. Given a set of minterm predicates M , we formally define its corresponding horizontal fragmentation over an RDF graph G as follows.

DEFINITION 12. (Horizontal Fragmentation) Given an RDF graph G and a structural minterm predicate mp , a horizontal fragment F generated from mp is defined as $F = \{V(F), E(F), L'\}$, where (1) $V(F) \subseteq V(G)$ is the set of vertices occurring in $\llbracket mp \rrbracket_G$; (2) $E(F) \subseteq E(G)$ is the set of edges occurring in $\llbracket mp \rrbracket_G$; and (3) $L' \subseteq L$ is the set of edge labels occurring in $\llbracket mp \rrbracket_G$.

Then, given a set of structural minterm predicates $M = \{mp_1, mp_2, \dots, mp_y\}$, the corresponding horizontal fragmentation is $\mathcal{F} = \{F_i | 0 \leq i \leq y \text{ and } F_i \text{ is the vertical horizontal generated from } mp_i.\}$

EXAMPLE 3. Given the structural simple predicates in Example 2, we can get all structural minterm predicates from frequent access pattern p_3 as follows: (1). $mp_1 : p_3(?x0) = Aristotle \wedge p_3(?x1) = Ethics$; (2) $mp_2 : p_3(?x0) = Aristotle \wedge p_3(?x1) \neq$

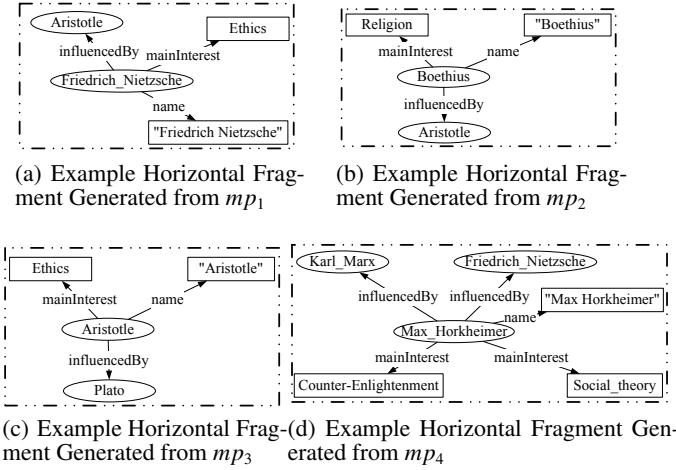

Figure 6: Example Horizontal Fragments

Ethics; (3). $mp_3 : p_3(?x0) \neq \text{Aristotle} \wedge p_3(?x1) = \text{Ethics}$; (4). $mp_4 : p_3(?x0) \neq \text{Aristotle} \wedge p_3(?x1) \neq \text{Ethics}$.

Figure 6 shows all horizontal fragments generated from the above structural minterm predicates.

6. ALLOCATION

After fragmenting the RDF graph, the next step is to allocate all fragments on several sites. In real applications, some frequent access patterns or structural minterm predicates are usually accessed together, so their corresponding fragments should be placed in one site to further avoid the cross-fragments joins. There is a need for some measures evaluating precisely the notion of “togetherness”. This measure is the affinity of fragments, which indicates how closely related the fragments are.

We define *fragment affinity metric* to measure the togetherness between two frequent access patterns or structural minterm predicates as follows:

DEFINITION 13. (Fragment Affinity Metric) The fragment affinity metric between two fragments F and F' with respect to the workload $Q = \{Q_1, Q_2, \dots, Q_q\}$ is defined as follows

- $aff(F, F') = \sum_{k=1}^q use(Q_k, p) \times use(Q_k, p')$, if F and F' are vertical fragments generated from frequent access patterns p and p' ;
- $aff(F, F') = \sum_{k=1}^q use(Q_k, mp) \times use(Q_k, mp')$, if F and F' are horizontal fragments generated from structural minterm predicates mp and mp' ;

Based on the fragment affinity metric, we can show how closely related the fragments are. If the affinity metric of two fragments is large, it means that these two fragments are often involved by the same query. Some fragments are so related that they should be placed together to reduce the number of cross-sites joins. Here, we group all fragments into some clusters. The result of clustering corresponds to an allocation \mathcal{A} , and each cluster corresponds to an element of \mathcal{A} , which means that all fragments in the cluster are placed into the same site.

There are many clustering algorithms to cluster all fragments and we need to select one of them. In this paper, we extend a graph clustering algorithm, PNN [5], to cluster all fragments into an allocation $\mathcal{A} = \{A_1, A_2, \dots, A_m\}$. All fragments of the same cluster are put into one site.

First, we build the *allocation graph* as follows.

DEFINITION 14. (Allocation Graph) Given a fragmentation $\mathcal{F} = \{F_1, F_2, \dots, F_n\}$, the corresponding allocation graph $AG = \{V(AG), E(AG), f_w\}$ is defined as follows:

- $V(AG)$ is a set of vertices that map to all fragments;
- $E(AG)$ is a set of undirected edges that $\overline{vv'} \in E(AG)$ if and only if the fragment affinity metric between the corresponding fragments of v and v' is larger than 0;
- f_w is a weight function $f_w : E(AG) \rightarrow N^+$. If v and v' correspond to fragments F and F' , $f_w(\overline{vv'}) = aff(F, F')$.

Then, the allocation problem is equivalent to cluster all fragments in m clusters, and all fragments in a cluster are connected in AG . We define the *density* of a cluster A_i in AG to rate the quality of A_i as follows.

$$\delta(A_i) = \frac{\sum_{v_i \in A_i \wedge v_j \in A_i \wedge \overline{v_i v_j} \in E(AG)} f_w(\overline{v_i v_j})}{\binom{|A_i|}{2}}$$

where $\sum_{v_i \in A_i \wedge v_j \in A_i \wedge \overline{v_i v_j} \in E(AG)} f_w(\overline{v_i v_j})$ is the sum of weights of all edges in A_i and $\binom{|A_i|}{2}$ is the maximum possible number of edges.

The objective of our allocation algorithm is to search for m sub-graphs of AG that have the highest densities. Unfortunately, this problem is NP-complete [20], so we propose a heuristic solution as Algorithm 2. Algorithm 2 is a variant of PNN and picks the locally optimal choice of merging two vertices in AG at each step. Because our objective function can guarantee the locally optimal choice is also the optimal choice for the overall solution, Algorithm 2 can find out the optimal clustering result of AG .

Generally speaking, we initialize a cluster for each fragment. Then, we repeatedly pick the two clusters (singletons or larger) that have the highest weight value to be merged. The weight between two clusters are the density value of merging them. Such merging is iterated until the size of the allocation graph has been reduced to m .

Algorithm 2: Allocation Algorithm

Input: The allocation graph AG and the preset threshold θ

Output: An allocation $\mathcal{A} = \{A_1, A_2, \dots, A_m\}$

```

1 for each vertex  $v_i$  in  $V(AG)$  do
2    $A_i \leftarrow \{v_i\}$ ;
3 Find the edge  $e_{max}$  with the highest weight in  $E(AG)$ ;
4 Initialize  $AG'$  that is the same to  $AG$ ;
5 while  $|V(AG')| \neq m$  do
6   Generating  $AG'$  from  $AG$  by merging  $e_{max} = \overline{A_i A_j}$  to  $A_{ij}$ ;
7   for each  $A_k$  adjacent to  $A_{ij}$  in  $E(AG')$  do
8      $f_w(\overline{A_k A_{ij}}) \leftarrow \frac{\sum_{v_i \in A_k \wedge (v_j \in A_i \vee v_j \in A_j) \wedge \overline{v_i v_j} \in E(AG)} f_w(\overline{v_i v_j})}{\binom{|A_k|}{2}}$ 
9   Find the edge  $e_{max}$  with the highest weight in  $E(AG')$ ;
```

7. DISTRIBUTED QUERY PROCESSING

In this section, we discuss how to process a SPARQL query. For query processing, the metadata is necessary and we introduce how to maintain the metadata in a data dictionary in Section 7.1. Then, we discuss how to decompose a query into some subqueries in Section 7.2. Last, we discuss how to produce a distributed execution plan and execute all subqueries based on the plan in Section 7.3.

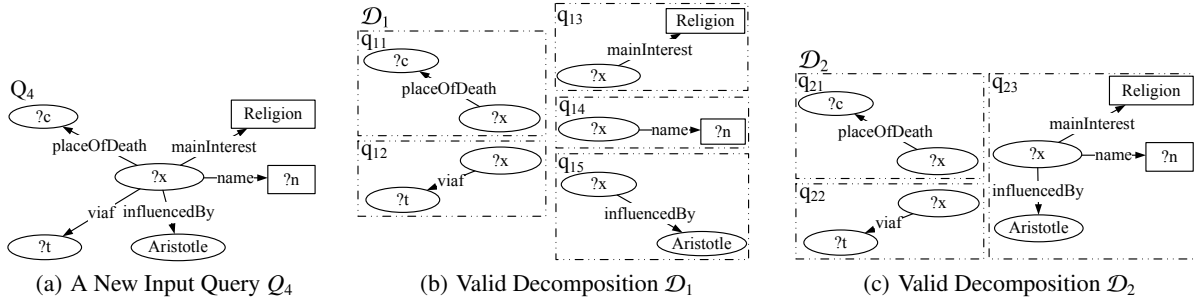

Figure 7: A New Input Query and Its Example Valid Decompositions

7.1 Data Dictionary

After fragmentation and allocation, the results of fragmentation and allocation need to be stored and maintained by the system. This information is necessary during distributed query processing. This information is stored in a data dictionary. The data dictionary stores a global statistics file generated at fragmentation and allocation time. It contains the following information: fragment definitions, their sizes, site mappings, access frequencies and so on.

Since each fragment corresponds to a frequent access pattern or a structural minterm predicate, the data dictionary uses the frequent access pattern with/without constraints as the representative of a fragment. Each frequent access pattern with/without constraints corresponds to a fragment and is associated with all statistics of the fragment. The data dictionary need to fast retrieve all frequent access patterns with/without constraints to determine the relevant frequent access pattern for a query.

We build a hash table to achieve the above objective. We first use the DFS coding [26] to translates frequent access patterns into sequences. With the DFS code of a frequent access pattern, we can map any frequent access pattern to an integer by hashing its canonical label. Then, we use the hash table to locate frequent access patterns and retrieve the statistics of their corresponding fragments

7.2 Query Decomposition

When users input a query Q , the system first uses the data dictionary to determine which fragments are involved in the query and decomposes the query into some subqueries on fragments.

Given a query Q , a decomposition of Q is a set of subqueries $\mathcal{D} = \{q_1, q_2, \dots, q_t\}$ such that (1) each q_i is a subgraph of Q and q_i maps to a frequent access pattern or structural minterm predicate; (2) $V(q_1) \cup \dots \cup V(q_t) = V(Q)$; and (3) $E(q_1) \cup \dots \cup E(q_t) = E(Q) \wedge \forall i \neq j, E(q_i) \cap E(q_j) = \emptyset$.

Since we partition the RDF graph based on the frequent access patterns, we also decompose the query based on the frequent access patterns. In other words, we decompose the query into subqueries that are homomorphic to frequent access patterns. If a query involves infrequent properties that cannot be decomposed into subqueries homomorphic to any frequent access patterns, then each connected subgraph of the query that only contains infrequent properties corresponds to a subquery. We define the *valid* decomposition as follows.

DEFINITION 15. (Valid Decomposition) Given a SPARQL query Q , a valid decomposition $\mathcal{D} = \{q_1, q_2, \dots, q_t\}$ of Q should meet the following constraint: if q_i ($1 \leq i \leq t$) is not homomorphic to any frequent access patterns, all edges in q_i should be cold edges.

There exist at least one valid decompositions. A possible decomposition is the decomposition of all subqueries of a single edge.

Because we select all frequent access patterns of one edge, the decomposition of all subqueries of a single edge is valid. Besides the valid decomposition, there may also exist some other valid decompositions. Hence, we propose a cost-model driven selection and the best valid decomposition is the valid decomposition with the smallest cost.

Here, we assume that the cost of a decomposition is the cost of joining all matches of the subqueries in \mathcal{D} and each pair of subqueries' matches can join together. The assumption is the worst case, so that we can quantify the worst-case performance. Then, we define the cost of a decomposition as follows.

$$\text{cost}(\mathcal{D}) = \prod_{q_i \in \mathcal{D}} \text{card}(q_i)$$

where $\text{card}(q_i)$ is the number of matches for q_i , which can be estimated by looking up the data dictionary.

EXAMPLE 4. Assume that an user inputs a new query Q_4 as shown in Figure 7(a). Given frequent access patterns in Figure 4, there can be two valid decompositions \mathcal{D}_1 and \mathcal{D}_2 as shown in Figures 7(b) and 7(c). For vertical fragmentation, q_{23} in \mathcal{D}_2 is evaluated on the vertical fragment of p_3 (Figure 5); for horizontal fragmentation, q_{23} is evaluated on the horizontal fragment of mp_2 (Figure 6(b)).

Whether in vertical or in horizontal fragmentation, it is obvious that \mathcal{D}_2 has fewer subqueries than \mathcal{D}_1 and $\text{card}(q_{23}) < \text{card}(q_{13}) \times \text{card}(q_{14}) \times \text{card}(q_{15})$. Hence, $\text{cost}(\mathcal{D}_2)$ is smaller than $\text{cost}(\mathcal{D}_1)$, and \mathcal{D}_2 is more of a priority as the final decomposition.

Based on the above definitions, we propose the query decomposition algorithm as Algorithm 3. Because the SPARQL query graphs in real applications usually contain 10 or fewer edges, we can use a brute-force implementation to enumerate all possible decompositions and find the decomposition with the smallest cost.

Algorithm 3: Query Decomposition Algorithm

Input: A query Q
Output: A valid decomposition $\mathcal{D} = \{q_1, q_2, \dots, q_t\}$ of query Q

- 1 $\text{MinCost} \leftarrow +\infty$;
- 2 Initialize \mathcal{D} as the decomposition of all subqueries of a single edge;
- 3 **for** each possible valid decomposition $\mathcal{D}' = \{q_1, \dots, q_t\}$ **do**
- 4 $\text{CurrentCost} \leftarrow 1$;
- 5 **for** each query q_i in \mathcal{D}' **do**
- 6 Estimate the number of results for q_i as $\text{card}(q_i)$ based on the data dictionary;
- 7 $\text{CurrentCost} \leftarrow \text{CurrentCost} \times \text{card}(q_i)$
- 8 **if** $\text{MinCost} > \text{CurrentCost}$ **then**
- 9 $\mathcal{D} \leftarrow \mathcal{D}'$;
- 10 $\text{MinCost} \leftarrow \text{CurrentCost}$;
- 11 **Return** \mathcal{D} ;

7.3 Query Optimization and Execution

After decomposing the query, the next step is to find an execution plan for the query which is close to optimal. In this section, we discuss the major optimization issue of finding execution plan, which deals with the join ordering of subqueries. We extend the algorithm of System-R [2] to find the optimal execution plan for distributed SPARQL queries. The algorithm is described in Algorithm 4.

Generally speaking, Algorithm 4 is a variant of System-R style dynamic programming algorithm. It firstly generates the best execution plan of $n - 1$ subqueries, and then join the matches of $n - 1$ subqueries with the matches of n -th subquery. The cost of an execution plan can also be estimated based on the number of subqueries' results, which is stored in the data dictionary.

Finally, each subquery is executed in the corresponding sites in parallel. The optimization of each subquery uses the existing methods in centralized RDF database systems. After the matches of all subqueries are generated, we join them together according to the optimal execution plan.

Algorithm 4: Query Optimization Algorithm

Input: A decomposition $\mathcal{D} = \{q_1, q_2, \dots, q_t\}$ of query Q
Output: An execution plan $(\dots((q_{i1} \bowtie q_{i2}) \bowtie q_{i3}) \bowtie \dots \bowtie q_{it})$

```

1 for each two subqueries  $(q_i)$  and  $(q_j)$  where  $1 \leq i \neq j \leq t$  do
2   Initialize an execution plan  $q_i \bowtie q_j$  and estimate its cost;
3   Store all execution plans and their costs in a table  $T_{ij}$ ;
4 for  $i = 3$  to  $t$  do
5   for each execution plan  $pl_j$  in  $T_{i-1}$  do
6     for each subquery  $q_k$  that is not contained by  $pl_j$  do
7       Build execution plan  $pl_j \bowtie q_k$  and estimate its cost;
8       Store this execution plan and its costs in a table  $T_i$ ;
9     for each two plans  $pl_j$  and  $pl_k$  in  $T_i$  do
10      if  $pl_j$  and  $pl_k$  map to the same set of subqueries then
11        Eliminate one of  $pl_j$  and  $pl_k$  that has the larger cost;
12 Return the execution plan with the minimum cost;
```

8. EXPERIMENTAL EVALUATION

We conducted extensive experiments to test the effectiveness of our proposed techniques on a real dataset, DBPedia, and a synthetic dataset, WatDiv. In this section, we report the setting of test data and various performance results.

8.1 Setting

DBPedia. DBPedia² is an RDF dataset extracted from Wikipedia. The DBPedia contains 163,977,110 triples. We use the DBPedia SPARQL query-log as the workload. This workload contains queries posed to the official DBPedia SPARQL endpoint in 14 days of 2012. After removing some queries that cannot be handled, there are 8,151,238 queries in the workload.

WatDiv. WatDiv [1] is a benchmark that enable diversified stress testing of RDF data management systems. In WatDiv, instances of the same type can have the different sets of attributes. For testing our methods, we generate five datasets varying sizes from 50 million to 250 million triples. By default, we use the RDF dataset with 100 million triples. In addition, WatDiv can generate a workload by instantiating some templates with actual RDF terms from the dataset. WatDiv provides 20 templates to generate test queries. We use these benchmark templates to generate a workload with 2000 test queries.

We conduct all experiments on a cluster of 10 machines running Linux, each of which has one CPU with four cores of 3.06GHz. Each site has 16GB memory and 150GB disk storage. We select one of these sites as a control site. At each site, we install gStore

²<http://km.aifb.kit.edu/projects/btc-2012/dbpedia/>

[31] to find matches. We use MPICH-3.0.4 running on C++ to join the results generated by subqueries.

For fair performance comparison, we use gStore and MPICH-3.0.4 to re-implement two recent distributed RDF fragmentation strategies. The first one is SHAPE [14], which defines a vertex and its neighbors as a triple group and assigns the triple groups according to the value of its center vertices. There are many different kinds of triple groups in [14] and we use the subject-object-based triple groups in this paper. The second one is WARP [8]. WARP first uses METIS [12] to divide the RDF graph into fragments. Then, it replicates all matches of a query pattern that cross two fragments in one fragment. We use all frequent access patterns to extend the fragments in WARP.

8.2 Parameter Setting

Our frequent access patterns selection method uses a parameter: *minSup*. In this subsection, we discuss how to set up *minSup* to optimize query processing. Note that, since the numbers of query templates and queries per query template in WatDiv are specified by users, the parameters can also be determined beforehand. Thus, we only discuss how to set the parameters for DBPedia.

Given a workload Q , we set the support threshold, *minSup*, to find patterns whose access frequencies are larger than *minSup*. It is clear that the smaller *minSup* is, the larger number of frequent access patterns there are. More frequent access patterns mean that a query in the workload may have a higher possibility to contain some frequent access patterns.

Figure 8: Effect of Frequent Access Patterns

Figure 8(a) shows the impact of *minSup*. As *minSup* increases, the number of frequent access patterns (FAPs) decreases. Hence, when we set *minSup* as 0.1% of the total number of queries in the workload, there are 163 frequent access patterns for DBPedia. When *minSup* is 1% of the total number of queries, the number of frequent access patterns is reduced to 44 for DBPedia. Furthermore, fewer frequent access patterns means that fewer queries in the workload are hit, as shown in Figure 8(b).

Even if we set *minSup* as 0.1% of the total number of queries, the number of frequent access patterns is not large. Hence, in the following, we set *minSup* as 0.1% of the total number of queries for DBPedia by default.

8.3 Throughput

In this experiment, we test the throughput of different fragmentation strategies. We sample 1% of all queries in the workload and measure the throughput in queries per minute. Figure 9 shows the number of queries answered in one minute of different fragmentation strategies.

For SHAPE and WARP, each query concerns all fragments, so queries are still processed sequentially. Since WARP is more balanced than SHAPE, the throughput of WARP is a little better than SHAPE. WARP can handle about 32 and 82 queries in one minute

Figure 9: Throughput Comparison

for DBPedia and WatDiv, while SHAPE can handle 24 and 75 queries.

For the vertical fragmentation strategy (VF), since a query often only contains a few frequent access patterns, it only involves a few fragments. Two queries involving different fragments can be evaluated in parallel. Hence, about 46 queries and 533 queries can be answered in one minute for DBPedia and WatDiv, respectively. For the horizontal fragmentation strategy (HF), each frequent access pattern specified by the query may map to many structural minterm predicates and the corresponding fragments of these structural minterm predicates may be allocated to different sites. Hence, the throughput of the horizontal fragmentation strategy is a little worse than the vertical fragmentation strategy, and 38 and 385 queries can be answered in one minute for DBPedia and WatDiv.

8.4 Response Time

In this experiment, we test the query performance of different fragmentation strategies. We also sample 1% of all queries in the workload and compute the average query response time of a query. Figure 10 shows the performance results.

SHAPE and WARP partition the RDF graph into some subgraphs, and distributes these subgraphs among different sites. The query should be processed in many sites in parallel. Hence, SHAPE is less balanced and sometime need cross-fragment joins, so SHAPE needs about 2.5 and 0.79 seconds to answer a query for DBPedia and WatDiv, while WARP takes 1.8 and 0.72 seconds.

For the vertical fragmentation strategy, only relevant fragments are searched for matches and the search space is reduced. Therefore, a query can be answered in about 0.8 seconds for DBPedia and 0.3 seconds for WatDiv. For the horizontal fragmentation strategy, we can filter out all irrelevant fragments mapping to the structural minterm predicates not specified by the query, which can further reduce the search space. Hence, a query can be answered with about 0.6 seconds for DBPedia and 0.15 seconds for WatDiv.

Figure 10: Performance Comparison

8.5 Scalability Test

In this experiment, we investigate the impact of dataset size on our fragmentation strategies. We generate five WatDiv datasets varying the from 50 million to 250 million triples to test our strate-

gies. Figure 11 shows the results. Generally speaking, as the size of RDF datasets gets larger, the average response times of one query increase and the numbers of queries answered in one minute decrease accordingly. However, the rates of increase and decrease are slow, and we can say that the query performance and throughput are scalable with RDF graph size on the datasets.

Figure 11: Varying Size of Datasets

8.6 Redundancy

Table 1 shows the redundancy ratio of the number of edges in all generated fragments to the total number of edges in the original RDF graph for each fragmentation strategy. For SHAPE, if a fragment contains a vertex with high degree, all adjacent edges of the high degree vertex are introduced. Most of these introduced edges are redundant, and cause the redundancy ratios of SHAPE nearly 3 for DBPedia and 1.74 for WatDiv. WARP divides the RDF graph while minimizing the edge cut, so the number of edges crossing two fragments for WARP is smaller than the number for SHAPE. Therefore, the redundancy ratio of WARP is smaller. Note that, WatDiv is much denser than DBPedia, so the minimum cut-set for WatDiv contains a higher proportion of edges. Hence, the redundancy ratio of WatDiv is 1.54, but the ratio of DBPedia is only 1.01.

	DBPedia	WatDiv
SHAPE	2.99	1.74
WARP	1.01	1.54
VF	1.38	1.04
HF	1.42	1.06

Table 1: Redundancy (Ratio to original dataset)

Our fragmentation strategies find and materialize some frequent access patterns (or structural minterm predicates). As discussed in Section 8.2, the number of frequent access patterns is limited. Hence, the redundancy ratios of our fragmentation strategies are limited. Note that, the horizontal strategy has a little larger redundancy ratio than the vertical fragmentation strategy. This is because that different structural minterm predicates derived from the same frequent access patterns share some common triple patterns. These common triple patterns may cause more redundant edges.

8.7 Offline Performance

Table 2 shows the data partitioning and loading time of the datasets for different fragmentation strategies. Although SHAPE has an almost perfect uniform distribution, its redundancy ratio is too large and each fragment contains too many redundant edges. Hence, loading fragments in SHAPE also takes much time. WARP uses METIS [12]. Since DBPedia is sparse (i.e. $|E(G)|/|V(G)| \approx 1$), METIS can guarantee that there are a few redundant edges and all fragments have a nearly uniform distribution. Then, WARP has less loading time than SHAPE. However, for WatDiv, the data graph is dense (i.e. $|E(G)|/|V(G)| \gg 1$), so the fragmentation result of

Figure 12: Query Performance of Benchmark Queries

METIS is unbalanced. Then, WARP takes more loading time than SHAPE to load the largest fragments.

Since nearly half of all edges for DBPedia are infrequent edges, loading the cold graph of DBPedia is the bottleneck in our fragmentation strategies. However, in WatDiv, there are not so many infrequent edges. Then, the loading time of our fragmentation strategies for WatDiv is more acceptable. Note that, because the structural minterm predicates are derived from the frequent access patterns, the cold graphs for the vertical and horizontal fragmentation strategies are the same. Thus, the loading times for the vertical and horizontal fragmentation strategies are the same.

	DBPedia			WatDiv		
Strategies	Partitioning	Loading	Total	Partitioning	Loading	Total
SHAPE	41	30	71	20	19	49
WARP	43	28	71	33	46	79
VF	50	97	147	31	28	59
HF	58	97	139	34	28	62

Table 2: Partitioning and Loading Time (in min)

8.8 Experiments for Benchmark Queries

In this experiment, we compare our methods with other fragmentation strategies on benchmark queries provided by WatDiv. There are 20 benchmark queries in WatDiv, and these queries can be classified into 4 structural categories: linear (L), star (S), snowflake (F) and complex (C). Figure 12 shows the performance of different approaches. Generally speaking, we find out that our methods outperforms other two methods in most cases. This is because that each benchmark query can be decomposed into some frequent access patterns or structural minterm predicates. Hence, our fragmentation strategies can filter out many irrelevant fragments. In contrast, SHAPE and WARP always concern all fragments, and SHAPE further needs some cross-fragment joins for complex queries.

Let us look deeper into Figure 12 and analyze each individual fragmentation strategy. SHAPE has to involve all fragments for any queries, so its performance is always worse than our fragmentation strategies. In particular, for star queries (S_1 to S_7), the difference between the query response times of SHAPE and our fragmentation strategies is not very large, because the subject-object-based triple groups that we use can guarantee that there is no intermediate result and all star queries can be answered at each fragment locally. However, for other shapes of queries, SHAPE has to decompose the queries and do cross-fragment joins to merge the intermediate results. Then, the performance of SHAPE decreases greatly. Especially for the unselective queries (L_1 , F_1 , F_2 , F_3 , F_4 , F_5 , C_1 and C_2), the performance of SHAPE is an order of magnitude worse than our fragmentation strategies.

Since WARP also use patterns to replicate triples for avoiding cross-fragment joins in complex queries, WARP has better performance than SHAPE in most case. However, WARP still always concerns all fragments in all sites for any kind of queries. The

search space of WARP for a query is higher than our fragmentation strategies. Thus, our fragmentation strategies always result in better performance. Especially for the query of very complex structure (C_2), our fragmentation strategies can filter out many irrelevant fragments, which can result in much smaller search space than WARP. Hence, for C_2 , our strategies is twice as fast as WARP.

Since all benchmark queries are generated from instantiating benchmark templates with actual RDF terms, these benchmark queries always correspond to a limited number of minterm predicates. Hence, the horizontal fragmentation is always faster than the vertical fragmentation.

9. RELATED WORK

For both the general graph and the RDF graph, as the graph size grows beyond the capability of a single machine, many works [6, 8, 9, 10, 29, 14, 15, 7, 23, 12, 30, 22, 25] have been proposed about graph fragmentation and allocation. We can divide all these methods into two categories: global goal-oriented graph fragmentation methods and local pattern-based graph fragmentation methods.

Global Goal-Oriented Graph Fragmentation. For this kind of methods [12, 9, 30, 22, 16], they divide G into several fragments while maximizing some goal function. They first transform a large graph into a small graph; then, apply some graph partitioning algorithms on the small graph; finally, the partitions on the small graph are projected back to the original graph. These methods often apply some existing methods (such as KL [13]) directly on the transformed graph in the second step. If we track the transforming step, the partitions on the small graph can be easily projected back to the original graphs in the third step. Hence, the largest difference among different graph coarsening-based methods is how to coarsen the original graph into a small graph.

In particular, METIS [12] uses the maximal matching to coarsen the graph. A matching of a graph is a set of edges that no two edges share an endpoint. A maximal matching of a graph is a matching to which no more edges can be added and remain a matching. GraphPartition [9] directly uses METIS in the RDF graph. WARP [8] uses some frequent structures in workload to further extend the results of GraphPartition. EAGRE [30] coarsens the RDF graph by using the entity concept in RDF data. It considers an entity to be a subject and its complete description. By grouping the entities of the same class, an RDF graph can be compressed as a compressed RDF entity graph. MLP [22] designs a method to coarsen the graph by label propagation. Vertices with the same label after the label propagation are coarsened to a vertex in the coarsened graph. Sheep [16] transform the graph into a elimination tree via a distributed map-reduce operation, and then partition this tree while reducing communication volume. Tomaszuk et. al. [21] briefly survey how to apply existing graph fragmentation solutions from the theory of graphs to RDF graphs.

Global goal-oriented graph fragmentation methods assume that if there are few edges crossing different fragments, the communi-

cation cost is little. If an application involves nearly all vertices in the graph, few cross-fragments edges indeed result in little communication. A typical application suitable for graph coarsening-based methods is PageRank.

In some applications, one static fragmentation cannot fit all. Hence, Sedge [28] maintains many fragmentations with different crossing edges, while Shang et. al. [19] move some vertices of one fragment to another fragment during graph computing according to the workload. Yan et. al. [27] propose a indexing scheme based on fragmentation to help query engine fast locate the instances.

Local Pattern-based Graph Fragmentation. For this kind of methods [10, 29, 14, 15, 7, 23, 25], they first find certain patterns as the fragmentation units to cover the whole graph; then, they distribute these patterns into sites. The local pattern-based methods mainly differ in their definitions of the fragmentation unit.

HadoopRDF [10] groups triples with the same property together and each group corresponds to a fragmentation unit. Then, they store all fragmentation units over HDFS. Yang et. al. [29] define some special query patterns, and subgraphs of a pattern are considered as a fragmentation unit. Lee et. al. [14, 15] define the fragmentation unit as a vertex and its neighbors, which they call a triple group. The triple groups are distributed based on some heuristic rules. For each vertex, SketchCluster [23] identifies the set of labeled vertices reachable within its one-hop neighborhood as its features and employs the KModes algorithm to group related vertices based on the features. Partout [6] extends the concepts of minterm predicates in relational database systems, and uses the results of minterm predicates as the fragmentation units. TriAD [7] uses METIS [12] to divide the RDF graph into many partitions. Then, each result partition is considered as a unit and distributed among different sites based on a hash function. PathPartitioning [25] uses paths in RDF graphs as fragmentation units.

Local pattern-based graph fragmentation methods assume that some real applications only concerns a part of the whole graph. If an application only concerns the vertices of some certain patterns, these methods only access the relevant fragments and reduce the communication cost across fragments. A typical example application is subgraph homomorphism checking.

10. CONCLUSION

In this paper, we discuss how to manage the large RDF graph in a distributed environment. First, we mine and select some frequent access patterns to partition the RDF graph into many smaller fragments. Then, we propose an allocation algorithm to distribute all fragments over different sites. Last, we discuss how process the query based on the results of fragmentation and allocation. Extensive experiments verify our approaches.

ABSTRACT

The rapid increase in generation and dissemination of online video data has recently raised the demand on efficient and effective query processing techniques in large video databases. In this paper, we first introduce a novel compact video representation model to achieve high effectiveness, and then propose to alleviate computational time complexity of the well-known *Earth Mover's Distance* by introducing a filter approximation analyzing earth flows locally and restricting the number of flows globally, ensuring *completeness*. Moreover, extensive experimental evaluation performed on high dimensional real world datasets points out high efficiency and effectiveness of the proposals, significantly reducing the number of Earth Mover's Distance computations and outperforming the state of the art by up to two orders of magnitude with respect to selectivity and query processing time.

1. INTRODUCTION

With increasing ubiquity of the internet and rich diversity of multimedia capture devices and social networking and data sharing web sites, recent years have witnessed an explosion in generation and collection of multimedia data, in particular videos. As reported in [26], 100 hours of video are uploaded to YouTube every minute, and over 6 billion

hours of video are watched each month on the same website. The resulting enormous amount of video data in the technological world today makes efficient and effective query processing indispensable for large video databases.

The Earth Mover's Distance (EMD) [15] denoting strong human perceptual similarity is proven to be a very effective distance-based similarity measure in various domains. The EMD determines the dissimilarity between two data objects by the minimum amount of work required to transform one feature representation into another one. Each data object, for example a video clip, can be represented by a *signature* denoting individual object-specific features, or by a *histogram* consisting of shared features in the feature space where histograms expose a special case of signatures. Signatures which are also referred to as *adaptive binning* or *individual binning* can be used to represent a wide spectrum of data types, such as uncertain [3], medical [2], probabilistic [25], and multimedia data [15, 24, 21, 22], as well as events [19] and molecules [6]. The major advantage of the utilization of the signatures is the high quality of content approximation coupled with similarity search and query processing in various type of databases.

A signature is basically defined as a set of features, also found as *representatives* in the literature, in a feature space. Each feature is assigned a real-valued weight denoting the number of features related to that corresponding feature. This is carried out by first extracting the features and then clustering them by using a clustering algorithm, such as k-means algorithm. The resulting counters of the features in the clusters form a signature which we refer to as an *absolute signature* exhibiting individual total weights. Absolute signatures are appropriate for applications for which different characteristics and properties of data are of high importance, such as different image resolution or different video clip length. Many applications rely on an additional preprocessing step by which the absolute signatures are normalized, leading to *relative signatures* exposing a uniform total weight among all data objects. Below, we will immediately show the limitations caused by this normalization step, and how important the usage of absolute signatures is, particularly if partial similarity is involved. Overall, this paper aims at efficient similarity query processing for absolute signatures which is supported only little by existing work.

Relative signatures have often been utilized in numerous applications [15, 1, 24, 21], however, absolute signatures and similarity search using them are still unexplored. The diagnosis of various types of cancer or neurological diseases, such as Alzheimer's Disease [9] require absolute signatures

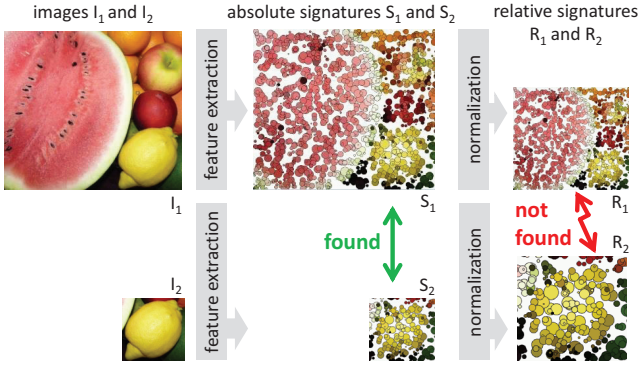

Figure 1: Given images I_1 and I_2 , the absolute signature S_2 is found to be a part of the absolute signature S_1 which consider individual absolute weights. However, a normalization step results in relative signatures R_1 and R_2 which are detected as non-similar.

in (bio)medical image classification and similarity search. Rough and coarse boundaries of a cell makes it difficult to determine if it is a cancer/tumor cell. Such biomedical images are commonly stored in fuzzy object databases where each image is partitioned in a specific number of shells where the assignment of a certain probability to each pixel is essential, i.e. the absolute number of pixels for each shell is important to store [20]. An extra normalization step after the feature extraction would lead to inappropriate fuzzy object representation of the cells and, thus, to irrelevant results. In biotechnology, the metabolite identification and quantification is an important task for which data normalization results in obscuring variation of data where the chemical properties cannot be preserved any more [10]. In addition, normalizing the metabolomic data affects its covariance structure which is undesired by the experts.

To contribute to the reader’s understanding, we illustrate the absolute and relative signatures in Figure 1. A common task in partial similarity search is to determine if a particular part of a given data object exists in the target dataset. Each signature comprises representatives visualized by circles and is based on the characteristic information of the presented image, such as color. Image I_1 comprises various fruits including also a lemon, while the image I_2 shows only a lemon where the user intends to determine if a lemon exists in the image I_1 . When the absolute signatures S_1 and S_2 are considered, S_2 is found to be similar to S_1 , since it is detected as a part of S_1 . However, if an additional normalization step is applied to attain the relative signatures R_1 and R_2 , they are detected as non-similar. A closer look reveals that the two images are evaluated as different images due to the utilization of the normalization step after the feature extraction, i.e. normalizing absolute signatures does not carry out the required partial similarity search task. Another example is the currently attractive and vital domain of video similarity search, in particular near-duplicate video detection, where a typical subclip video detection task [8], required for various purposes as copyright protection and management, entails the need to utilize absolute signatures so that a query subclip can be detected in a given video dataset. Hence, depending on the application, it is explicitly crucial to utilize absolute signatures for queries and datasets, as normalization does

not attain partial similarity search tasks formulated and demanded by the user.

Since the empiric time complexity of the EMD is super-cubic with respect to feature dimensionality, database community has devised research to propose efficient query processing techniques for the EMD [15, 4, 1, 24, 25, 21]. While existing efficiency improvement techniques for the EMD have been successfully utilized on relative signatures, nevertheless most of them have unfortunately the shortcoming that they can only be applied to fixed-binned relative signatures. Furthermore, they cannot be applied to absolute signatures denoting individual total weights which come up in numerous applications and domains, such as in computer vision [13, 4], multimedia databases [11], fuzzy object databases [20], and biotechnology [10]. While the lower-bounding technique IM-Sig (Independent Minimization for Signatures) [21] is proven to result in efficient results, it can only be applied to relative signatures, not to absolute signatures.

In this paper, we introduce a lower-bounding filter approximation technique *IM-Sig** which is applicable to both fixed-binned and adaptive-binned absolute and relative signatures. In particular, our approach computes the same filter distance as for IM-Sig on relative signatures, and on top of this, our proposal can also be applied to the absolute signatures, hence, filling the gap with respect to lower-bounding the EMD on absolute signatures. To this end, we focus on efficient query processing with the EMD on both relative and absolute signatures in order to introduce a comprehensive solution, which is carried out by analyzing earth flows locally and restricting the number of flows globally. In addition, we take the video domain as an example in this paper, however, it is noteworthy that our efficiency improvement technique can be applied to all domains where complex data objects need to be represented by relative or absolute signatures, as mentioned above. The main contributions of our paper are listed as follows:

- We introduce an adaptive-binning video representation model applicable to the EMD (Section 3).
- We propose an analytic solution *IM-Sig** for adaptive-binned signatures without any weight restriction (Section 5.1-5.2).
- We show the optimality of our solution leading to the lower-bounding property of the *IM-Sig**, ensuring exact query processing with the EMD (Section 5.3).
- We develop an algorithm for our proposal and analyze the computational time complexity (Section 5.4).
- Experiments on real world data show the efficiency and efficacy of our approach (Section 6).

2. RELATED WORK

Efficient Query Processing with the EMD. Various efficient query processing techniques have been proposed for the EMD on histograms, i.e. fixed-binned signatures. [1] proposed to lower-bound the EMD via L_p -based distances and constraint relaxation. [24] developed dimensionality reduction techniques for the EMD where reduced cost matrices are utilized relying on the original cost matrix. Furthermore, [25] derived a lower bound of the EMD by utilizing the primal-dual theory in linear programming on top of B^+ -trees. In addition, [16] proposed to lower-bound the EMD by

Table 1: Overview of the lower bounds to the Earth Mover’s Distance regarding feature representations

lower bounds to the EMD	signatures	
	adaptive binning	individual signature weight
L_p -based [1]

IM-Sig*	✓	✓

projecting histograms on a vector and approximating their distance by a normal distribution. It is noteworthy that the limitation of all aforementioned approaches is that they are applicable to histograms sharing the same features in a feature space, not to adaptive-binned signatures denoting individual features per data object. As mentioned in the previous section, since histograms denote a special case of signatures by utilizing shared features instead of individual features per data object, it is of vital importance to propose comprehensive methods applicable to signatures. [15] proposed to lower-bound the EMD by computing the distance between mean signatures. Although the filter time is remarkably low, the efficiency of the query processing is hampered by the worse selectivity resulting in high refinement time. Moreover, a considerable limitation lies in the fact that it cannot be applied to absolute signatures, as will be presented in Section 4. Another efficiency improvement technique for signatures is proposed by [21], which is based on the relaxation of the target constraint of the EMD by local examination of each feature in the source signature. While this method indicates high efficiency improvement, it is nevertheless not applicable to absolute signatures with individual total weights. Furthermore, [4] proposed to lower-bound the EMD on signatures by computing the EMD values for projected signatures each of which comprises features projected on an individual dimension of the feature space. Note that the latter approach is applicable to both relative and absolute signatures. The overview of the applicability of existing lower-bounding methods and our approach IM-Sig* with respect to feature representations is depicted in Table 1.

Video Similarity Search Models. Video similarity search in video databases has been a challenging research area where there have been numerous attempts to provide effective similarity search techniques. [18] (*vitri*) summarizes each video into a small number of clusters each of which includes similar frames. The similarity between two videos is determined by simply estimating the number of similar frames, neglecting the temporal information. [27] (*fras*) is another approach which is an improvement of [18], symbolizing video sequences on a frame basis. The limitation of both approaches lies in the determination of a threshold which is supposed to specify the similarity between any two frames. [8] (*vdt*) proposes to transform a video from a sequence of histograms denoting frames into a one-dimensional distance trajectory where the distance is determined via a reference point. This model is contingent upon frame elements which may lead to performance limitations regarding generation of

Figure 2: Illustration of a video clip and a subclip with the visualization of their *video signatures*.

video representations of a high number of frames, and the segmentation of linear segments requires the determination of a threshold regarding the distance between two consecutive frames, which is not robust to outliers. [7] (*bcs*) is another video clip representation model utilizing the principal component analysis in order to specify a bounded range of data projections along each coordinate axis. This method neglects temporal information causing a restriction, in particular for long video clips. Not least, all aforementioned approaches propose to represent each frame only by a histogram in RGB color space.

3. NOVEL VIDEO REPRESENTATION

In this section, we propose our novel video model *Video Signature (vis)* which utilizes the determination of individual features and related weights denoting the number of assigned features, leading to a particular compact video clip representation. Unlike frame-based and sequence-based models [7, 8, 18, 27], our model is not contingent upon frames or keyframes, attaining great flexibility via exploiting any requested feature types, such as color, position, contrast, and coarseness. On top of this, the proposal implicitly takes the temporal information into consideration which does not require extra effort at all, since the temporal information is utilized as an individual dimension of the underlying feature space. Mathematically, let (\mathbb{F}, δ) be a feature space where \mathbb{F} is a set of features coupled with a ground distance function $\delta : \mathbb{F} \times \mathbb{F} \rightarrow \mathbb{R}$. Any video clip is represented by a finite set of features $x_1, \dots, x_n \in \mathbb{F}$. We refer to a *video signature* as a finite set of features (so-called representatives) each of which is assigned a non-negative real number corresponding to the number of features assigned to that representative. The formal definition is given below.

DEFINITION 1 (VIDEO SIGNATURE). *Given a feature space (\mathbb{F}, δ) , a video signature V is defined as $V : \mathbb{F} \rightarrow \mathbb{R}^{\geq 0}$, subject to $|R_V| < \infty$, where $R_V := \{x \in \mathbb{F} \mid V(x) > 0\} \subseteq \mathbb{F}$ denotes the set of representatives of V .*

According to the definition above, each representative contributes to the video representation by taking a positive real number $V(x) \in \mathbb{R}^{\geq 0}$ as weight. Any video signature, hence, includes an individual set of representatives and weights which leads to an appropriate video representation.

The illustration of a video clip and a subclip with their corresponding video signature visualizations are depicted in Figure 2. The signatures comprise 50 representatives which are visualized as spheres based on position, color, texture, and temporal information. In the visualization, positional (X,Y) and temporal (T) dimensions are explicitly utilized to contribute to the reader’s understanding, where the size of each sphere refers to the weight of that representative. This figure epitomizes the video approximation and modeling with respect to subclip video detection: Obviously, the individual total weight of the absolute signature of the video clip (b) is greater than that for the subclip video (d) which facilitates the utilization of the EMD to determine the dissimilarity between them in order to solve the desired subclip detection task. If they were normalized, the desired task would not be solved, since the EMD would then determine *total similarity* between the two videos, which does not correspond to the user’s intention. In the upcoming sections, the term *signature* refers to a video signature. As will be presented in Section 6, modeling videos as *video signatures* highly contributes to effectiveness results. For the sake of simplicity, in the following sections, we utilize the class of non-negative signatures $\mathbb{S}^+ := \{V | V \in \mathbb{R}^{\mathbb{F}} \wedge 0 < |R_V| < \infty \forall x \in \mathbb{F} : V(x) \in \mathbb{R}^{\geq 0}\}$ including video signatures whose representatives denote non-negative weights. In the following section, we present the EMD and the utilized filter-and-refine architecture.

4. EARTH MOVER’S DISTANCE

In this section, we present the well-known Earth Mover’s Distance which can be utilized in a filter-and-refine architecture in order to boost the query processing. Initially introduced in the computer vision domain, the Earth Mover’s Distance (EMD) [15] computes the dissimilarity between two signatures by transforming one signature into another one. The formal definition is given below.

DEFINITION 2. Let $X, Y \in \mathbb{S}^+$ be two signatures over a feature space (\mathbb{F}, δ) and $\delta : \mathbb{F} \times \mathbb{F} \rightarrow \mathbb{R}$ be a ground distance function. The Earth Mover’s Distance $EMD : \mathbb{S}^+ \times \mathbb{S}^+ \rightarrow \mathbb{R}$ between X and Y is defined as a minimum-cost flow of all possible flows $F = \{f | f : \mathbb{F} \times \mathbb{F} \rightarrow \mathbb{R}\} = \mathbb{R}^{\mathbb{F} \times \mathbb{F}}$ as:

$$EMD(X, Y) = \min_{f \in F} \left\{ \frac{\sum_{x \in \mathbb{F}} \sum_{y \in \mathbb{F}} f(x, y) \cdot \delta(x, y)}{\min\left\{ \sum_{x \in \mathbb{F}} X(x), \sum_{y \in \mathbb{F}} Y(y) \right\}} \right\},$$

subject to constraints $NC \wedge SC \wedge TAC \wedge FC$ with:

$NC: \forall x, y \in \mathbb{F} f(x, y) \geq 0$, $SC: \forall x \in \mathbb{F} \sum_{y \in \mathbb{F}} f(x, y) \leq X(x)$,

$TAC: \forall y \in \mathbb{F} \sum_{x \in \mathbb{F}} f(x, y) \leq Y(y)$, and

$FC: \sum_{x \in \mathbb{F}} \sum_{y \in \mathbb{F}} f(x, y) = \min\left\{ \sum_{x \in \mathbb{F}} X(x), \sum_{y \in \mathbb{F}} Y(y) \right\}$.

The EMD is the minimum cost required to transform one signature into another one by guaranteeing the non-negativity (NC), source (SC), target (TAC), and total flow constraints (FC), as given above. Hence, the EMD denotes a linear optimization problem and can be solved by simplex

Figure 3: (a) The EMD between absolute signatures X and Y is $EMD(X, Y) = 1$. (b) $Rubner(X, Y) = \delta(x', y') = 2 \not\leq EMD(X, Y)$ holds, i.e. Rubner filter is not a lower bound to the EMD on absolute signatures denoting individual total weights.

algorithms. Figure 3(a) illustrates an example EMD computation between two signatures X, Y where 1 unit earth is transferred from $x_2 \in R_X$ with a distance of 1, resulting in the EMD value of $1 \times 1 = 1$. It is worth noting that the absolute signatures X and Y exhibit individual total weights of 2 and 1, respectively, where the total flow constraint FC guarantees that the minimum of the total weights is transferred from the source signature X to the target signature Y .

Given two signatures X, Y with total weights m_X, m_Y , and a norm-based ground distance function δ , the Rubner filter distance [15] is defined as: $\delta((\sum_{x \in R_X} X(x) \cdot x)/m_X, (\sum_{y \in R_Y} Y(y) \cdot y)/m_Y)$, as depicted in Figure 3(b): x' and y' refer to weighted mean features of X and Y from (a), respectively. The Rubner filter computes $\delta(x', y') = 2$ which, however, does not lower-bound the EMD. As illustrated by this example, the restriction of the Rubner filter is that it cannot be applied to absolute signatures.

Filter-and-refine Architecture. One of the efficiency improvement methods utilized in k-nearest-neighbor (k-nn) query processing is the filter-and-refine architecture model comprising filter and refinement steps [5, 17, 12], as summarized in Figure 4. In the filter step, a filter LB_d generates a set of candidates which is then refined in the refinement step by utilizing the exact distance d (here EMD). A filter ideally fulfills the following properties: First, its computation is attained more efficiently than for the exact distance computation (*efficiency*). Second, LB_d lower-bounds d , i.e. the final refined set includes all objects from the result set, guaranteeing no false dismissals, as it holds $\forall x, y : LB_d(x, y) \leq d(x, y)$ (*completeness*). Third, the generated set of candidates is smaller if LB_d is tighter, leading to lower computation cost.

Figure 4: Multistep query processing

In this paper, we utilize a multistep approach which is proven to be optimal in the number of candidates [17]. After a ranking is generated by using a filter distance, it is processed as long as the filter distance does not exceed the exact distance of the current k^{th} -nearest neighbor where the result set and the k^{th} -nearest neighbor distance are continuously updated. After giving the EMD and filter-and-refine architecture, we below present our proposed technique IM-Sig* applicable to both absolute and relative signatures.

5. LOWER-BOUNDING THE EMD ON SIGNATURES

In this section, we first deal with the shortcoming of the existing approach IM-Sig, and then present our proposed comprehensive lower-bounding technique IM-Sig* on signatures, irrespective of any prior information about their total weights. Then, we theoretically show that our analytic solution is both feasible and optimal, which is thus a lower bound to the EMD on all type of signatures including absolute and relative signatures with individual and uniform total weights, respectively. We finally present the computational algorithm of our technique and its complexity analysis.

Our approach has two attractive advantages: First, it is applicable to both relative and absolute signatures, yielding high flexibility with respect to query processing and explicit user-driven tasks, such as subclip video detection, as mentioned before. Second, it is a generic solution regarding efficient query processing which is not restricted to the video domain, and, hence, can be applied to any other domain, such as multimedia, computer vision, and medicine.

5.1 IM-Sig* and the Limitations of IM-Sig

The filter approximation technique Independent Minimization for Signatures (IM-Sig) [21], based on target constraint relaxation of the EMD, was originally proposed to lower-bound the EMD on signatures with uniform total weight. Below, we first give the formal definition of the comprehensive lower-bounding technique IM-Sig*, irrespective of any prior information about the total weights of signatures, and then present the shortcoming of IM-Sig via illustrative examples.

DEFINITION 3 (IM-Sig* FILTER DISTANCE). Let (\mathbb{F}, δ) be a feature space with a distance function δ and $X, Y \in \mathbb{S}^+$ be two non-empty positive signatures with weights $m_X = \sum_{x \in \mathbb{F}} X(x)$ and $m_Y = \sum_{y \in \mathbb{F}} Y(y)$. The comprehensive filter distance Independent Minimization for Signatures IM-Sig* : $\mathbb{S}^+ \times \mathbb{S}^+ \rightarrow \mathbb{R}^{\geq 0}$ between X and Y is defined as a minimization over all possible flows $F = \{f | f : \mathbb{F} \times \mathbb{F} \rightarrow \mathbb{R}\}$:

$$\text{IM-Sig}^*(X, Y) = \min_{f \in F} \left\{ \sum_{x \in \mathbb{F}} \sum_{y \in \mathbb{F}} \frac{\delta(x, y)}{\min(m_X, m_Y)} f(x, y) \right\},$$

subject to constraints $NC \wedge SC \wedge TC \wedge FC$ with:

$NC: \forall x, y \in \mathbb{F} f(x, y) \geq 0$, $SC: \forall x \in \mathbb{F} \sum_{y \in \mathbb{F}} f(x, y) \leq X(x)$,

$TC: \forall x, y \in \mathbb{F} : f(x, y) \leq Y(y)$, and

$FC: \sum_{x \in \mathbb{F}} \sum_{y \in \mathbb{F}} f(x, y) = \min\{\sum_{x \in \mathbb{F}} X(x), \sum_{y \in \mathbb{F}} Y(y)\}$.

While the non-negativity (NC), source (SC), and total flow constraints (FC) remain unchanged for the EMD and IM-Sig*, the target constraint (TC) of IM-Sig* relaxes that for the EMD by allowing that any single incoming flow (instead of total incoming flows) may not exceed the target capacity. If the signatures exhibit uniform total weights, i.e. if they are relative signatures, the approach IM-Sig [21] can be applied. However, in other cases an appropriate solution is required for the computation of the filter approximation on any kind of signatures with relative or absolute weights. For all possible cases, we propose to compute the comprehensive IM-Sig* by analyzing earth flows locally and restricting

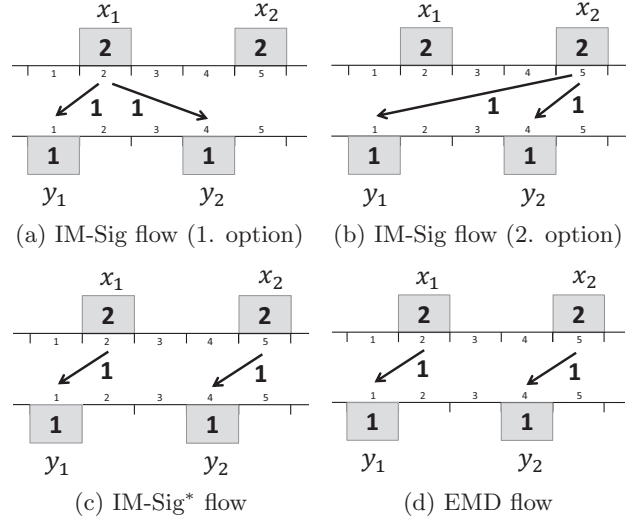

Figure 5: IM-Sig, IM-Sig*, and EMD flows illustrated on two absolute signatures. Since IM-Sig is not defined on absolute signatures exhibiting individual total weights, there is neither a deterministic solution nor a computable minimum-cost flow (a-b). IM-Sig* flow (c) computes an optimal flow which fulfills the minimum-cost property, lower-bounding the EMD (d) on both absolute and relative signatures.

the number of flows globally. In other words, our approach IM-Sig* computes the same flow as for IM-Sig for relative signatures and on top of this, IM-Sig* can be applied to the absolute signatures to lower-bound the EMD.

In order to give the underlying basic notion and to clarify the difference between our approach IM-Sig* and IM-Sig, we examine the illustrations given in Figure 5. Numbers 1-5 denote the positions in the 1-dimensional feature space, and the ground distance between any representatives with positions i and j is computed via $|i - j|$, such as $\delta(x_2, y_2) = 1$. The signatures X, Y are illustrated with 2 representatives each, where their weights are denoted in buckets. Since IM-Sig is not defined on absolute signatures, there does not exist a computable minimum-cost flow. Nonetheless, if we try to apply the naive IM-Sig algorithm to these absolute signatures denoting individual total weights, we face two main problems: First, there exists no deterministic solution since IM-Sig basically transfers earth from each representative x_i to its nearest neighbors in the target signature Y . Since there is no specific predefined order of the representatives for the earth transfer from X to Y , one can arbitrarily start with any representative. The first non-deterministic solution of IM-Sig (Fig. 5(a)) would transfer earth from x_1 to its nearest neighbors y_1 and y_2 , resulting in $\text{IM-Sig}(X, Y) = \frac{1}{2} \times (1 \cdot 1 + 1 \cdot 2) = 1.5$. Another non-deterministic solution of IM-Sig (Fig. 5(b)) would transfer earth from x_2 to its nearest neighbors y_2 and y_1 , resulting in $\text{IM-Sig}(X, Y) = \frac{1}{2} \times (1 \cdot 1 + 1 \cdot 4) = 2.5$. Second, the computed IM-Sig values do not necessarily yield optimal solutions, which can be inferred from the application of the optimal IM-Sig* on the example (Fig. 5(c)): Our approach first ranks the representative pairs (x_i, y_j) with respect to their ground distance values in ascending order, and then the earth is

transferred from X to Y by taking this order into consideration, as well as all constraints given in Def. 3. Hence, we consider the permutation of $((x_1, y_1), (x_2, y_2), (x_1, y_2), (x_2, y_1))$ with the ground distance values of 1, 1, 2, and 4. In this way, first 1 unit earth is transferred from x_1 to y_1 and then again 1 unit earth is transferred from x_2 to y_2 after which the optimal solution is attained, fulfilling the IM-Sig* constraints: $\text{IM-Sig}^*(X, Y) = \frac{1}{2} \times (1 \cdot 1 + 1 \cdot 1) = 1$. In addition, the EMD (Fig. 5(d)) is computed as $\text{EMD}(X, Y) = \frac{1}{2} \times (1 \cdot 1 + 1 \cdot 1) = 1$, where we observe that the IM-Sig* computes not only the minimum-cost flow but also the feasible solution, lower-bounding the EMD on these absolute signatures. As a result, this example illustrates that IM-Sig is unfortunately not applicable to absolute signatures with individual total weights and there is demand on novel efficient query processing techniques to solve the existing problem.

So far, we have seen the shortcomings of IM-Sig and deduce that there is need for new comprehensive lower-bounding techniques applicable to any kind of signatures without any restriction. Below, we present our novel analytic solution with respect to the computation of IM-Sig*. For the definitions and theoretical analysis in the remainder of the paper, we assume that a feature space (\mathbb{F}, δ) is given with a distance function δ , and we refer to non-empty positive signatures $X, Y \in \mathbb{S}^+$.

5.2 Analytic Solution

In order to propose our novel analytic solution for IM-Sig*, we first give the definitions of the local feasible set, extensive flow, and global feasible set which are required to define the IM-Sig* flow, as will be given in Definition 7. The local feasible set of a representative x in the source signature X exhibits the greatest set of nearest neighbors in the target signature Y , where the total weight of its nearest neighbors may not exceed the capacity of x . The formal definition is given below.

DEFINITION 4 (LOCAL FEASIBLE SET). *Given two signatures $X, Y \in \mathbb{S}^+$, let (y_1, \dots, y_l) be a permutation of R_Y with respect to a feature $x \in \mathbb{F}$ such that $i \leq j \Rightarrow \delta(x, y_i) \leq \delta(x, y_j)$. The local feasible set $S_{X,Y}^x \subseteq R_Y$ is defined as the greatest set of nearest neighbors of x in R_Y whose total weight does not exceed $X(x)$: $y_i \in S_{X,Y}^x \Leftrightarrow \sum_{j=1}^i Y(y_j) < X(x)$. Let further $k = |S_{X,Y}^x|$ be the greatest index in $S_{X,Y}^x$, then $\hat{y}_x \notin S_{X,Y}^x$ is defined as the feature directly following y_k regarding the same permutation:*

$$\hat{y}_x = \begin{cases} y_{k+1} & \text{if } k < l = |R_Y| \\ y^* \in \mathbb{F} \setminus R_Y & \text{else} \end{cases}$$

Note that if $|S_{X,Y}^x| = |R_Y|$, i.e. the cardinality of the local feasible set of the representative x is the same as that for the representative set of the target signature Y , $\hat{y}_x \notin R_Y$ is an arbitrarily chosen feature in the feature space which does not belong to R_Y , since the capacity of x exceeds the total signature weight of the target signature, i.e. $X(x) > m_Y$.

The aim of the extensive flow f_e is to transfer earth from the source signature X to the target signature Y by filling up the nearest neighbors of each $x \in R_X$ in the target signature so that for each x all the earth it owns is completely transferred to its nearest neighbors in the target signature. Note that the extensive flow does not take the individual total weights of the signatures into consideration. Techni-

cally, the local feasible set $S_{X,Y}^x$ is utilized to define the flow whose definition is given as follows.

DEFINITION 5 (EXTENSIVE FLOW). *Given two signatures $X, Y \in \mathbb{S}^+$, let $S_{X,Y}^x(x)$ be the local feasible set for any feature $x \in \mathbb{F}$ (Def. 4). The extensive flow $f_e : \mathbb{F} \times \mathbb{F} \rightarrow \mathbb{R}$ is defined as follows:*

$$f_e(x, y) = \begin{cases} Y(y) & \text{if } y \in S_{X,Y}^x \\ X(x) - \sum_{y' \in S_{X,Y}^x} Y(y') & \text{if } y = \hat{y}_x \wedge \hat{y}_x \in R_Y \\ 0 & \text{else} \end{cases}$$

The extensive flow fulfills three constraints of IM-Sig*, namely the non-negativity, source, and IM-Sig* target constraint, which can be summarized in Corollary 1 as follows.

COROLLARY 1. *Given two signatures $X, Y \in \mathbb{S}^+$, f_e fulfills the following constraints: non-negativity(NC): $\forall x, y \in \mathbb{F} \ f_e(x, y) \geq 0$, source(SC): $\forall x \in \mathbb{F} \ \sum_{y \in \mathbb{F}} f_e(x, y) \leq X(x)$, IM-Sig* target(TC): $\forall x, y \in \mathbb{F} \ f_e(x, y) \leq Y(y)$.*

The corollary above directly follows from Def. 4 and Def. 5. After defining the local feasible set and extensive flow, we now define *global feasible set* which is required for IM-Sig* flow. The global feasible set $S_{X,Y}$ exhibits the greatest set including pairs (x_i, y_j) of representatives from both signatures, where the set includes all pairs for which the corresponding representative y_j receives a positive amount of earth from x_i . An important condition which needs to be fulfilled is that the pairs (x_i, y_j) are ranked according to their ground distance values in ascending order. Hence, the pairs are tracked at a *global* level, i.e. both signatures' representatives are taken into consideration, not only those of the target signature.

DEFINITION 6 (GLOBAL FEASIBLE SET). *Given two signatures $X, Y \in \mathbb{S}^+$, let $p = ((x_1, y_1), \dots, (x_n, y_n))$ be a permutation of $R_X \times R_Y$ such that $i \leq j \Rightarrow \delta(x_i, y_i) \leq \delta(x_j, y_j)$. The global feasible set $S_{X,Y} \subseteq R_X \times R_Y$ is the greatest set satisfying $(x_i, y_i) \in S_{X,Y} \Leftrightarrow \sum_{j=1}^i f_e(x_j, y_j) < \min(m_X, m_Y)$, where $k = |S_{X,Y}|$ is the greatest index in $S_{X,Y}$ and $(\hat{x}, \hat{y}) \notin S_{X,Y}$ is defined as $(\hat{x}, \hat{y}) = (x_{k+1}, y_{k+1})$ which directly follows (x_k, y_k) regarding p .*

The global feasible set $S_{X,Y}$ comprises all pairs from $R_X \times R_Y$ sorted according to their ground distances in ascending order where the total amount of the flow coupled with such pairs may not exceed the minimum of the total weights of the signatures. The pair (\hat{x}, \hat{y}) is concerned in denoting the last possible flow in the permutation p so that the total flow constraint is guaranteed.

Recall that our goal is to introduce a solution for any pair of signatures, including both relative and absolute total weights, and overcome current limitations. To this end, we explicate our proposed technique IM-Sig* flow which transfers the minimum amount of total weights of given two signatures from the source signature X to the target signature Y . This is achieved by transferring earth by the utilization of the global feasible set which tracks the pairs of representatives allowing for appropriate flows with respect to non-negativity, source, and target constraints. IM-Sig* flow additionally takes the total flow constraint into consideration which is significantly required to yield both feasible and optimal solution to the IM-Sig* minimization problem. The formal definition of IM-Sig* flow is given below.

Figure 6: Illustration of the novel IM-Sig* flow and the EMD flow on signatures.

DEFINITION 7 (IM-Sig* FLOW). Given two signatures $X, Y \in \mathbb{S}^+$, let $S_{X,Y}$ be the global feasible set with $m = \min(m_X, m_Y)$. For any $x, y \in \mathbb{F}$ IM-Sig* flow is defined as:

$$f_S(x, y) = \begin{cases} f_e(x, y) & \text{if } (x, y) \in S_{X,Y} \\ m - \sum_{(x', y') \in S_{X,Y}} f_e(x', y') & \text{if } (x, y) = (\hat{x}, \hat{y}) \\ 0 & \text{else} \end{cases}$$

In order to contribute to the reader's understanding, we illustrate the novel comprehensive IM-Sig* flow by means of an example in Figure 6(a). Numbers 1-7 expose the positions in the 1-dimensional feature space, and the ground distance between any representatives with positions i and j is computed via $|i - j|$. Two signatures X, Y are illustrated with 2 representatives each, where their weights are depicted in buckets. The required permutation is given as $p = ((x_1, y_1), (x_2, y_1), (x_2, y_2), (x_1, y_2))$ with distances 1, 2, 3, 6, respectively. The global feasible set $S_{X,Y} = \{(x_1, y_1), (x_2, y_1)\}$ is then determined as the greatest set whose total flow may not reach the minimum of the total weights of X, Y , i.e. $1 + 1 < \min(10, 6) = 6$. Thus, the pair $(\hat{x}, \hat{y}) = (x_2, y_2)$ is the last element in the permutation which allows for flow with an amount of only 4 to fulfill the total flow constraint. Hence, IM-Sig* is computed as $\frac{1}{6} \times (1 \times 1 + 2 \times 1 + 3 \times 4) = 2.5$. Not least, when compared with the EMD (Figure 6(b)) computed as $\frac{1}{6} \times (1 \times 1 + 3 \times 5) = 2.66$, it is obvious that the novel IM-Sig* flow leads to a very tight lower bound to the EMD on absolute signatures.

So far, we have seen that the analytic solution IM-Sig* flow can be introduced in order to boost the query processing with the EMD on signatures irrespective of their total weights. Below, we would like to show that our analytic solution is feasible and optimal with respect to the IM-Sig* constraints which leads to the conclusion that the utilization of IM-Sig* flow indeed leads to a lower bound to the EMD on any kind of signatures.

5.3 Theoretical Investigation

Now, we investigate our proposal with respect to its feasibility and optimality regarding IM-Sig* constraints. First, we show that the proposed IM-Sig* flow is a feasible flow fulfilling 4 constraints of non-negativity, source, IM-Sig* target, and total flow, which is given by Theorem 1. Then, we show that IM-Sig* flow is an optimal flow, i.e. there exists no other flow which results in lower overall cost than that for IM-Sig* flow (Theorem 2). Finally, by the utilization of both theorems, we deduce that the utilization of the proposed IM-Sig* flow leads to the lower bound to the EMD on signatures, irrespective of their total weights.

Feasibility Analysis. In order to show the feasibility of our approach, we consider the constraints in Def. 3 and show that these constraints are fulfilled.

THEOREM 1 (FEASIBILITY OF IM-Sig* FLOW). Given signatures $X, Y \in \mathbb{S}^+$ with total weights $m_X = \sum_{x \in \mathbb{F}} X(x)$ and $m_Y = \sum_{y \in \mathbb{F}} Y(y)$, IM-Sig* flow f_S fulfills the following constraints: non-negativity (NC): $\forall x, y \in \mathbb{F} f_S(x, y) \geq 0$, source (SC): $\forall x \in \mathbb{F} \sum_{y \in \mathbb{F}} f_S(x, y) \leq X(x)$, IM-Sig target (TC): $\forall x, y \in \mathbb{F} f_S(x, y) \leq Y(y)$, and total flow (FC): $\sum_{x \in \mathbb{F}} \sum_{y \in \mathbb{F}} f_S(x, y) = \min(m_X, m_Y)$.

PROOF. For the proof we consider each constraint given above and show that they are fulfilled regarding the definition of IM-Sig* flow given in Def. 7. For any pair of features x, y , IM-Sig* flow between these features does not exceed the extensive flow between them, i.e. given two signatures $X, Y \in \mathbb{S}^+$, for any $x, y \in \mathbb{F}$ it holds: $f_S(x, y) \leq f_e(x, y)$, following from Def 5 and Def. 7. We denote this fact by the notation \otimes and use it below, where necessary. **NC:** $\forall x, y \in \mathbb{F} : f_S(x, y) \geq 0$. There exist three cases to examine: *Case 1:* $(x, y) \notin S_{X,Y} \wedge (x, y) \neq (\hat{x}, \hat{y}) \Rightarrow f_S(x, y) = 0$. *Case 2:* $(x, y) \in S_{X,Y} \Rightarrow f_S(x, y) = f_e(x, y) \geq 0$, by Cor. 1. *Case 3:* $(x, y) = (\hat{x}, \hat{y})$. Since $\sum_{(x, y) \in S_{X,Y}} f_e(x, y) <$

$\min(m_X, m_Y)$ holds for any two signatures X and Y , we can write the following statement:

$$\begin{aligned} \sum_{(x', y') \in S_{X,Y}} f_e(x', y') &< \min(m_X, m_Y) \Rightarrow \min(m_X, m_Y) - \sum_{(x', y') \in S_{X,Y}} f_e(x', y') > 0 \stackrel{\text{Def. 7}}{\Rightarrow} f_S(x, y) \geq 0. \\ \text{SC: } \forall x \in \mathbb{F} : \sum_{y \in \mathbb{F}} f_S(x, y) &\leq X(x). \quad \sum_{y \in \mathbb{F}} f_S(x, y) \stackrel{\otimes}{\leq} \sum_{y \in \mathbb{F}} f_e(x, y) \stackrel{\text{SC Cor. 1}}{\leq} \\ X(x). \quad \text{TC: } \forall x, y \in \mathbb{F} : f_S(x, y) &\leq Y(y). \quad f_S(x, y) \stackrel{\otimes}{\leq} \\ f_e(x, y) \stackrel{\text{TC Cor. 1}}{\leq} Y(y). \quad \text{FC: } \sum_{x \in \mathbb{F}} \sum_{y \in \mathbb{F}} f_S(x, y) &= \min(m_X, m_Y). \quad \sum_{x \in \mathbb{F}} \sum_{y \in \mathbb{F}} f_S(x, y) = \\ \sum_{(x, y) \in R_X \times R_Y} f_S(x, y) &= \sum_{(x, y) \in S_{X,Y}} f_S(x, y) + f_S(\hat{x}, \hat{y}) \stackrel{\text{Def. 7}}{=} \\ \sum_{(x, y) \in S_{X,Y}} f_e(x, y) + \min(m_X, m_Y) - \sum_{(x', y') \in S_{X,Y}} f_e(x', y') &= \min(m_X, m_Y). \quad \square \end{aligned}$$

Optimality Analysis. To prove that IM-Sig* with the proposed flow lower-bounds the EMD, we present that it yields the minimum overall cost among all possible flows by showing that any arbitrarily chosen feasible flow f results in a higher or equal overall cost than that for the IM-Sig* flow.

THEOREM 2 (OPTIMALITY OF IM-Sig* FLOW). Given signatures $X, Y \in \mathbb{S}^+$ with $m_X = \sum_{x \in \mathbb{F}} X(x)$, $m_Y = \sum_{y \in \mathbb{F}} Y(y)$, and set of all possible flows F , f_S is the minimum-cost flow minimizing the overall cost with respect to IM-Sig*:

$$f_S = \arg \min_{f \in F} \left\{ \sum_{x \in \mathbb{F}} \sum_{y \in \mathbb{F}} \frac{\delta(x, y)}{\min(m_X, m_Y)} f(x, y) \right\}.$$

PROOF. We show that any arbitrarily chosen flow f different from the proposed flow f_S does not lead to lower overall cost. Due to space limitations, we present the idea of the proof instead of giving all the theoretical details. Since f and f_S are feasible, the total amount of earth moved is $\min(m_X, m_Y)$. Let $R_X = E \cup L \cup M$, where E, L, M include features from which f_S transfers an equal, smaller, or greater amount of earth than f , respectively:

$$E := \{x \in R_X \mid \sum_{y \in R_Y} f_S(x, y) = \sum_{y \in R_Y} f(x, y)\}$$

$$L := \{x \in R_X \mid \sum_{y \in R_Y} f_S(x, y) < \sum_{y \in R_Y} f(x, y)\}$$

$$M := \{x \in R_X \mid \sum_{y \in R_Y} f_S(x, y) > \sum_{y \in R_Y} f(x, y)\}.$$

For any $x \in R_X$ and any amount of earth $m \leq X(x)$, the minimum-cost local earth distribution regarding the target constraint is attained by transferring earth from x to its nearest neighbors y_1, \dots, y_l in R_Y where it holds $1 \leq i \leq j \leq l \Rightarrow \delta(x, y_i) \leq \delta(x, y_j)$, which can also be inferred from [21]. We refer this fact via the notation \star below, where required. Now, we consider 3 cases:

Case 1: For any $x \in E$, the amount of earth transferred by f_S is the same as that of f . By Def.7, f_S transfers earth from any x to its nearest neighbors in R_Y , and by (\star) it is guaranteed that it yields the lowest cost regarding any $x \in E$. Thus, we can conclude:

$$\sum_{x \in E} \sum_{y \in R_Y} \delta(x, y) \cdot f_S(x, y) \leq \sum_{x \in E} \sum_{y \in R_Y} \delta(x, y) \cdot f(x, y).$$

Case 2: For any $x \in M$, the total amount of earth f_S transfers from x exceeds that of f . We partition the amount of earth $X(x)$ belonging to the feature x into two parts: $m_M^-(x)$ is the amount of earth which each flow transfers to the features in R_Y . The remaining $X(x) - m_M^-(x)$ amount of earth is then transferred only by f_S so that it totally transfers more earth than f . Regarding $m_M^-(x)$, by (\star) f_S attains the minimum cost by filling up its nearest-neighbors in R_Y (consideration of local distance order of $y \in R_Y$). By Def.7, f_S only transfers earth regarding the pairs (x, y) with $\delta(x, y) \leq \delta(\hat{x}, \hat{y})$ (consideration of the global distance order of $(x, y) \in R_X \times R_Y$).

Case 3: For any $x \in L$, the total amount of earth f_S transfers from x is smaller than that of f . We partition the amount of earth $X(x)$ belonging to the feature x into two parts: $m_L^-(x)$ is the amount of earth which each flow transfers to the features in R_Y . The remaining $X(x) - m_L^-(x)$ amount of earth is then transferred by only f so that it totally transfers more earth than f_S . Regarding $m_L^-(x)$, by (\star) f_S attains the minimum cost by filling up its nearest-neighbors in R_Y (consideration of local distance order of $y \in R_Y$). We know f_S can only transfer earth regarding pairs (x, y) with $\delta(x, y) \leq \delta(\hat{x}, \hat{y})$, and it does not transfer all the earth from x . In addition, it fills up the features $y \in R_Y$ regarding all pairs (x, y) with $x \in L$ and $\delta(x, y) < \delta(\hat{x}, \hat{y})$. In best case, f distributes $m_L^-(x)$ amount of earth as f_S distributes, or f distributes it in another way. In the latter case, the last pair (x', y') used for the distribution by f satisfies $\delta(\hat{x}, \hat{y}) \leq \delta(x', y')$. Thus, the only place where f transfers the remaining $X(x) - m_L^-(x)$ amount of earth involves only the pairs (x, y) satisfying $\delta(\hat{x}, \hat{y}) \leq \delta(x', y') \leq \delta(x, y)$ (consideration of the global distance order again).

By the facts elucidated in Case 2 and 3, and the constraint **FC**, it is concluded: $\sum_{x \in M} \sum_{y \in R_Y} \delta(x, y) \cdot (f_S(x, y) - f(x, y)) \leq$

$$\sum_{x \in L} \sum_{y \in R_Y} \delta(x, y) \cdot (f(x, y) - f_S(x, y)).$$

As a result, after considering all the facts, we attain the final statement as follows:

$$\sum_{x \in R_X} \sum_{y \in R_Y} \delta(x, y) \cdot f_S(x, y) \leq \sum_{x \in R_X} \sum_{y \in R_Y} \delta(x, y) \cdot f(x, y),$$

which indicates that the overall cost induced by any feasible flow f does not lead to lower overall cost than that of f_S . In other words, the proposed flow f_S is proven to be the minimum-cost flow. \square

As mentioned above, Theorem 2 states that IM-Sig* flow is an optimal flow by showing that there exists no other flow

resulting in lower overall cost than that for IM-Sig* flow.

Lower-bounding the EMD with IM-Sig*. After presenting that IM-Sig* flow is feasible and optimal, we below show the third significant theoretical result (Theorem 3) from which we deduce that the utilization of IM-Sig* flow leads to the lower bound to the EMD on signatures, regardless of their total weights.

THEOREM 3 (LOWER-BOUNDING EMD). *Given any two signatures $X, Y \in \mathbb{S}^+$ with total weights m_X, m_Y , it holds:*

$$IM-Sig^*(X, Y) \leq EMD(X, Y).$$

PROOF. By Theorem 1 and 2, f_S (Def. 7) is a feasible and minimum-cost flow regarding constraints of IM-Sig*. Hence, there exists no other flow leading to smaller overall cost. \square

Consequently, the theoretical results provide confirmatory evidence that the proposed IM-Sig* flow can be utilized as a filter distance function lower-bounding the EMD on signatures, including both absolute and relative signatures. To this end, we can present a computational algorithm to compute IM-Sig* between any signatures, given as below.

5.4 Computational Algorithm

Algorithm 1: IM-Sig* computation

input : signatures X, Y , ground distance δ

output: IM-Sig* between signatures X and Y

```

1  cost = 0
2  construct minHeap for  $R_X \times R_Y$  regarding  $\delta$ 
3  minWeight =  $\min(m_X, m_Y)$ 
4  initialize sourceCap( $x$ ) =  $X(x)$  for each  $x \in R_X$ 
5  remainingEarth = minWeight
6  while remainingEarth > 0 do
7      ( $x, y$ ) = minHeap.poll()
8      if sourceCap( $x$ ) > 0 then
9          if  $Y(y) \geq \text{remainingEarth}$  then
10             | earth =  $\min\{\text{remainingEarth}, \text{sourceCap}(x)\}$ 
11             | else
12             | earth =  $\min\{\text{sourceCap}(x), Y(y)\}$ 
13             | end
14             | cost = cost +  $\delta(x, y) \cdot \text{earth}$ 
15             | sourceCap( $x$ ) =  $\text{sourceCap}(x) - \text{earth}$ 
16             | remainingEarth =  $\text{remainingEarth} - \text{earth}$ 
17         end
18 end
19 return cost/minWeight
```

Algorithm. The pseudo code of IM-Sig* computation for both absolute and relative signatures with our proposed flow construction is depicted in Algorithm 1. After a min-heap is constructed over $R_X \times R_Y$ with respect to distance values in ascending order (line 2), the algorithm extracts (x, y) with the smallest distance from the min-heap (line 7), until earth in an amount of the minimum weight of both signatures is transferred to Y totally (line 6). Each extracted pair from the min-heap refers to an element in the global feasible set $S_{X,Y}$, and the amount of earth transferred is determined by taking the remaining earth, current source capacity of x , and target capacity of y into consideration (lines 8-17).

Complexity Analysis. Assuming $n = |R_X|, m = |R_Y|$, the min-heap construction is performed in computation time

Figure 7: Precision-recall graphs.

complexity $O(n \cdot m)$. For each pair extraction from the min-heap, in worst case $\log(n \cdot m)$ many steps are required to ensure the heap property again.

Note that for any given signatures X, Y , it holds that $|S_{X,Y}| < |R_X \times R_Y|$, i.e. the global feasible set $S_{X,Y}$ which is the greatest set whose total flow may not reach the minimum of the total weights of both signatures, and hence, its cardinality is smaller than the number of all possible pairs of representatives in the signatures X and Y . Since the number of extractions from the min-heap is contingent on $\min(m_X, m_Y)$ and is bounded by $|S_{X,Y}| < |R_X \times R_Y|$, only t many pair extractions are required with $t < n \cdot m$. Thus, the filter distance computation can be carried out in time complexity $O(t \cdot \log(n \cdot m))$ with the proposed IM-Sig* flow.

6. EXPERIMENTAL EVALUATION

Experimental Setup. Results presented in this section expose averages over a query workload of 50 where queries are randomly chosen. All methods are implemented in JAVA and evaluated on a single-core 2.3 GHz machine with Windows Server 2008 and 10 GB of main memory, without parallelization. While we utilize Manhattan distance as ground distance, our approach can, nevertheless, be combined with any ground distance function.

We use three real world datasets. First, we take the data in [14] of 3636 videos and generate approximately 100 near-duplicate copies for each video by altering brightness, contrast, playback speed, resolution, frame order, adding overlay text, borders, and modifying content by frame deletion, yielding a database (NDVINE) of 350,000 videos with 3636 ground truth categories. Second, we use WORLD consisting of 1020 videos we downloaded from *vine.co* (Vine) and *youtube.com*, sorted manually into 34 categories (such as soccer, beach, and forest) of videos which are determined as visually similar according to human perception. For effectiveness experiments, we use the aforementioned databases incorporating video category information. Third, we use the dataset from [23] including 250,000 public social videos of Vine, which we refer as PUBVID. We conduct efficiency experiments with the latter and NDVINE to attain appropri-

Table 2: Single distance computation time (ms)

16	0.0224	0.0229	0.0452	0.0137	0.0006	0.0858
32	0.1021	0.1035	0.2053	0.0287	0.0012	0.4784
64	0.4740	0.4801	0.9535	0.0651	0.0022	3.9208

ate evaluation regarding data cardinality. We generate video signatures of different dimensionalities as described in Section 3 with position, color, contrast, coarseness and temporal information, while for effectiveness experiments we generate 2 different types of video signatures to recognize the contribution of the temporal information to results: *vis_t* and *vis* denote our novel video signature model with and without temporal information, respectively. In addition, since for any signatures X, Y , $\text{IM-Sig}^*(X, Y) \leq \max(\text{IM-Sig}^*(X, Y), \text{IM-Sig}^*(Y, X)) \leq \text{EMD}(X, Y)$ holds, we implement 3 variations of the algorithm from [17] to evaluate efficiency of query processing, and let *Fqdb*, *Fdbq*, *Fmax* refer to filter distance functions with our proposed flow computation where earth is transferred from query signatures to database signatures, from database signatures to query signatures, and where the maximum of both filter distances is utilized in multistep algorithm, respectively. Furthermore, in efficiency experiments we set $k=100$ for k -nearest-neighbor query processing. The databases used here are available upon request.

Effectiveness Experiments. Figure 7 shows precision-recall graphs of our novel video signature models (*vis_t*, *vis*), in comparison to four state-of-the-art methods: video triplets (*vitri*) [18], frame-sequence symbolization (*fras*) [27], bounded coordinate systems (*bcs*) [7], and video distance trajectories (*vdt*) [8]. Results summarized in Figure 7(a)-(b) provide confirmatory evidence that our model outperforms the state of the art for both near-duplicate detection (NDVINE) and visual similarity search (WORLD). Considering temporal dimension in the signature model yields better precision for NDVINE, since videos in the same category exhibit a similar temporal ordering. As illustrated in Figure 7(c)-(d), the precision of our models increases with higher signature dimensionality (10-50), as we expected.

Efficiency Experiments. It is noteworthy to remind again that our approach computes the same filter distance as for IM-Sig on relative signatures, and it corresponds to *Fdbq* in the experimental results presented in this section. First, we evaluate the influence of signature dimensionality on processing time of single distance computation on PUBVID dataset (Table 2). Note that *Pemd* and *Rubner* refer to the existing methods of projected EMD filter [4] and Rubner filter [15]. Since EMD can be computed in super-cubic time in signature dimensionality, it exhibits the highest values, while *Fmax*' performance is almost 2 times slower than *Fqdb* and *Fdbq*, corresponding to our expectation. Rubner shows the lowest time cost by only computing the ground distance among average signatures.

Figure 8 presents efficiency results of the state of the art (Rubner, *Pemd*) and our methods (*Fqdb*, *Fdbq*, *Fmax*). With increasing data cardinality, Rubner exhibits the highest time cost, directly followed by *Pemd*, which are substantially outperformed by our methods regarding selectivity and overall query time. In particular, *Fmax* computes 49.9

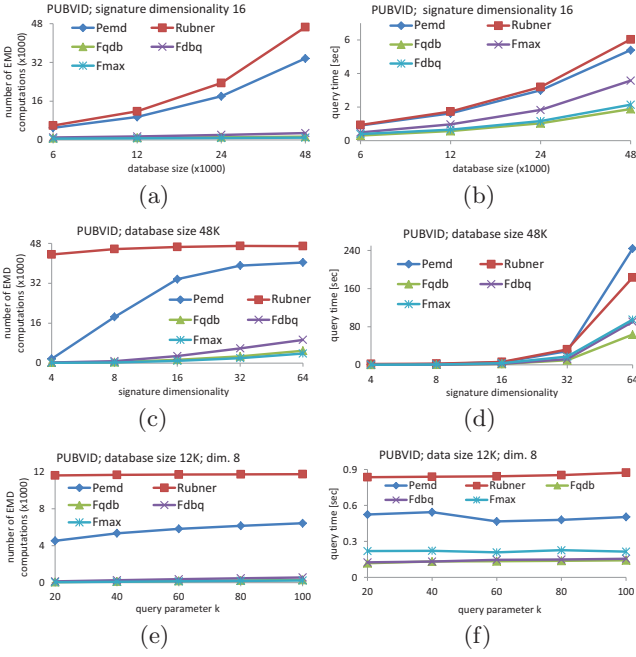

Figure 8: Selectivity and efficiency results with the state of the art.

and 36.1 times less EMD computations than Rubner and Pemd at data cardinality 48K, respectively. Another result matching our expectation is the constant behavior of Rubner with the worst selectivity, irrespective of dimensionality, while efficiency deterioration of Pemd is remarkable at a very high rate with increasing dimensionality, where, again, our methods outperform both existing approaches. The reason behind these observations is that Rubner simply utilizes distance between average signatures, and Pemd considers single EMD computations performed on each projected dimension, neglecting flow approximation, as given in Section 2. In contrast, our methods explicitly approximate the original EMD flow at a global level by tracking source and target capacity of representatives, and ensuring constraints given in Def. 3, attaining very high efficiency improvement. Furthermore, experiments analyzing the effect of query parameter k for k -nn query processing point out higher efficiency improvement of our proposals. Moreover, we conduct experiments to investigate the applicability to absolute signatures by using video subclip query signatures with varying total weights (0.1-1.0), while ensuring that the weight of any database video signature remains as 1 (Figure 9). Recall that Rubner is not a lower bound here, as illustrated in Section 4, and we observe considerably high selectivity difference between Pemd and our methods, confirming our methods' successful application on absolute signatures. In particular, Pemd refines 99% of all videos between query weights 0.1-0.4, while Fmax refines only at most 0.1%, performing 432 times less EMD computations than Pemd, attaining a selectivity improvement by two orders of magnitude. Note that query time results regarding Figure 9 are omitted, since they expose very similar behavior as those for the number of EMD computations.

After observing that our methods outperform the state of the art, we below perform extensive experiments for our

Figure 9: Results with the state of the art regarding selectivity vs. individual total weight of query signatures (absolute signatures).

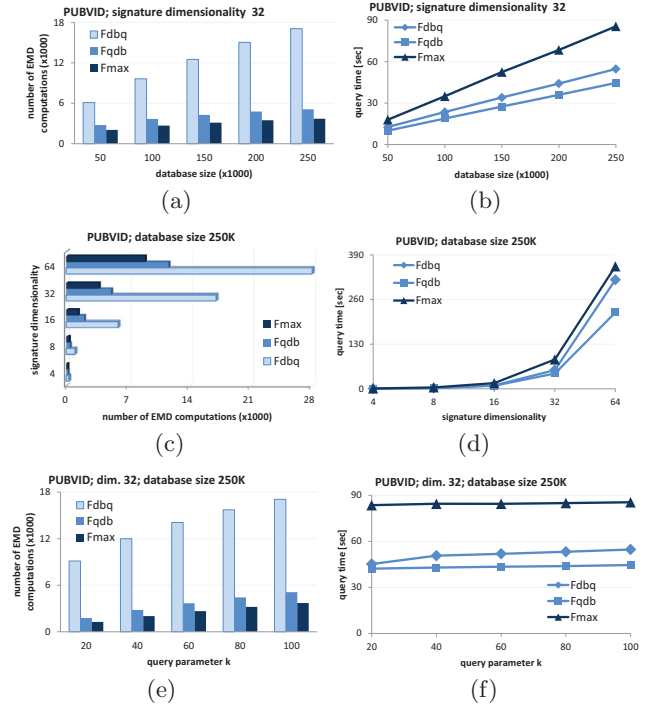

Figure 10: Results regarding selectivity and efficiency on PUBVID database.

methods, by varying signature dimensionality, database cardinality, and query parameter k for k -nn query processing.

Figure 10 summarizes the efficiency improvement achieved on PUBVID: Fmax indicates the best selectivity, in comparison to other proposed variations, exhibiting the lowest number of EMD computations with increasing data cardinality (50K-250K), and signature dimensionality (4-64), resulting from the computation of a tighter lower bound in the ranking phase of the multistep filter-and-refine algorithm [17]. Since Fmax shows higher filter time, its overall time cost is higher than that for the other two methods. Fqdb shows similar selectivity results, but its lower filter time cost than that for Fmax leads to the fact that Fqdb achieves the highest efficiency improvement regarding database size, dimensionality, and query parameter.

As depicted in Figure 11, evaluation results on NDVINE first indicate an almost constant selectivity behavior for Fqdb and Fmax regardless of increasing data size, when compared to Fdbq. This can be elucidated by the intrinsic essence of

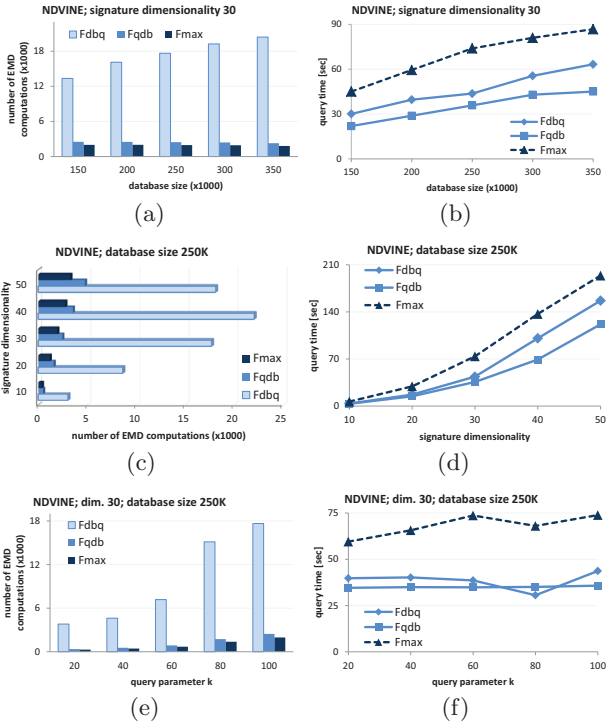

Figure 11: Results regarding selectivity and efficiency on NDVINE database.

this database: With increasing data size near-duplicates of videos emerging via various editing tasks can have similar distances to each other, which affects the filter step. Hence, the higher the data cardinality of near-duplicate video databases, it is more worth using Fqdb to attain an almost constant, low time cost, yielding a considerable advantage. Second, with increasing signature size at a constant data cardinality (250K), the number of promising objects passing Fdbq decreases after dimensionality 40, while Fmax and Fqdb show lower time cost, in particular 1.3 % of selectivity at dimensionality 50 for Fmax. Third, we observe that for all query parameters k (20-100), Fqdb and Fdbq show almost constant behavior for query time due to their lower filter time, matching our expectation.

For both databases, interestingly, Fdbq results in a higher number of EMD computations than for Fqdb. To expound this result, we perform experiments on another real world dataset which we omit due to space limitations, and recognize that selectivity results of Fdbq and Fqdb do not necessarily differ from each other at a high rate. Hence, the observed difference in selectivity and query time can be attributed to the feature distributions of these databases and the utilized queries, which cause Fqdb flow to be more similar to the EMD flow than that for Fdbq. A future research direction involves in further investigating this issue in detail.

Figure 12(a)-12(b) exhibit the effect of individual query signature weights on the number of EMD computations by fixing the total weight of any database video signature to 1. In particular for Fqdb, the number of EMD computations decreases with decreasing query weight, expounded by the fact that the smaller the query weight, the closer Fqdb approximates the EMD flow. To understand it in more detail, we analyze relative approximation error of Fqdb and Fdbq

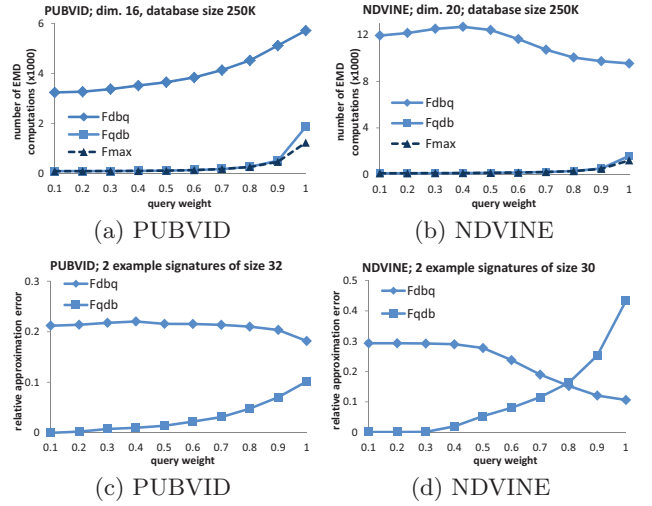

Figure 12: (a)-(b): Selectivity vs. individual total weight of query signatures. (c)-(d): Relative approximation error vs. individual total weight of query signatures for example signature pairs.

on example pairs of video signatures, summarized in Figure 12(c)-12(d). For smaller query weights, EMD distributes the weight of query representatives more locally among representatives of the database video, since capacities of target representatives are far greater than those for query representatives. Accordingly, since Fqdb distributes earth optimally for each query representative, its flow is similar to the EMD flow, allowing for a better approximation of the EMD than for Fdbq, which meets our expectation. Note that the flow approximation error increases especially after the query weight of 0.5 for both variations. Analogously, the higher the query weight, the better Fdbq approximates the EMD, as a higher query weight causes the EMD to distribute the weight of the database representatives more locally among those of query, resulting in a similar flow to that for Fdbq.

Figure 13 summarizes absolute filter and refinement distances for 10-nn queries on an example from PUBVID at a data cardinality of 1000 and dimensionality 16. Unlike comprehensive overall results for PUBVID, we observe that Fqdb leads to a higher number of refinements (75 in ranking according to filter distance), while Fdbq and Fmax perform 50 and 43 EMD computations, respectively. A significant result gathered from these figures is Fmax leads to the lowest number of exact distance computations, irrespective of the fact how well the other variants approximate the EMD flow. All query time cost results depicted in aforementioned figures point out the advantage of Fqdb with respect to dimensionality, data cardinality, and query parameter k .

7. CONCLUSION

In this paper, we presented how efficient and effective query processing can be performed on high dimensional video databases. We introduced a new compact video representation model, and proposed to alleviate computational time complexity of the Earth Mover’s Distance (EMD) by a novel filter approximation guaranteeing completeness (no false dismissals). Furthermore, we presented both an extensive theoretical analysis of our techniques and a computational al-

Figure 13: Filter and refinement distance values on an example from PUBVID dataset for 10-nn queries.

gorithm. Moreover, proposed techniques expose two vital advantages: First, they are applicable to both relative and absolute signatures exhibiting uniform and individual total weights, respectively, yielding high flexibility with respect to query processing and explicit user-driven tasks, such as subclip video detection. Second, they exhibit a comprehensive solution which is not restricted to the video domain, and, hence, can be applied to other domains, such as biotechnology and biomedicine. Extensive experimental evaluation on real world data indicates high efficiency, significantly reducing the number of EMD computations and outperforming the state of the art by up to two orders of magnitude regarding selectivity and query time. As future work, we plan to integrate our filter approximation in relational databases.

ABSTRACT

Strings form a fundamental data type in computer systems. String searching has been extensively studied since the inception of computer science. Increasingly many applications have to deal with imprecise strings or strings with fuzzy information in them. String matching becomes a probabilistic event when a string contains uncertainty, i.e. each position of the string can have different probable characters with associated probability of occurrence for each character. Such uncertain strings are prevalent in various applications such as biological sequence data, event monitoring and automatic ECG annotations. We explore the problem of indexing uncertain strings to support efficient string searching. In this paper we consider two basic problems of string searching, namely substring searching and string listing. In substring searching, the task is to find the occurrences of a deterministic string in an uncertain string. We formulate the string listing problem for uncertain strings, where the objective is to output all the strings from a collection of strings, that contain probable occurrence of a deterministic query string. Indexing solution for both these problems are significantly more challenging for uncertain strings than for deterministic strings. Given a construction time probability value τ , our indexes can be constructed in linear space and supports queries in near optimal time for arbitrary values of probability threshold parameter greater than τ . To the best of our knowledge, this is the first indexing solution for searching in uncertain strings that achieves strong theoretical bound and supports arbitrary values of probability threshold parameter. We also propose an approximate substring search index that can answer substring search queries with an additive error in optimal time. We conduct experiments to evaluate the performance of our indexes.

1. INTRODUCTION

String indexing has been one of the key areas of computer science. Algorithms and data structures of string searching finds application in web searching, computational biology, natural language processing, cyber security, etc. The classical problem of string indexing is to preprocess a string such that query substring can be searched efficiently. Linear space data structures are known for this problem which can answer such queries in optimal $O(m + occ)$ time, where m is the substring length and occ is the number of occurrences reported.

Growth of the internet, digital libraries, large genomic projects have contributed to enormous growth of data. As a consequence, noisy and uncertain data has become more prevalent. Uncertain data naturally arises in almost all applications due to unreliability of source, imprecise measurement, data loss, and artificial noise. For example sequence data in bioinformatics is often uncertain and probabilistic. Sensor networks and satellites inherently gather noisy information.

Existing research has focused mainly on the study of regular or deterministic string indexing. In this paper we explore the problem of indexing uncertain strings. We begin by describing the uncertain string model, possible world semantics and challenges of searching in uncertain strings.

Current literature models uncertain strings in two different ways: the string level model and the character level model. In string level model, we look at the probabilities and enumerate at whole string level, whereas character level model represents each position as a set of characters with associated probabilities. We focus on the character level model which arises more frequently in applications. Let S be an uncertain string of length n . Each character c at position i of S has an associated probability $pr(c^i)$. Probabilities at different positions may or may not contain correlation among them. Figure 1(a) shows an uncertain string S of length 5. Note that, the length of an uncertain string is the total number of positions in the string, which can be less than the total number of possible characters in the string. For example, in Figure 1(a), total number of characters in string s with nonzero probability is 9, but the total number of positions or string length is only 5.

"Possible world semantics" is a way to enumerate all the possible deterministic strings from an uncertain string. Based on possible world semantics, an uncertain string S of length n can generate a deterministic string w by choosing one possible character from each position and concatenating them in order. We call w as one of the possible world for S . Probability of occurrence of

$w = w_1 w_2 \dots w_n$ is the partial product $pr(w_1^1) \times pr(w_2^2) \times \dots \times pr(w_n^n)$. The number of possible worlds for S increases exponentially with n . Figure 1(b) illustrates all the possible worlds for the uncertain string S with their associated probability of occurrence.

A meaningful way of considering only a fraction of the possible worlds is based on a probability threshold value τ . We consider a generated deterministic string $w = w_1 w_2 \dots w_n$ as a valid occurrence with respect to τ , only if it has probability of occurrence more than τ . The probability threshold τ effectively removes lower probability strings from consideration. Thus τ plays an important role to avoid the exponential blowup of the number of generated deterministic strings under consideration.

Character	S[1]	S[2]	S[3]	S[4]	S[5]
a	.3	.6	0	.5	1
b	.4	0	0	0	0
c	0	.4	0	.5	0
d	.3	0	1	0	0

(a) Uncertain string S

(b) Possible worlds of S

Figure 1: An uncertain string S of length 5 and its all possible worlds with probabilities.

Given an uncertain string S and a deterministic query substring $p = p_1 \dots p_m$, we say that p matched at position i of S with respect to threshold τ if $pr(p_1^i) \times \dots \times pr(p_m^{i+m-1}) \geq \tau$. Note that, $O(m + occ)$ is the theoretical lower bound for substring searching where m is the substring length and occ is the number of occurrence reported.

1.1 Formal problem definition

Our goal is to develop efficient indexing solution for searching in uncertain strings. In this paper, we discuss two basic uncertain string searching problems which are formally defined below.

PROBLEM 1. Substring Searching: Given an uncertain string S of length n , our task is to index S so that when a deterministic substring p and a probability threshold τ come as a query, report all the starting positions of S where p is matched with probability of occurrence greater than τ .

PROBLEM 2. Uncertain String Listing: Let $\mathcal{D} = \{d_1, \dots, d_D\}$ be a collection of D uncertain strings of n positions in total. Our task is to index \mathcal{D} so that when a deterministic substring p and a probability threshold τ come as a query, report all the strings d_j such that d_j contains atleast one occurrence of p with probability of occurrence greater than τ .

Note that the string listing problem can be naively solved by running substring searching query in each of the uncertain string from the collection. However, this naive approach will take $O(\sum_{d_i \in \mathcal{D}} \text{search time on } d_i)$ time which can be very inefficient if the actual number of documents containing the substring is small. Figure 2 illustrates an example for string listing. In this example, only the string d_1 contains query substring "BF" with probability of occurrence greater than query threshold 0.1. Ideally, the query time should be proportionate to the actual number of documents reported as output. Uncertain strings considered in both these problems can contain correlation among string positions.

String collection $\mathcal{D} = \{d_1, d_2, d_3\}$:

$d_1[1]$ A.4 B.3 F.3	$d_1[2]$ B.3 L.3 F.3 J.1	$d_1[3]$ F.5 J.5	$d_2[1]$ A.6 C.4	$d_2[2]$ B.5 F.3 J.2	$d_2[3]$ B.4 C.3 E.2 F.1	$d_3[1]$ A.4 F.4 P.2	$d_3[2]$ L.3 L.3 P.3 T.3	$d_3[3]$ A.1
-------------------------------	--------------------------------------	------------------------	------------------------	-------------------------------	--------------------------------------	-------------------------------	--------------------------------------	-----------------

Output of string listing query (" BF ", 0.1) on \mathcal{D} is: d_1

Figure 2: String listing from an uncertain string collection $\mathcal{D} = \{d_1, d_2, d_3\}$.

1.2 Challenges in uncertain string searching

We summarize some challenges of searching in uncertain strings.

- An uncertain string of length n can have multiple characters at each position. As the length of an uncertain string increases, the number of possible worlds grows exponentially. This makes a naive technique that exhaustively enumerates all possible worlds infeasible.
- Since multiple substrings can be enumerated from the same starting position, care should be taken in substring searching to avoid possible duplication of reported positions.
- Enumerating all the possible sequences for arbitrary probability threshold τ and indexing them requires massive space for large strings. Also note that, for a specific starting position in the string, the probability of occurrence of a substring can change arbitrarily (non-decreasing order) with increasing length, depending on the probability of the concatenated character. This makes it difficult to construct index that can support arbitrary probability threshold τ .
- Correlated uncertainty among the string positions is not uncommon in applications. An index that handles correlation appeals to a wider range of applications. However, handling the correlation can be a bottleneck on space and time.

1.3 Related work

Although, searching over clean data has been widely researched, indexing uncertain data is relatively new. Below we briefly mention some of the previous works related to uncertain strings.

Algorithmic approach: Li et al. [19] tackled the substring searching problem where both the query substring and uncertain sequence comes as online query. They proposed a linear time and linear space dynamic programming approach to calculate the probability that a substring is contained in the uncertain string.

Approximate substring matching: Given as input a string p , a set of strings $\{x_i | 1 \leq i \leq r\}$, and an edit distance threshold k , the substring matching problem is to find all substrings s of x_i such that $d(p, s) \leq k$, where $d(p, s)$ is the edit distance between p and s . This problem has been well studied on clean texts (see [22] for a survey). Most of the ideas to solve this problem is based on partitioning p . Tiangjian et al. [12] extended this problem for uncertain strings. Their index can handle strings of arbitrary lengths.

Frequent itemset mining: Some articles discuss the problem of frequent itemset mining in uncertain databases [6, 7, 3], where an itemset is called frequent if the probability of occurrence of the itemset is above a given threshold.

Probabilistic database: Several works [5, 26, 25] have developed indexing techniques for probabilistic databases, based on R-trees and inverted indices, for efficient execution of nearest neighbor

bor queries and probabilistic threshold queries. Dalvi et al. [8] proposed efficient evaluation method for arbitrary complex SQL queries in probabilistic database. Later on efficient index for ranked top- k SQL query answering on a probabilistic database was proposed ([24, 18]). Kanagal et al. [16] developed efficient data structures and indexes for supporting inference and decision support queries over probabilistic databases containing correlation. They use a tree data structure named junction tree to represent the correlations in the probabilistic database over the tuple-existence or attribute-value random variables.

Similarity joins: A string similarity join finds all similar string pairs between two input string collections. Given two collections of uncertain strings R, S , and input (k, τ) , the task is to find string pairs (r, s) between these collections such that $Pr(ed(R, S) \leq k) > \tau$ i.e., probability of edit distance between R and S being at most k is more than probability threshold τ . There are some works on string joins, e.g., [4, 13, 17], involving approximation, data cleaning, and noisy keyword search, which has been discussed in the probabilistic setting [15]. Patil et al. [23] introduced filtering techniques to give upper and (or) lower bound on $Pr(ed(R, S) \leq k)$ and incorporate such techniques into an indexing scheme with reduced filtering overhead.

1.4 Our approach

Since uncertain string indexing is more complex than deterministic string indexing, a general solution for substring searching is challenging. However efficiency can be achieved by tailoring the data structure based on some key parameters, and use the data structure best suited for the purposed application. We consider the following parameters for our index design.

Threshold parameter τ_{min} : The task of substring matching in uncertain string is to find all the probable occurrences, where the probable occurrence is determined by a query threshold parameter τ . Although τ can have any value between 0 to 1 at query time, real life applications usually prohibits arbitrary small value of τ . For example, a monitoring system does not consider a sequence of events as a real threat if the associated probability is too low. We consider a threshold parameter τ_{min} , which is a constant known at construction time, such that query τ does not fall below τ_{min} . Our index can be tailored based on τ_{min} at construction time to suit specific application needs.

Query substring length: The query substring searched in the uncertain string can be of arbitrary length ranging from 1 to n . However, most often the query substrings are smaller than the indexed string. An example is a sensor system, collecting and indexing big amount of data to facilitate searching for interesting query patterns, which are smaller compared to the data stream. We show that more efficient indexing solution can be achieved based on query substring length.

Correlation among string positions: Probabilities at different positions in the uncertain string can possibly contain correlation among them. In this paper we consider character level uncertainly model, where a probability of occurrence of a character at a position can be correlated with occurrence of a character at a different position. We formally define the correlation model and show how correlation is handled in our indexes.

Our approach involves the use of suffix trees, suffix arrays and range maximum query data structure, which to the best of our knowledge, is the first use for uncertain string indexing. Succinct and compressed versions of these data structures are well known to have

good practical performance. Previous efforts to index uncertain strings mostly involved dynamic programming and lacked theoretical bound on query time. We also formulate the uncertain string listing problem. Practical motivation for this problem is given in Section 6. As mentioned before, for a specific starting position of an uncertain string, the probability of occurrence of a substring can change arbitrarily with increasing length depending on the probability of the concatenated character. We propose an approximate solution by discretizing the arbitrary probability changes with conjunction of a linking structure in the suffix tree.

1.5 Our contribution:

In this paper, we propose indexing solutions for substring searching in a single uncertain string, searching in a uncertain string collection, and approximate index for searching in uncertain strings. More specifically, we make the following contributions:

1. For the substring searching problem, we propose a linear space solution for indexing a given uncertain string S of length n , such that all the occurrences of a deterministic query string p with probability of occurrence greater than a query threshold τ can be reported. We show that for frequent cases our index achieves optimal query time proportional to the substring length and output size. Our index can be designed to support arbitrary probability threshold $\tau \geq \tau_{min}$, where τ_{min} is a constant known at index construction time.
2. For the uncertain string listing problem, given a collection of uncertain strings $\mathcal{D} = \{d_1, \dots, d_D\}$ of total size n , we propose a linear space and near optimal time index for retrieving all uncertain strings that contain a deterministic query string p with probability of occurrence greater than a query threshold τ . Our index supports queries for arbitrary $\tau \geq \tau_{min}$, where τ_{min} is a constant known at construction time.
3. We propose an index for approximate substring searching, which can answer substring searching queries in uncertain strings for arbitrary $\tau \geq \tau_{min}$ in optimal $O(m + occ)$ time, where τ_{min} is a constant known at construction time and ϵ is the bound on desired additive error in the probability of a matched string, i.e. outputs can have probability of occurrence $\geq \tau - \epsilon$.

1.6 Outline

The rest of the paper is organized as follows. In section 2 we show some practical motivations for our indexes. In section 3 we give a formal definition of the problem, discuss some definitions related to uncertain strings and supporting tools used in our index. In section 4 we build a linear space index for answering a special form of uncertain strings where each position of the string has only one probabilistic character. In section 5 we introduce a linear space index to answer substring matching queries in general uncertain strings for variable threshold. Section 6 discusses searching in an uncertain string collection. In section 7, we discuss approximate string matching in uncertain strings. In section 8, we show the experimental evaluation of our indexes. Finally in section 9, we conclude the paper with a summary and future work direction.

2. MOTIVATION

Various domains such as bioinformatics, knowledge discovery for moving object database trajectories, web log analysis, text mining, sensor networks, data integration and activity recognition generates large amount of uncertain data. Below we show some practical motivation for our indexes.

Biological sequence data: Sequence data in bioinformatics is often uncertain and probabilistic. For instance, reads in shotgun sequencing are annotated with quality scores for each base. These quality scores can be understood as how certain a sequencing machine is about a base. Probabilities over long strings are also used to represent the distribution of SNPs or InDels (insertions and deletions) in the population of a species. Uncertainty can arise due to a number of factors in the high-throughput sequencing technologies. NC-IUB committee standardized incompletely specified bases in DNA to address this common presence of uncertainty [20]. Analyzing these uncertain sequences is important and more complicated than the traditional string matching problem.

We show an example uncertain string generated by aligning genomic sequence of Tree of At4g15440 from OrthologID and deterministic substring searching in the sequence. Figure 3 illustrates the example.

S[1]	S[2]	S[3]	S[4]	S[5]	S[6]	S[7]	S[8]	S[9]	S[10]	S[11]
P.1	S.7	F.1	P.1	Q.5	P.1	A.4	I.3	A.1	S.5	A.1
	F.3			T.5		F.4	L.3		T.5	
						P.2	P.3			
							T.3			

Figure 3: Example of an uncertain string S generated by aligning genomic sequence of the tree of At4g15440 from OrthologID.

Consider the uncertain string S of Figure 3. A sample query can be $\{p = "AT", \tau = 0.4\}$, which asks to find all the occurrences of string AT in S having probability of occurrence more than $\tau = .4$. AT can be matched starting at position 7 and starting at position 9. Probability of occurrence for starting position 7 is $0.4 \times 0.3 = 0.12$ and for starting position 9 is $1 \times 0.5 = 0.5$. Thus position 9 should be reported to answer this query.

Automatic ECG annotations: In the Holter monitor application, for example, sensors attached to heart-disease patients send out ECG signals continuously to a computer through a wireless network ([9]). For each heartbeat, the annotation software gives a symbol such as N (Normal beat), L (Left bundle branch block beat), and R, etc. However, quite often, the ECG signal of each beat may have ambiguity, and a probability distribution on a few possibilities can be given. A doctor might be interested in locating a pattern such as $\hat{A}\hat{A}I\hat{J}NNAV\hat{A}\hat{A}I$ indicating two normal beats followed by an atrial premature beat and then a premature ventricular contraction, in order to verify a specific diagnosis. The ECG signal sequence forms an uncertain string, which can be indexed to facilitate deterministic substrings searching.

Event monitoring: Substring matching over event streams is important in paradigm where continuously arriving events are matched. For example a RFID-based security monitoring system produces stream of events. Unfortunately RFID devices are error prone and associate probability with the gathered events. A sequence of events can represent security threat. The stream of probabilistic events can be modeled with uncertain string and can be indexed so that deterministic substring can be queried to detect security threats.

3. PRELIMINARIES

3.1 Uncertain string and deterministic string

An uncertain string $S = s_1 \dots s_n$ over alphabet Σ is a sequence of sets $s_i, i = 1, \dots, n$. Every s_i is a set of pairs of the form $(c_j, pr(c_j^i))$, where every c_j is a character in Σ and $0 \leq pr(c_j^i) \leq 1$ is the probability of occurrence of c_j at position i in the string. Uncertain string length is the total number of positions in the string,

which can be less than the total number of characters in the string. Note that, summation of probability for all the characters at each position should be 1, i.e. $\sum_j pr(c_j^i) = 1$. Figure 3 shows an example of an uncertain string of length 11. A deterministic string has only one character at each position with probability 1. We can exclude the probability information for deterministic strings.

3.2 Probability of occurrence of a substring in an uncertain string

Since each character in the uncertain string has an associated probability, a deterministic substring occurs in the uncertain string with a probability. Let $S = s_1 \dots s_n$ is an uncertain string and p is a deterministic string. If the length of p is 1, then probability of occurrence of p at position i of S is the associated probability $pr(p^i)$. Probability of occurrence of a deterministic substring $p = p_1 \dots p_k$, starting at a position i in S is defined as the partial product $pr(p_1^i) \times \dots \times pr(p_k^{i+k-1})$. For example in Figure 3, $SFPQ$ has probability of occurrence $0.7 \times 1 \times 0.5 = 0.35$ at position 2.

3.3 Correlation among string positions

We say that character c_k at position i is correlated with character c_l at position j , if the probability of occurrence of c_k at position i is dependent on the probability of occurrence of c_l at position j . We use $pr(c_k^i)^+$ to denote the probability of c_k^i when the correlated character is present, and $pr(c_k^i)^-$ to denote the probability of c_k^i when the correlated character is absent. Let $x_g \dots x_h$ be a the substring generated from an uncertain string. $c_{k,g}^i \leq i \leq h$ is a character within the substring which is correlated with c_l^j . Depending on the position j , we have 2 cases:

Case 1, $g \leq j \leq h$: The correlated probability of (c_k^i) is expressed by $(c_l^j \implies a, \neg c_l^j \implies b)$, i.e. if c_l^j is taken as an occurrence, then $pr(c_k^i) = pr(c_k^i)^+$, otherwise $pr(c_k^i) = pr(c_k^i)^-$. We consider a simple example in Figure 4 to illustrate this. In this string, z^3 is correlated with e^1 . For the substring eqz , $pr(z^3) = .3$, and for the substring $f qz$, $pr(z^3) = .4$.

Case 2, $j < g$ or $j > h$: c_l^j is not within the substring. In this case, $pr(c_k^i) = pr(c_l^j) * pr(c_k^i)^+ + (1 - pr(c_l^j)) * pr(c_k^i)^+$. In Figure 4, for substring qz , $pr(z^3) = .6 * .3 + .4 * .4$.

S[1]	S[2]	S[3]
e: .6	q: 1	z: $e^1 \implies .3, \neg e^1 \implies .4$
f: .4		

Figure 4: Uncertain string S with correlated characters.

3.4 Suffix tree and generalized suffix tree

The suffix tree [28, 21] of a deterministic string $t[1 \dots n]$ is a lexicographic arrangement of all these n suffixes in a compact trie structure of $O(n)$ words space, where the i -th leftmost leaf represents the i -th lexicographically smallest suffix of t . For a node i (i.e., node with pre-order rank i), $path(i)$ represents the text obtained by concatenating all edge labels on the path from root to node i in a suffix tree. The locus node i_p of a string p is the node closest to the root such that the p is a prefix of $path(i_p)$. The suffix range of a string p is given by the maximal range $[sp, ep]$ such that for $sp \leq j \leq ep$, p is a prefix of (lexicographically) j -th

smallest suffix of t . Therefore, i_p is the lowest common ancestor of sp -th and ep -th leaves. Using suffix tree, the locus node as well as the suffix range of p can be computed in $O(p)$ time, where p denotes the length of p . The suffix array A of t is defined to be an array of integers providing the starting positions of suffixes of S in lexicographical order. This means, an entry $A[i]$ contains the position of i -th leaf of the suffix tree in t . For a collection of strings $\mathcal{D} = \{d_1, \dots, d_D\}$, let $t = d_1 d_2 \dots d_D$ be the text obtained by concatenating all the strings in \mathcal{D} . Each string is assumed to end with a special character $\$$. The suffix tree of t is called the generalized suffix tree (GST) of \mathcal{D} .

4. STRING MATCHING IN SPECIAL UNCERTAIN STRINGS

In this section, we construct index for a special form of uncertain string which is extended later. Special uncertain string is an uncertain string where each position has only one probable character with associated non-zero probability of occurrence. Special-uncertain string is defined more formally below.

DEFINITION 1. A special uncertain string $X = x_1 \dots x_n$ over alphabet Σ is a sequence of pairs. Every x_i is a pair of the form $(c_i, pr(c_i))$, where every c_i is a character in Σ and $0 < pr(c_i) \leq 1$ is the probability of occurrence of c_i at position i in the string.

Before we present an efficient index, we discuss a naive solution similar to deterministic substring searching.

4.1 Simple index

Given a special uncertain string $X = x_1 \dots x_n$, construct the deterministic string $t = c_1 \dots c_n$ where c_i is the character in x_i . We build a suffix tree over t . We build a suffix array A which maps each leaf of the suffix tree to its original position in t . We also build a successive multiplicative probability array C , where $C[j] = \prod_{i=1}^j pr(c_i)$, for $j = 1, \dots, n$. For a substring $x_i \dots x_{i+j}$, probability of occurrence can be easily computed by $C[i+j]/C[i-1]$. Given an input (p, τ) , we traverse the suffix tree for p and find the locus node and suffix range of p in $O(m)$ time, where m is the length of p . Let the suffix range be $[sp, ep]$. According to the property of suffix tree, each leaf within the range $[sp, ep]$ contains an occurrence of p in t . Original positions of the occurrence in t can be found using suffix array, i.e., $A[sp], \dots, A[ep]$. However, each of these occurrence has an associated probability. We traverse each of the occurrence in the range $A[sp], \dots, A[ep]$. For an occurrence $A[i]$, we find the probability of occurrence by $C[A[i] + m - 1]/C[A[i] - 1]$. If the probability of occurrence is greater than τ , we report the position $A[i]$ as an output. Figure 5 illustrates this approach.

Handling correlation: Correlation is handled when we check for the probability of occurrence. If $A[i]$ is a possible occurrence, then we need to consider any existing character within the substring $x_i \dots x_{i+m-1}$, that is correlated with another character. Let c_k is a character at position j within $x_i \dots x_{i+m-1}$, which is correlated with character c_l' , i.e. if c_l' is included in the substring, then $pr(c_k) = pr(c_k)^+ \cdot pr(c_l') + (1 - pr(c_l')) \cdot pr(c_k)^-$. To find the correct probability of (c_k^j) , if j' we check the j' -th position (j' depth character on the root to locus path in the suffix tree) of the substring. If the j' -th character is c_l , then $C[A[i] + m - 1]/C[A[i] - 1]$ is the correct probability of occurrence for $x_i \dots x_{i+m}$. Otherwise, $C[A[i] + m - 1]/C[A[i] - 1]$ contains the incorrect probability of c_k^j . Dividing $C[A[i] + m - 1]/C[A[i] - 1]$ by $pr(c_k^j)^+$ and multiplying by $pr(c_k^j)^-$ gives the correct probability of occurrence

Figure 5: Simple index for special uncertain strings.

in this case. If c_l falls before or after the substring $x_i \dots x_{i+m-1}$, $pr(c_k^j) = pr(c_l') \cdot pr(c_k^j)^+ + (1 - pr(c_l')) \cdot pr(c_k^j)^-$. Dividing $C[A[i] + m - 1]/C[A[i] - 1]$ by $pr(c_k^j)^+$ and multiplying by $pr(c_k^j)^-$ gives the correct probability of occurrence. Note that, we can identify and group all the characters with existing correlation, and search in the suffix tree in one scan for improved efficiency.

The main drawback in this approach is the query time. Within the suffix range $[sp, ep]$, possibly very few number of positions can qualify as output because of τ . So spending time on each element of the range $[sp, ep]$ is not justifiable.

4.2 Efficient index:

Bottleneck of the simple index comes from traversing each element within the suffix range. For the efficient index, we iteratively retrieve the element with maximum probability of occurrence in the range in constant time. Whenever the next maximum probability of occurrence falls below τ , we conclude our search. We use range maximum query (RMQ) data structure for our index which is briefly explained below.

Range Maximum Query: Let B be an array of integers of length n , a range maximum query (RMQ) asks for the position of the maximum value between two specified array indices $[i, j]$, i.e., the RMQ should return an index k such that $i \leq k \leq j$ and $B[k] \geq B[x]$ for all $i \leq x \leq j$. We use the result captured in following lemma for our purpose.

LEMMA 1. [10, 11] By maintaining a $2n + o(n)$ bits structure, range maximum query (RMQ) can be answered in $O(1)$ time (without accessing the array).

Every leaf of the suffix tree denotes a suffix position in the original text and a root to leaf path represents the suffix. For uncertain string, every character in this root to leaf path has an associated probability which is not stored in the suffix tree. Let y_j^i , for $j = 1, \dots, n$ denote a deterministic substring which is the i -length prefix of the j -th suffix, i.e. the substring on the root to i -th leaf path. Let Y^i is the set of y_j^i , for $j = 1, \dots, n$.

For $i = 1, \dots, n$, we define C_i as the successive multiplicative probability array for the substrings of Y^i . j -th element of C_i is the successive multiplicative probability of the i -length prefix of the j -th suffix. More formally $C_i[j] = \prod_{k=A[j]}^{A[j]+i-1} pr(c_k) = C[A[j] + i - 1]/C[A[j] - 1]$ ($1 \leq j \leq n$). For each C_i ($i = 1, \dots, \log n$) we

use range maximum query data structure RMQ_i of n bits over C_i and discard the original array C_i . We convert C_i into an integer array by multiplying each element by a sufficiently large number and then build the RMQ_i structure over it. We obtain $\log n$ number of such RMQ data structures resulting in total space of $O(n \log n)$ bits or $O(n)$ words. We also store the global successive multiplicative probability array C , where $C[j] = \prod_{i=1}^j Pr(c_i^j)$. Given a query (p, τ) , idea is to use RMQ_i for iteratively retrieving maximum probability of occurrence elements in constant time each and validate using C . To maintain linear space, we can support query substring length of $m = 0, \dots, \log n$ in this approach. Algorithm 1 illustrates the index construction phase for short substrings.

Query answering for short substrings ($m \leq \log n$): Given an input (p, τ) , we first retrieve the suffix range $[l, r]$ in $O(m)$ time using suffix tree, where m is the length of p . We can find the maximum probability occurrence of p in $O(1)$ time by executing query $RMQ_m(l, r)$. Let max be the position of maximum probability occurrence and $max' = A[max]$ be the original position in t . We can find the corresponding probability of occurrence by $C[max' + i - 1]/C[max' - 1]$. If the probability is less than τ , we conclude our search. If it is greater than τ , we report max' as an output. For finding rest of the outputs, we recursively search in the ranges $[l, max - 1]$ and $[max + 1, r]$. Since each call to $RMQ_m(l, r)$ takes constant time, validating the probability of occurrence takes constant time, we spend $O(1)$ time for each output. Total query time is optimal $O(m + occ)$. Algorithm 2 illustrates the query answering for short substrings. Note that, correlation is handled in similar way as described for the naive index, and we omit the details here.

Query answering for long substrings ($m > \log n$): We use a blocking scheme for answering long query substrings ($m > \log n$). Since exhaustively enumerating all possible substrings and storing the probabilities for each of them is infeasible, we only store selective probability values at construction time and compute the others at query time. We partition the entire suffix range of suffix array into different size blocks. More formally, for $i = \log n, \dots, n$, we divide the suffix range $[1, n]$ of suffix array $A[1, n]$ into $O(n/i)$ number of blocks each of size i . Let B_i be the set of length i blocks, i.e. $B_i = \{[A[1] \dots A[i]], [A[i+1] \dots A[2i]], \dots, [A[n-i+1] \dots A[n]]\}$ and let $B = \{B_{\log n}, \dots, B_n\}$. For a suffix starting at $A[j]$ and for B_i , we only consider the length i prefix of that suffix, i.e. $A[j \dots j+i]$. The idea is to store only the maximum probability value per block. For $B_i, i = \log n, \dots, n$, we define a probability array PB_i containing n/i elements. $PB_i[j]$ is the maximum probability of occurrence of all the substrings of length i belonging to the j -th block of B_i . We build a range maximum query structure RMQ_i for PB_i . RMQ_i takes $O(n/i)$ bits, total space is bounded by $\sum_i O(n/i) = O(n \log n)$ bits or $O(n)$ words.

For a query (p, τ) , we first retrieve the suffix range $[l, r]$. This suffix range can spread over multiple blocks of B_m . We use RMQ_m to proceed to next step. Note that RMQ_m consists of N/m bits, corresponding to the N/m blocks of B_m in order. Our query proceeds by executing range maximum query in $RMQ_m(l, r)$, which will give us the index of the maximum probability element of string length m in that suffix range. Let the maximum probability element position in RMQ_m is max and the block containing this element is B_{max} . Using C array, we can find out if the probability of occurrence is greater than τ . Note that, we only stored one maximum element from each block. If the maximum probability found is greater than τ , we check all the other elements in that block in $O(m)$ time. In the next step, we recursively query $RMQ_m(l, max - 1)$ and $RMQ(max + 1, r)$ to find out subsequent blocks. Whenever RMQ query for a range returns an element having probability less than τ , we stop the recursion in that range. Number of blocks visited during query answering is equal to the number of outputs and inside each of those block we check m elements, obtaining total query time of $O(m \times occ)$.

In practical applications, query substrings are rarely longer than $\log n$ length. Our index achieves optimal query time for substrings of length less than $\log n$. We show in the experimental section that on average our index achieves efficient query time proportional to substring length and number of outputs reported.

5. SUBSTRING MATCHING IN GENERAL UNCERTAIN STRING

In this section we construct index for general uncertain string based on the index of special uncertain string. The idea is to convert a general uncertain string into a special uncertain string, build the data structure similar to the previous section and carefully eliminate the duplicate answers. Below we show the steps of our solution in details.

5.1 Transforming general uncertain string

We employ the idea of Amihood et al [1] to transform general uncertain string into a special uncertain string. **Maximal factor** of an uncertain string is defined as follows.

DEFINITION 2. A **maximal factor** of a uncertain string S starting at location i with respect to a fixed probability threshold τ_c is a string of maximal length that when aligned to location i has probability of occurrence at least τ_c .

For example in figure 3, maximal factors of the uncertain string S at location 5 with respect to probability threshold 0.15 are "QPA", "QPF", "TPA", "TPF".

An uncertain string S can be transformed to a special uncertain string by concatenating all the maximal factors of S in order. Suffix tree built over the concatenated maximal factors can answer substring searching query for a fixed probability threshold τ_c . But this method produces a special uncertain string of $\Omega(n^2)$ length, which is practically infeasible. To reduce the special uncertain string length, Amihood et al. [1] employs further transformation to obtain a set of extended maximal factors. Total length of the extended maximal factors is bounded by $O((\frac{1}{\tau_c})^2 n)$.

LEMMA 2. Given a fixed probability threshold value $\tau_c (0 < \tau_c \leq 1)$, an uncertain string S can be transformed into a special uncertain string X of length $O((\frac{1}{\tau_c})^2 n)$ such that any deterministic substring p of S having probability of occurrence greater than τ_c is also a substring of X .

Simple suffix tree structure for answering query does not work for the concatenated extended maximal factors. A special form of suffix tree, namely property suffix tree is introduced by Amihood et al. [1]. Also substring searching in this method works only on a fixed probability threshold τ_c . A naive way to support arbitrary probability threshold is to construct special uncertain string and property suffix tree index for all possible value of τ_c , which is practically infeasible due to space usage.

We use the technique of lemma 2 to transform a given general uncertain string to a special uncertain string of length $O((\frac{1}{\tau_{min}})^2 n)$ based on a probability threshold τ_{min} known at construction time, and employ a different indexing scheme over it. Let X be the transformed special uncertain string. A running example is shown in Appendix B in the full version of this paper [27]. Following section elaborates the subsequent steps of the index construction.

5.2 Index construction on the transformed uncertain string

Our index construction is similar to the index of section 4. We need some additional components to eliminate duplication and position transformation.

Let $N = |X|$ be the length of the special uncertain string X . Note that $N = O((\frac{1}{\tau_{min}})^2 n) = O(n)$, since τ_{min} is a constant known in construction time. For transforming the positions of X into the original position in S , we store an array Pos of size N ,

where $Pos[i]$ =position of the i -th character of X in the original string S . We construct the deterministic string $t = c_1 \dots c_N$ where c_i is the character in X_i . We build a suffix tree over t . We build a suffix array A which maps each leaf of the suffix tree to its position in t . We also build a successive multiplicative probability array C , where $C[j] = \prod_{i=1}^j Pr(c_i^j)$, for $1 \leq j \leq N$. For a substring of length j starting at position i , probability of occurrence of the substring in X can be easily computed by $C[i+j-1]/C[i-1]$. For $i = 1, \dots, n$, we define C_i as the successive multiplicative probability array for substring length i i.e. $C_i[j] = \prod_{k=A[j]}^{A[j]+i-1} Pr(c_k^i) = C[A[j] + i - 1] / C[A[j] - 1]$ ($1 \leq j \leq n$). Appendix B of the full version [27] shows Pos array and C array after transformation of an uncertain string. Below we explain how duplicates may arise in outputs and how to eliminate them.

Possible duplicate positions in the output arises because of the general to special uncertain string transformation. Note that, distinct positions in X can correspond to the same position in the original uncertain string S , resulting in same position possibly reported multiple times. A key observation here is that for two different substrings of length m , if the locus nodes are different than the corresponding suffix ranges are disjoint. These disjoint suffix ranges collectively cover all the leaves of the suffix tree. For each such disjoint ranges, we need to store probability values for only the unique positions of S . Without loss of generality we store the value for leftmost unique position in each range.

For any node u in the suffix tree, $depth(u)$ is the length of the concatenated edge labels from root to u . We define by L_i as the set of nodes u_i^j such that $depth(u_i^j) \geq i$ and $depth(parent(u_i^j)) \leq i$. For $L_i = u_i^1, \dots, u_i^k$, we have a set of disjoint suffix ranges $[sp_i^1, ep_i^1], \dots, [sp_i^k, ep_i^k]$. A suffix range $[sp_i^j, ep_i^j]$ can contain duplicate positions of S . Using the Pos array we can find the unique positions for each range and store only the values corresponding to the unique positions in C_i .

We use range maximum query data structure RMQ_i of n bits over C_i and discard the original array C_i . Note that, RMQ data structure can be built over an integer array. We convert C_i into an integer array by multiplying each element by a sufficiently large number and then build the RMQ_i structure over it. We obtain $\log n$ number of such RMQ data structures resulting in total space of $O(n \log n)$ bits or $O(n)$ words. For long substrings ($m > \log n$), we use the blocking data structure similar to section 4. Detailed construction phase is shown in Algorithm 3 of Appendix A in the full version of this paper [27].

5.3 Query answering

Query answering procedure is almost similar to the query answering procedure of section 4. Only difference being the transformation of position which is done using the Pos array. Detailed query answering Algorithm for short query substrings is included in Appendix A of the full version of this paper [27]. See Appendix B for an illustrative example of query answering.

5.4 Space complexity

For analyzing the space complexity, we consider each component of our index. Length of the special uncertain string X and deterministic string t are $O(n)$, where n is the number of positions in S . Suffix tree and suffix tree each takes linear space. We store a successive probability array of size $O(n)$. We build probability array C_i for $i = 1, \dots, \log n$, where each C_i takes of $O(n)$. However we build RMQ_i of n bits over C_i and discard the original array C_i . We obtain $\log n$ number of such RMQ data structures resulting in total space of $O(n \log n)$ bits or $O(n)$ words. For the blocking scheme, we build RMQ_i data structure for

$i = \log n, \dots, n$. RMQ_i takes n/i bits, total space is $\sum_i n/i = O(n \log n)$ bits or $O(n)$ words. Since each component of our index takes linear space, total space taken by our index is $O(n)$ words.

5.5 Proof of correctness

In this section we discuss the correctness of our indexing scheme.

Substring conservation property of the transformation: At first we show that any substring of S with probability of occurrence greater than query threshold τ can be found in t as well. According to lemma 2, a substring having probability of occurrence greater than τ_{min} in S is also a substring of the transformed special uncertain string X . Since query threshold value τ is greater than τ_{min} , and entire character string of X is same as the deterministic string t , a substring having probability of occurrence greater than query threshold τ in S will be present in the deterministic string t .

Complete set of occurrences are outputted: For contradiction, we assume that an occurrence position z of substring p in S having probability of occurrence greater than τ is not included in the output. From the aforementioned property, p is a substring of t . According to the property of suffix tree, z must be present in the suffix range $[sp, ep]$ of p . Using RMQ structure, we report all the occurrence in $[sp, ep]$ in their decreasing order of probability of occurrence value in S and stop when the probability of occurrence falls below τ , which ensures inclusion of z .

No incorrect occurrence appears in output: An output z can be incorrect occurrence if it is not present in uncertain string S or its probability of occurrence is less than τ . We query only the occurrences in the suffix range $[sp, ep]$ of p , according to the property of suffix tree all of which are valid occurrences. We also validate the probability of occurrence for each of them using the successive multiplicative probability array C .

6. STRING LISTING FROM UNCERTAIN STRING COLLECTION

In this section we propose an indexing solution for problem 2. We are given a collection of D uncertain strings $\mathcal{D} = \{d_1, \dots, d_D\}$ of n positions in total. Let i denotes the string identifier of string d_i . For a query (p, τ) , we have to report all the uncertain string identifiers j such that d_j contains p with probability of occurrence more than τ . In other words, we want to list the strings from a collection of a string, that are relevant to a deterministic query string based on probability parameter.

Relevance metric: For a deterministic string t and an uncertain string S , we define a relevance metric, $Rel(S, t)$. If t does not have any occurrence in S , then $Rel(S, t)=0$. If s has only one occurrence of t , then $Rel(S, t)$ is the probability of occurrence of t in S . If s contains multiple occurrences of t , then $Rel(S, t)$ is a function of the probability of occurrences of t in S . Depending on the application, various functions can be chosen as the appropriate relevance metric. A common relevance metric is the maximum probability of occurrence, which we denote by $Rel(S, t)_{max}$. The OR value of the probability of occurrences is another useful relevance metric. More formally, if a deterministic string t has nonzero probable occurrences at positions i_1, \dots, i_k of an uncertain string S , then we define the relevance metric of t in S as $Rel(S, t)_{OR} = \sum_{j=i_1}^{i_k} pr(t_j) - \prod_{j=i_1}^{i_k} pr(t_j)$, where $pr(t_j)$ is the probability of occurrence of t in S at position j . Figure 6 shows an example.

Practical motivation: Uncertain string listing finds numerous practical motivation. Consider searching for a virus pattern in a collection of text files with fuzzy information. The objective is to

Uncertain string S :

$S[1]$	$S[2]$	$S[3]$	$S[4]$	$S[5]$	$S[6]$
A .4	B .3	A .5	A .6	B .5	A .4
B .3	L .3	F .5	B .4	F .3	C .3
F .3	F .3			J .2	E .2
	J .1				F .1

$$Rel(S, "BFA")_{max} = .09$$

$$Rel(S, "BFA")_{OR} = (.06 + .09 + .048) - (.06 * .09 * .048) = .19786$$

Figure 6: Relevance metric for string listing.

quarantine the files that contain the virus pattern. This problem can be modeled as a uncertain string listing problem, where the collection of text files is the uncertain string collection D , the virus pattern is the query pattern P , and τ is the confidence of matching. Similarly, searching for a gene pattern in genomic sequences of different species can be solved using uncertain string listing data structure.

The index: As explained before, a naive search on each of the string will result in $O(\sum_i \text{search time on } d_i)$ which can be much larger than the actual number of strings containing the string. Objective of our index is to spend only one search time and time proportional to the number of output strings. We construct a generalized suffix tree so that we have to search for the string only once. We concatenate d_1, \dots, d_D by a special symbol which is not contained in any of the document and obtain a concatenated general uncertain string $S = d_1\$ \dots \d_D . Next we use the transformation method described in previous section to obtain deterministic string t , construct suffix tree and suffix array for t . According to the property of suffix tree, the leaves under the locus of a query substring t contains all the occurrence positions of t . However, these leaves can possibly contain duplicate positions and multiple occurrence of the same document. In the query answering phase, duplicate outputs can arise because of the following two reasons:

1. Distinct positions in t can correspond to the same position in the original uncertain string S
2. Distinct positions in S can correspond to the same string identifier d_j which should be reported only once

Duplicate elimination is important to keep the query time proportional to the number of output strings. At first we construct the successive multiplicative probability array C_i similar to the substring searching index, then show how to incorporate $Rel(S, t)$ value for the multiple occurrences cases in the same document and duplicate elimination.

Let y_j^i , for $j = 1, \dots, n$ denote a deterministic substring which is the i -length prefix of the j -th suffix, i.e. the substring on the root to i -th leaf path. Note that, multiple y_j^i can belong to the same locus node in the suffix tree. Let Y^i is the set of y_j^i , for $j = 1, \dots, n$. The i -depth locus nodes in the suffix tree constitutes disjoint partitions in Y^i . For $i = 1, \dots, n$, we define C_i as the successive multiplicative probability array for the substrings of Y^i . j -th element of C_i is the successive multiplicative probability of the i -length prefix of the j -th suffix. More formally $C_i[j] = \prod_{k=A[j]}^{A[j]+i-1} Pr(c_k^i) = C[A[j] + i - 1] / C[A[j] - 1] (1 \leq j \leq n)$.

The i -depth locus nodes in the suffix tree constitutes disjoint partitions in C_i . Let u be a i -depth locus node having suffix range $[j \dots k]$ and root to u substring t . Then the partition $C_i[j \dots k]$ belongs to u . For this partitions, we store only one occurrence of

a string d_j with the relevance metric value $Rel(S, t)$, and discard the other occurrences of d_j in that range. We build RMQ structure similar to section 5.

Query answering: We explain the query answering for short substrings. Blocking scheme described in previous section can be used for longer query substrings. Given an input (p, τ) , we first retrieve the suffix range $[l, r]$ in $O(m)$ time using suffix tree, where m is the length of p . We can find the maximum relevant occurrence of p in $O(1)$ time by executing query $RMQ_m(l, r)$. Let max be the position of maximum relevant occurrence and $max' = A[max]$ be the original position in t . For relevance metric $Rel(S, t)_{max}$, we can find the corresponding probability of occurrence by $C[max' + i - 1] / C[max' - 1]$. In case of the other complex relevance metric, all the occurrences need to be considered to retrieve the actual value of $Rel(S, t)$. If the relevance metric is less than τ , we conclude our search. If it is greater than τ , we report max' as an output. For finding rest of the outputs, we recursively search in the ranges $[l, max - 1]$ and $[max + 1, r]$. Each call to $RMQ_m(l, r)$ takes constant time. For simpler relevance metrics (such as $Rel(S, t)_{max}$), validating the relevance metric takes constant time. Total query time is optimal $O(m + occ)$. However, for more complex relevance metric, all the occurrences of t might need to be considered, query time will be proportionate to the total number of occurrences.

7. APPROXIMATE SUBSTRING SEARCHING

In this section we introduce an index for approximate substring matching in an uncertain string. As discussed previously, several challenges of uncertain string matching makes it harder to achieve optimal theoretical bound with linear space. We have proposed index for exact matching which performs near optimally in practical scenarios, but achieves theoretical optimal bound only for shorter query strings. To achieve optimal theoretical bounds for any query, we propose an approximate string matching solution. Our approximate string matching data structure answers queries with an additive error ϵ , i.e. outputs can have probability of occurrence $\geq \tau - \epsilon$.

At first we begin by transforming the uncertain string S into a special uncertain string X of length $N = O((\frac{1}{\tau_{min}})^2 n)$ using the technique of lemma 2 with respect to a probability threshold value τ_{min} . We obtain a deterministic string t from X by concatenating the characters of X . We build a suffix tree for t . Note that, each leaf in the suffix tree has an associated probability of occurrence $\geq \tau_{min}$ for the corresponding suffix. Given a query p , substring matching query for threshold τ_{min} can now be answered by simply scanning the leafs in subtree of locus node i_p . We first describe the framework (based on Hon et. al. [14]) which supports a specific probability threshold τ and then extend it for arbitrary $\tau \geq \tau_{min}$.

We begin by marking nodes in the suffix tree with positional information by associating $Pos_{id} \in [1, n]$. Here, Pos_{id} indicates the starting position in the original string S . A leaf node l is marked with a $Pos_{id} = d$ if the suffix represented by l begins at position d in S . An internal node u is marked with d if it is the lowest common ancestor of two leaves marked with d . Notice that a node can be marked with multiple position ids. For each node u and each of its marked position id d , define a link to be a triplet $(origin, target, Pos_{id})$, where $origin = u$, target is the lowest proper ancestor of u marked with d , and $Pos_{id} = d$. Two crucial properties of these links are listed below.

- Given a substring p , for each position d in S where p matches with probability $\geq \tau_{min}$, there is a unique link whose origin

is in the subtree of i_p and whose target is a proper ancestor of i_p , i_p being the locus node of substring p .

- The total number of links is bounded by $O(N)$.

Thus, substring matching query with probability threshold τ_{min} can now be answered by identifying/reporting the links that originate in the subtree of i_p and are targeted towards some ancestor of it. By referring to each node using its pre-order rank, we are interested in links that are stabbed by locus node i_p . Such queries can be answered in $O(m + occ)$, where $|p| = m$ and occ is the number of answers to be reported (Please refer to [14] for more details).

As a first step towards answering queries for arbitrary $\tau \geq \tau_{min}$, we associate probability information along with each link. Thus each link is now a quadruple $(origin, target, Pos_{id}, prob)$ where first three parameters remain same as described earlier and $prob$ is the probability of $prefix(u)$ matching uncertain string S at position $Pos_{id} = d$. It is evident that for substring p and arbitrary $\tau \geq \tau_{min}$, a link stabbed by locus node i_p with $prob \geq \tau$ corresponds to an occurrence of p in S at position d with probability $\geq \tau$. However, a link stabbed by i_p with $prob < \tau$ can still produce an outcome since $prefix(i_p)$ contains additional characters not included in p , which may be responsible for matching probability to drop below τ . Even though we are interested only in approximate matching this observation leads up the next step towards the solution. We partition each link $(origin = u, target = v, Pos_{id} = d, prob)$ into multiple links $(or_1 = u, tr_1, d, prob_1)$, $(or_2 = tr_1, tr_2, d, prob_2)$, ..., $(or_k = tr_{k-1}, tr_k = v, d, prob_k)$ such that $prob_j - prob_{j-1} \leq \epsilon$ for $2 \leq j \leq k$. Here or_2, \dots, or_k may not refer to the actual node in the suffix tree, rather it can be considered as a dummy node inserted in-between an edge in suffix tree. In essence, we move along the path from node $u = or_1$ towards its ancestors one character at a time till the probability difference is bounded by ϵ i.e., till we reach node tr_1 . The process then repeats with tr_1 as the origin node and so on till we reach the node v . It can be seen that the total number of links can now be bounded by $O(N/\epsilon)$. In order to answer a substring matching query with threshold $\tau \geq \tau_{min}$, we need to retrieve all the links stabbed by i_p with $prob \geq \tau$. Occurrence of substring p in S corresponding to each such link is then guaranteed to have its matching probability at least $\tau - \epsilon$ due to the way links are generated (for any link with (u, v) as origin and target probability of $prefix(v)$ matching in S can be more than that of $prefix(u)$ only by ϵ at the most).

8. EXPERIMENTAL EVALUATION

In this section we evaluate the performance of our substring searching and string listing index. We use a collection of query substrings and observe the effect of varying the key parameters. Our experiments show that, for short query substrings, uncertain string length does not affect the query performance. For long query substrings, our index fails to achieve optimal query time. However this does not deteriorate the average query time by big margin, since the probability of match also decreases significantly as substring gets longer. Index construction time is proportional to uncertain string size and probability threshold parameter τ_{min} .

We have implemented the proposed indexing scheme in C++. The experiments are performed on a 64-bit machine with an Intel Core i5 CPU 3.33GHz processor and 8GB RAM running Ubuntu. We present experiments along with analysis of performance.

8.1 Dataset

We use a synthetic datasets obtained from their real counterparts. We use a concatenated protein sequence of mouse and human (alphabet size $|\Sigma| = 22$), and break it arbitrarily into shorter strings.

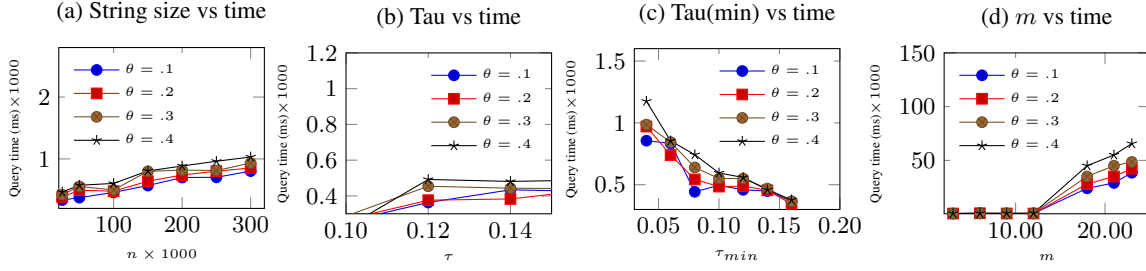

Figure 7: Substring searching query time for different string lengths (n), query threshold value τ , construction time threshold parameter τ_{min} and query substring length m .

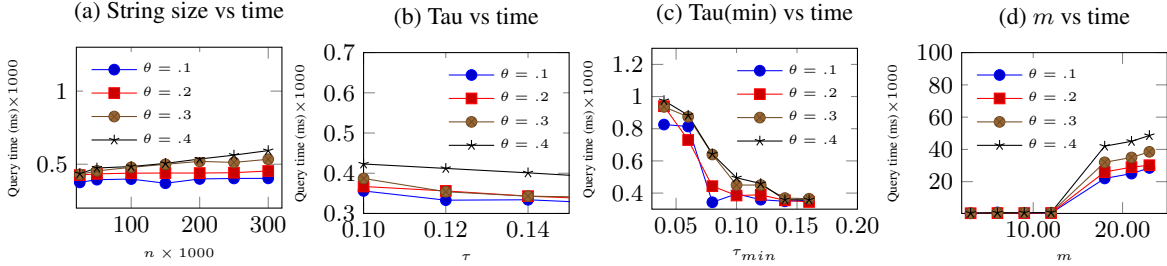

Figure 8: String listing query time for different string lengths (n), query threshold value τ , construction time threshold parameter τ_{min} and query substring length m .

For each string s in the dataset we first obtain a set $A(s)$ of strings that are within edit distance 4 to s . Then a character-level probabilistic string S for string s is generated such that, for a position i , the pdf of $S[i]$ is based on the normalized frequencies of the letters in the i -th position of all the strings in $A(s)$. We denote by θ the fraction of uncertain characters in the string. θ is varied between 0.1 to 0.5 to generate strings with different degree of uncertainty. The string length distributions in this dataset roughly follows a normal distribution in the range of [20, 45]. The average number of choices that each probabilistic character $S[i]$ may have is set to 5.

8.2 Query time for different string lengths (n) and fraction of uncertainty (θ)

We evaluate the query time for different string lengths n , ranging from 2K to 300K and θ ranging from 0.1 to 0.5. Figure 7(a) and Figure 8(a), shows the query times for substring searching and string listing. Note that, n is number of positions in the uncertain string where each position can have multiple characters. We take the average time for query lengths of 10,100,500,1000. We use $\tau_{min} = 0.1$ and query threshold $\tau = 0.2$. As shown in the figures, query times does not show much irregularity in performance when the length of string goes high. This is because for shorter query length, our index achieves optimal query time. Although for longer queries, our index achieves $O(m \times occ)$ time, longer query strings probability of occurrence gets low as string grows longer resulting in less number of outputs. However when fraction of uncertainty(θ) increases in the string, performance shows slight decrease as query time increases slightly. This is because longer query strings are more probable to match with strings with high level of uncertainty.

8.3 Query time for different τ and fraction of uncertainty (θ)

In Figure 7(b) and Figure 8(b), we show the average query times for string matching and string listing for probability threshold $\tau =$

0.04, 0.06, 0.08, 0.1, 0.12 for fixed $\tau_{min} = 0.1$. In terms of performance, query time increases with decreasing τ . This is because more matching is probable for smaller τ . Larger τ reduces the output size, effectively reducing the query time as well.

8.4 Query time for different τ_{min} and fraction of uncertainty (θ)

In Figure 7(c) and Figure 8(c), we show the average query times for string matching and string listing for probability threshold $\tau_{min} =$ 0.04, 0.06, 0.08, 0.1, 0.12 which shows slight impact of τ_{min} over query time.

8.5 Query time for different substring lengths (m) and fraction of uncertainty (θ)

In figure 7(d) and figure Figure 8(d), we show the average query times for string matching and string listing. As it can be seen long pattern length drastically increases the query time.

8.6 Construction time for different string lengths and fraction of uncertainty (θ)

Figure 9(a) shows the index construction times for uncertain string length n ranging from 2K to 300K. We can see that the construction time is proportional to the string length n . Increasing uncertainty factor θ also impacts the construction time as more permutation is possible with increasing uncertain positions. Figure 9(b) shows the impact of θ on construction time.

8.7 Space usage

Theoretical bound for our index is $O(n)$. However, this bound can have hidden multiplicative constant. Here we elaborate more on the actual space used for our index.

For our indexes, we construct the regular string t of length $N = O((\frac{1}{\tau_{min}})^2 n)$ by concatenating all the extended maximal factors based on threshold τ_{min} . We do not store the string t in our index.

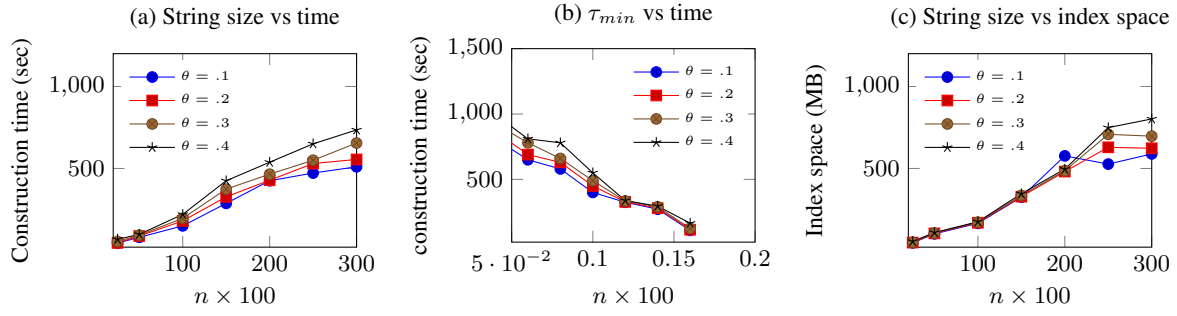

Figure 9: Construction time and index space for different string lengths (n) and probability threshold $\tau_{min} = .1$

We built RMQ structures RMQ_i for $i = 1, \dots, \log n$ which takes $O(N \log n)$ bits. The practical space usage of RMQ is usually very small with hidden multiplicative constant of $2 - 3$. So the average space usage of our RMQ structure in total can be stated as $3N$ words. For a query string p , we find the suffix range of p in the concatenated extended maximum factor string t . For this purpose, instead of using Generalized Suffix Tree (GST), we use its space efficient version i.e., a compressed suffix array (CSA) of t . There are many versions of CSA's available in literature. For our purpose we use the one in [2] that occupies $N \log \sigma + o(N \log \sigma) + O(N)$ bits space and retrieves the suffix range of query string p in $O(p)$ time. In practice, this structure takes about $2.5N$ words space. We also store an array D of size N storing the partial probabilities, which takes approximately $4N$ bytes of space. Finally Pos array is used for position transformation, taking N words space. Summing up all the space usage, our index takes approximately $3N + 2.5N + 4N + N = 10.5N = (\frac{1}{\tau_{min}})^2 10.5n$. Figure 9(c) shows the space usage for different string length (n) and θ .

9. CONCLUSIONS

In this paper we presented indexing framework for searching in uncertain strings. We tackled the problem of searching a deterministic substring in uncertain string and proposed both exact and approximate solution. We also formulated the uncertain string listing problem and proposed index for string listing from a uncertain string collection. Our indexes can support arbitrary values of probability threshold parameter. Uncertain string searching is still largely an unexplored area. Constructing more efficient index, variations of the string searching problem satisfying diverse query constraints are some interesting future work direction.

ABSTRACT

Complex event processing is a popular technology for continuously monitoring high-volume event streams from health care to traffic management to detect complex compositions of events. These event compositions signify critical “application contexts” from hygiene violations to traffic accidents. Certain event queries are only appropriate in particular contexts. Yet state-of-the-art streaming engines tend to execute all event queries continuously regardless of the current application context. This wastes tremendous processing resources and thus leads to delayed reactions to critical situations. We have developed the first context-aware event processing solution, called CAESAR, which features the following key innovations. (1) The CAESAR model supports application contexts as first class citizens and associates appropriate event queries with them. (2) The CAESAR optimizer employs context-aware optimization strategies including context window push-down strategy and query workload sharing among overlapping contexts. (3) The CAESAR infrastructure allows for lightweight event query suspension and activation driven by context windows. Our experimental study utilizing both the Linear Road stream benchmark as well as real-world data sets demonstrates that the context-aware event stream analytics consistently outperforms the state-of-the-art strategies by factor of 8 on average.

1. INTRODUCTION

Complex Event Processing (CEP) has emerged as a prominent technology for supporting applications from financial fraud [30] to health care [32]. Traditionally, CEP systems consume event streams produced by smart digital devices like sensors and mobile phones and *continuously* evaluate the query workload to monitor the input event streams.

In many stream-based applications, events convey particular *application contexts* such that the system reaction to an event may significantly vary depending on the current context. Therefore, some event queries may only need to be executed under certain circumstances while others can

be safely suspended. The following examples highlight the challenges and opportunities of context-aware event stream processing that have been overlooked in the prior research.

Motivating Example. Traffic has both a huge economic and environmental impact on our daily lives. Drivers traveling the 10-worst U.S. traffic corridors annually spend an average of 140 hours idling in traffic [2]. Due to pollution and noise, congestion in the USA’s 83 largest urban areas in 2010 led to a related public health cost of \$18 billion [3]. Further, road traffic injuries caused an estimated 1.24 million deaths worldwide in 2010 [4].

An intelligent traffic control center could reduce these crippling impacts. The center receives vehicle position reports, analyzes them, infers the current situation in the monitored road segments and reacts instantaneously to ensure safe and smooth traffic flow. Early detection and prompt reaction to critical situations are eminently important. They prevent time and fuel waste, reduce pollution, avoid property damage and in some cases even save human lives.

Figure 1: CAESAR model of traffic management

System reaction to a position report should thus be modulated depending on the *current situation on the road* (here referred to as context¹). Indeed, if an *accident* is detected, all vehicles downstream should be warned and possibly alternative routes should be suggested (Figure 1). If a road segment becomes *congested*, drivers may be charged toll to discourage them from driving to control smooth traffic flow. If a road segment is *clear*, none of the above actions should take place. Clearly, *current application contexts* must be rapidly detected and continuously maintained to determine appropriate reactions of the system at all times.

Conditions implying an *application context* can be complex. They are specified on both the event streams and the current contexts. For example, if over 50 cars per minute

¹Here we utilize the term *application context* to refer to the state of a sub-network such as *accident*, *congestion*, etc. We deliberately avoid using the notion *state* since it is a too overloaded term in the CEP literature.

move with an average speed less than 40 mph and the current context is no *congestion* then the *context deriving query* updates the context to *congestion* for this road segment. To save resources and thus to ensure prompt system responsiveness, such complex context detection should happen once. Its results must be available on-time and shared among all queries that belong to the detected context. In other words, *context processing* queries are *dependent* on the results of *context deriving* queries and a mechanism ensuring their correct execution must be employed.

The system responsiveness can be substantially improved by exploiting the optimization opportunities enabled by the application contexts. (1) Only those event queries that are relevant in the current contexts should be executed. All irrelevant computations should be suspended. (2) Workloads of overlapping contexts should be shared. Furthermore, application contexts break the application semantics into modules that facilitate the modular development and runtime maintenance of an event stream processing application.

Challenges. To enable such event stream processing applications, the following challenges must be tackled:

Context-aware specification model. As motivated above, event stream processing applications need to express rich semantics. In particular, they have to specify application contexts as first class citizens and enable linkage of appropriate event queries to their respective context. Furthermore, this model must be in a convenient human-readable format to facilitate on-the-fly reconfiguration, easy maintenance and avoid fatal specification mistakes.

Context-exploiting optimization techniques. To meet the demanding latency constraints of time-critical applications, this powerful context-aware application model must be translated into an efficient physical query plan. This query plan must be optimized by exploiting the optimization opportunities enabled by context-aware event stream analytics. This is complicated by the fact that the duration of a context is unknown at compile time and potentially unbounded.

Context-driven execution infrastructure. An efficient runtime execution infrastructure is required to support multiple concurrent contexts. To ensure correct query execution, the inter-dependencies between complex context deriving and context processing queries must be taken into account.

State-of-the-Art. The challenges described above have so far not been addressed in a comprehensive fashion.

Since the duration of a context varies, state-of-the-art window semantics such as fixed-length tumbling and sliding windows [22, 8] are inadequate to model the proposed notion of a context. Classical predicate windows [15] have variable duration. However, conditions leading to an application context can be rather complex and thus resource-consuming, worse yet they can be dependent on the previous contexts (Figure 1). Since predicate windows are independent from each other, they fail to express context windows.

While some event query languages (e.g., CQL [10], SASE [5, 34]) could be used to hard-code the equivalent of a context construct by queries that detect the context bounds. However, this approach is cumbersome and error-prone – requiring the careful specification of multiple complex inter-dependent event queries [25]. Furthermore, no optimization techniques have been developed to exploit the benefits of context-awareness such as suspension of irrelevant event queries nor the sharing workloads of overlapping contexts.

Business models [16, 28] focus on powerful modeling con-

structs to capture the semantics of processes and in that sense express application contexts. However, these models, targeting business process specification, were not designed for event stream processing. Thus, they neglect its core peculiarities such as the event-driven nature of context detection achieving high performance analytics and the importance of temporal windows and their processing techniques.

The Proposed CAESAR Approach. In [25], we formally defined the first context-aware event query processing model for which we now design the Context-Aware Event Stream Analytics in Real time system, CAESAR for short.

Our CAESAR model supports *context windows* as first-class citizens and associates appropriate event queries with each context window. Event queries that process events within a context are called *context processing queries*. Event queries that derive a context are called *context deriving queries*. Both types of queries operate within *context windows*, a new class of event query window we define.

To achieve near real-time system responsiveness, the CAESAR model is transformed into a stream query plan composed of context-aware operators of the *CAESAR algebra*. This algebra serves as foundation for the CAESAR optimizer. The optimizer exploits the notion of context windows to avoid unnecessary computations by suspending those operators which are irrelevant to the current context. Furthermore, the optimizer saves computations by sharing workloads of overlapping context windows. Finally, we built the *CAESAR runtime infrastructure* for correct yet efficient execution of inter-dependent context-aware event queries.

Contributions can be summarized as follows:

- 1) We introduce a new notion of windows, called *context windows*, to enable context-aware event query processing critical to modeling event-based systems. The proposed human-readable context-aware CAESAR model significantly simplifies the specification of rich event-driven application semantics by explicit support of context windows². It also opens new multi-query optimization opportunities by associating appropriate event queries with each context.

- 2) We define the *CAESAR algebra* for our context-aware event query processing. The *CAESAR optimizer* pushes the context windows down to suspend the execution of irrelevant operators. Furthermore, we propose the context window grouping algorithm that exploits the sharing opportunities from workloads of overlapping context windows.

- 3) We built the *CAESAR runtime execution infrastructure* that guarantees correct and efficient execution of inter-dependent context deriving and context processing queries.

- 4) We evaluate the performance of the CAESAR system and its optimization strategies using the Linear Road stream benchmark [9] as well as the real world data set [26]. Our CAESAR system performs on average 8-fold faster than the context-independent solution for a wide range of cases.

Outline. We start with preliminaries in Section 2 and introduce the CAESAR model in Section 3. We present our algebraic execution paradigm in Section 4 and its optimization techniques in Section 5. Section 6 is devoted to the runtime execution infrastructure. We conduct the performance study in Section 7. Related work is discussed in Section 8, and Section 9 concludes the article.

²Visual editor for the CAESAR model and its evaluation, out of the scope of this article, are subjects for future research. In [25] we compare our model to a set of CQL event queries.

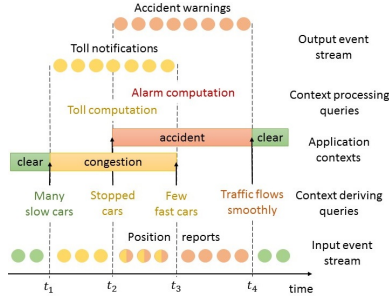

Figure 2: Key concepts of the CAESAR model

2. PRELIMINARIES

Time. Time is represented by a linearly ordered set of time points (\mathbb{T}, \leq) , where $\mathbb{T} \subseteq \mathbb{Q}^+$ and \mathbb{Q}^+ denotes the set of non-negative rational numbers. The set of time intervals is $\mathbb{TI} = \{[start, end] \mid start \in \mathbb{T}, end \in \mathbb{T}, start \leq end\}$. For a time point $t \in \mathbb{T}$ and an interval $w \in \mathbb{TI}$ we say that t is within w , denoted $t \sqsubseteq w$, if $w.start \leq t \leq w.end$.

Event. An event is a message indicating that something of interest happens in the real world. Each event e belongs to a particular event type E , denoted $e.type = E$. An event type E is defined by a schema which specifies the set of event attributes and the domains of their values. An event e has an occurrence time $e.time \in \mathbb{T}$ assigned by the event source. For example, a vehicle position report in [9] has the following attributes: expressway, direction, segment, car identifier etc. The values of these attributes are integers.

Event Stream. Events can be simple or complex. Simple events are sent by event producers (e.g., sensors) to event consumers (e.g., a traffic control center) on an input event stream I to be processed to derive higher-level complex events. The occurrence time of a complex event comprises the occurrence time of all events it was derived from [23].

3. CAESAR MODEL

3.1 Key Concepts of the CAESAR Model

Application contexts are real-world higher-order situations the duration of which is not known at their detection time and potentially unbounded. This differentiates contexts from events. The duration of a context is called a *context window*. For example, *congestion* is a higher-order situation in the traffic control application (Figure 2). Its bounds are detected based on position reports sent from cars in the same road segment in the same time period. As long as a road segment remains congested, the context window *congestion* is said to hold. Hence, the duration of a context window cannot be predetermined.

Context deriving queries associated with a particular context determine when this context should be terminated and when a particular other context is to be initiated based on events. For example, two context transitions are possible from the *congestion* context. If the number of cars reduces and they start moving at higher speed the system transitions into the *clear* context. If two cars stop in the same location and at the same time the *accident* context is activated.

Context processing queries correspond to the workload associated with a particular context, i.e., the analytics to be computed based on events received while the system remains in this context. For example, cars entering a con-

gested road segment are charged toll to discourage drivers from driving during rush hours.

3.2 Benefits of Context-Awareness Property

Event Query Relevance. At each point of time, a context window re-targets all efforts of the system to the current situation by activating only those event queries (both context deriving and context processing queries) which belong to one of the currently active application contexts. All other event queries are suspended as they are irrelevant within the current contexts. This saves both CPU and memory resources. For example, toll is charged only during *congestion* on a road. This query is neither relevant in the *clear* nor in the *accident* contexts. Thus, it is evaluated only during *congestion* and suspended in all other contexts.

Event Query Simplification. The concept of an application context provides event queries with *situational knowledge* that allows us to specify simpler event queries. For example, if the event query computing toll is evaluated only during the *congestion* context, the complex conditions that determine that there is a traffic jam on the road are already implied by the context. Thus, there is no need to repeatedly double-check them in each of the active workload queries.

Context Derivation. The task of context derivation is the dedicated responsibility of the context deriving queries. For example, once too many slow cars in a road segment are detected, the context *congestion* is activated. Thereafter, the query detecting *congestion* is no longer evaluated. Also, all event queries that are evaluated during *congestion* leverage the insight detected by the context deriving query rather than re-evaluating the *congestion* condition over and over at each individual event query level.

3.3 Context Window

Definition 1. (Context type and Context window.)

A context type is defined by a name c and a workload of context deriving queries Q_d^c and context processing queries Q_p^c which are appropriate in this context.

Let C be the set of context types. Then, a context window w_c is defined by a type $c \in C$ and a duration $(t_i, t_t] \in \mathbb{TI}$ where t_i is the time point when a query $q_i \in Q_d^c$ matched the event stream and thus w_c got initiated and t_t is the time point when a query $q_t \in Q_p^c$ matched the event stream and thus w_c got terminated where $c' \in C$.

Context windows of different types may overlap. Indeed, there can be a *congestion* and an *accident* in the same road segment at the same time such that two sets of event queries handling both situations must be executed concurrently.

Definition 2. (Context window relationships.) Context windows of type c_1 and c_2 are guaranteed to overlap if based on the predicates of the respective context deriving queries it can be determined that for each window of type c_1 there is a window of type c_2 with $w_{c_1}.start \sqsubseteq w_{c_2}$. If in addition $w_{c_1}.end \sqsubseteq w_{c_2}$ can be determined, a window of type c_1 is contained in a window of type c_2 .

In general, the predicates of the context deriving queries can be analyzed to determine if they imply such conditions. For example, Figure 7 shows the predicates that determine the bounds of the context windows w_{c_1} and w_{c_2} . It is easy

to conclude that the windows overlap. CAESAR employs established approaches for predicate subsumption [14].

The same event query can be appropriate in several different application contexts. For example, accident detection happens in both the *clear* and the *congestion* contexts. In contrast to that, the event query detecting accident clearance is executed only in the *accident* context.

For simplicity, we have made two assumptions: (1) Event queries associated with different contexts are independent, meaning that they do not produce events that are consumed by event queries in other contexts. (2) Only one context window of the same type can hold at a time per road segment. If there are multiple accidents in a road segment the context window *accident* holds until all of them are cleared.

3.4 Context-aware Event Queries

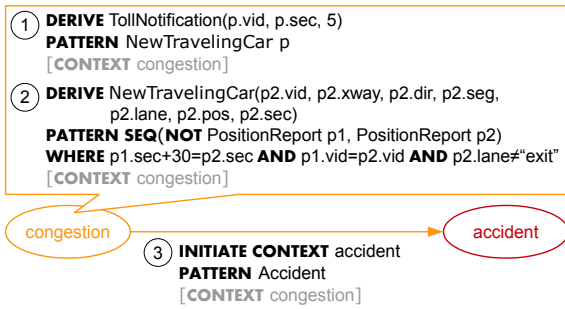

Figure 3: Context-aware event queries

The two application contexts, *congestion* and *accident*, are shown in Figure 3. Different event queries are appropriate within them. For compactness, only three of them within the *congestion* context are shown. Clauses in square brackets are optional since they are implied by the model. The CAESAR event query language grammar is defined in Figure 4.

Definition 3. (Context-aware event queries.)

A context-aware event query consists of several clauses. Each clause performs one of the following tasks:

- Context initiation (INITIATE CONTEXT clause).
- Context switch (SWITCH CONTEXT clause).
- Context termination (TERMINATE CONTEXT clause).
- Complex event derivation (DERIVE clause).
- Event pattern matching (PATTERN clause).
- Event filtering (WHERE clause).
- Context window specification (CONTEXT clause).

Context deriving queries perform three actions: (1) initiate a new context window w_c , (2) terminate an existing context window w_c , or (3) switch from the current context window w_{c_1} into a new context window w_{c_2} .

Context initiation and termination can be used to express overlapping context windows. For example, *accident* and *congestion* may overlap. That is, query 3 initiates the context window *accident* when an accident is detected (Figure 3). However, query 3 does not terminate the context window *congestion*. The event queries that detect accidents are not shown for compactness.

In contrast, context switch expresses a sequence of two non-overlapping context windows. It corresponds to the termination of the previous context window w_{c_1} and the initiation of the new context window w_{c_2} . For example, the *clear* context overlaps neither *accident* nor *congestion* contexts.

Context processing queries analyze the stream of simple or complex events to derive higher-level knowledge in form of complex events. For example, query 2 detects the cars entering a congested road segment. These are vehicles which are not on an exit lane and for which there is no previous position report from the same road segment within 30 seconds. Query 1 derives toll notifications for such vehicles.

Both context deriving and context processing queries consume events that arrive during the context windows that these queries are associated with. Hence, both types of queries utilize event pattern matching and event filtering clauses which are commonly used in event queries [34, 23]. Section 4.1 defines when these clauses match.

```

Query      := <Window> | <Retrieval>
Window     := (INITIATE | SWITCH | TERMINATE)
              CONTEXT Context
Retrieval  := <Derive> <Pattern> <Where>? <Context>
Derive     := DERIVE EventType ((Var.)? Attr, ?)+
Pattern    := PATTERN <Patt>
Where      := WHERE <Expr>
Context    := CONTEXT (Context, ?)+
Patt       := NOT? EventType Var? | SEQ( <Patt>, ?)+
Expr       := Constant | Attr | <Expr> <Op> <Expr>
Op         := + | - | / | * | % | = | ≠ | > | ≥ | < | ≤ | AND | OR

```

Figure 4: CAESAR event query language grammar

Putting the application contexts, transitions between them (Definitions 1 and 2) and context-aware event queries (Definition 3) together, we now define the CAESAR model.

Definition 4. (CAESAR model.) A CAESAR model is a tuple (I, O, C, c_d) where I and O are unbounded input and output event streams and C is a finite set of context types with the default context type $c_d \in C$.

While the goal of classical automata is to define a language, the CAESAR model is designed for context-aware event query execution. Thus, final contexts are omitted. The CAESAR model has a default context that holds when no other context does, e.g., at the system startup (the *clear* context in our example). The runtime processing of the model is defined in Section 4.1.

4. CAESAR ALGEBRA

The CAESAR model explicitly supports application contexts and the transition network to facilitate context-aware event query specification (Figure 3). However, at execution level an algebraic query plan tends to be easier to optimize than an automaton-based model [30].³ We thus define the CAESAR algebra and the translation rules of the CAESAR model into an algebraic query plan.

4.1 CAESAR Operators

The CAESAR algebra consists of six operators. While event pattern, filter and projection are quite common for other stream algebras [30], [34], context initiation, termination and context window are unique operators of the CAESAR algebra. Context initiation and termination consume a stream I of events produced by other operators of the context deriving queries and the set of current context windows

³There are approaches to optimization and distribution of simpler automata than the CAESAR model however. We describe them in detail in Section 8.

W . They update the set of the current context windows and return the updated set.

Context initiation Cl_c starts a new context window w_c , adds it to the set of current context windows and removes the default context window w_{cd} from the set, if there.
 $Cl_c(I, W) := \{W' \mid \text{If } w_c \in W \text{ then } W' = W. \text{ Otherwise } W' = W \cup w_c \text{ and if } w_{cd} \in W \text{ then } W' = W' / w_{cd} \text{ where } e \in I \text{ and } e.time = w_{cd}.end = w_c.start\}$.

Context termination CT_c ends the context window w_c , removes it from the set of current context windows, if the set becomes empty adds the default context window w_{cd} to it.
 $CT_c(I, W) := \{W' \mid \text{If } |W| > 1 \text{ then } W' = W / w_c \text{ else } W' = \{w_{cd}\} \text{ where } e \in I \text{ and } e.time = w_c.end = w_{cd}.start\}$.

Context window CW_c consumes an event stream I and the set of all current context windows W and returns the stream of events that occur during the current context window w_c .
 $CW_c(I, W) := \{e \mid w_c \in W, e \in I, e.time \sqsubseteq w_c\}$.

Filter Fl_θ with a predicate θ consumes an event stream I and returns a stream composed of all events that satisfy θ .
 $Fl_\theta(I) := \{e \mid e \in I, e \text{ satisfies } \theta\}$.

Projection $PR_{A,E}$ with a set of attributes A and an event type E consumes an event stream I , restricts each input event to the set of attributes A and returns the stream of these restricted events of type E .

$PR_{A,E}(I) := \{e \mid e.type = E, e' \in I, e.a = e'.a \text{ for } a \in A\}$.

Pattern P consumes an event stream I and constructs event sequences matched by the pattern P . For each event sequence, the operator outputs an event consisting of the attribute values of all events in the sequence. Let A be the set of all attributes of events of types E_1, \dots, E_n and $1 \leq i \leq n$. The pattern P is one of the following:

1) Event matching E returns input events of type E .

$E(I) := \{e \mid e \in I, e.type = E\}$.

2) Sequence without negation $SEQ_{(E_1, \dots, E_n)}$ constructs sequences of n events such that an i^{th} event is of type E_i .

$SEQ_{(E_1, \dots, E_n)}(I) := \{e \mid e_1, \dots, e_n \in I, e_1.type = E_1, \dots, e_n.type = E_n, e_1.time < \dots < e_n.time, e.a = e_i.a \text{ for } a \in A, e.time = [e_1.time, e_n.time]\}$.

3) Sequence with negation $SEQ_{(S_1, \text{NOT } E, S_2)}$ constructs event sequences SEQ_{S_1, S_2} without negation such that there is no event of type E between the sub-sequences constructed by SEQ_{S_1} and SEQ_{S_2} .

$SEQ_{(S_1, \text{NOT } E, S_2)}(I) := \{e \mid e_1, \dots, e_m \in SEQ_{S_1}, e_{m+1}, \dots, e_n \in SEQ_{S_2}, \nexists e' \in I \text{ with } e'.type = E, e_m.time < e'.time < e_{m+1}.time, e.a = e_i.a \text{ for } a \in A, e.time = [e_1.time, e_n.time]\}$.

A negated event can start or end an event sequence. In this case, temporal constraints must define the time interval within which the negated event may not occur [34].

4.2 Context-preserving Plan Generation

At compile time, the CAESAR model (Figure 3) is translated into an executable query plan that is then input to the CAESAR optimizer (Section 5). The CAESAR model translation happens in two phases (Figure 5). They are:

Phase 1: CAESAR model to a query set. First, the model is translated into a machine-readable query set. During this phase, contexts that are implied by the CAESAR model (the optional clauses in square brackets in Figure 3) become mandatory clauses of the CAESAR event queries. As a result, an event query that belongs to a context c has a mandatory clause **CONTEXT** c . For example, all queries in Figure 5 explicitly specify the context they belong to.

Phase 2: Query set to a combined query plan. Dur-

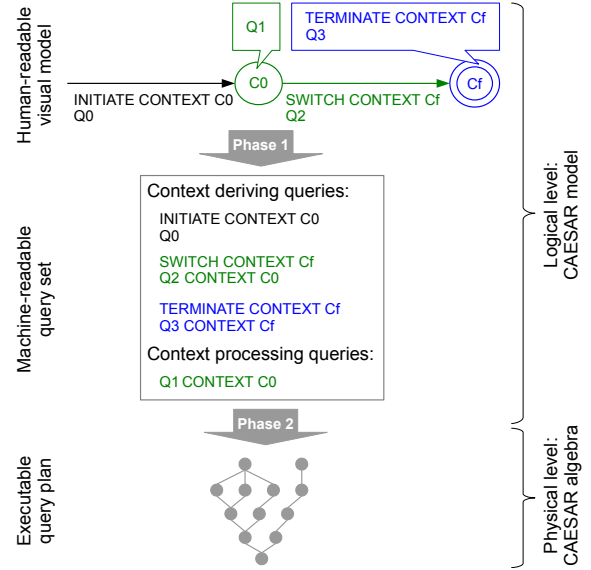

Figure 5: CAESAR model translation

Event query clause	Operator
INITIATE CONTEXT c	Cl_c
SWITCH CONTEXT c	Cl_c, CT_{curr}
TERMINATE CONTEXT c	CT_c
DERIVE $E(A)$	$PR_{A,E}$
PATTERN P	P
WHERE θ	Fl_θ
CONTEXT c	CW_c

Table 1: Individual query plan construction

ing this phase, the machine-readable query set is translated into an executable query plan. This happens in two steps:

1) *Individual query plan construction.* Each event query is translated into a sequence of algebra operators such that each clause of the query corresponds to a set of operators as defined in Table 1. *curr* denotes the current context the context deriving query is associated with.

2) *Combined query plan construction.* Individual query plans are composed into a combined query plan such that if one query plan produces events which are consumed by another query plan then the output of the first plan is the input of the second plan. Since event queries in different contexts are independent (Section 3.3), all event queries in a combined query plan belong to the same context.

For example, queries 1 and 2 in Figure 3 are translated into the combined query plan in Figure 6(a). Query 1 is translated into the individual query plan consisting of operators 1–4. Query 2 corresponds to the individual query plan composed of operators 5–7. Since the first query plan produces complex events consumed by the second query plan, they are composed into a single combined query plan.

5. CAESAR OPTIMIZATION

5.1 CAESAR Optimization Problem Statement

Definition 5. Given a workload of context-aware event queries where each query is associated with an application

context. Our CAESAR optimization problem is to find an optimized query plan for all queries such that the CPU costs are minimized by suspending event queries that are irrelevant to the current application contexts and sharing the workload of overlapping context windows.

To avoid reinventing the wheel, we borrow the CPU cost estimation of event pattern construction from [24], and thus do not repeat here. Instead, we now discuss the cost of the context-specific operators. We maintain the information about current context windows in the *context bit vector* W with one bit for each context type. Since the number of possible context types for an application is predefined and constant, the size of the vector is also constant. The context initiation and termination operators update one bit and the time stamp of the context bit vector. Context windows look up one value in the vector to determine whether a context window of a certain type currently holds. In other words, the CPU cost of these operators is constant. Section 6 provides further implementation details.

5.2 Context Window Push Down

Since some operators of the CAESAR algebra are similar to other stream algebras, existing approaches, from operator reordering [24] to operator merging [30, 6], can be exploited by the CAESAR optimizer as well. For example, projections and filters can be executed in any order assuming that a projection that is pushed down below a filter discards no attributes accessed by the filter. Adjacent filters can be merged into a single filter by combining their predicates. However, these existing techniques are oblivious to the notion of contexts, and consequently do not avoid superfluous computations in the current contexts.

To avoid unnecessary computations when event queries are executed “out” of their respective context windows, we introduce the context window push-down strategy. Context window push-down can prevent the continuous execution of operators in the query plan. In other words, no event will be passed up by the context window operator if the current event stream does not qualify for the context window.

For instance, the two bottom most operators in Figure 6(a) are always executed regardless of the application contexts. Once the context window is pushed down to the bottom in Figure 6(b), it avoids the execution of all operators higher in the plan when they are irrelevant to the current contexts.

All event queries in a combined query plan belong to the same context (Section 4.2). By definition, a context window specifies the scope of its queries. Thus, pushing a context window down does not change the semantics of its queries. That is, context window push down strategy is correct.

Pushing a context window down seems similar to pushing a predicate or a traditional window down only at first sight. Differences are twofold:

- 1) Context windows *suspend* the entire query plan “above them” as long as the application is in different contexts. In contrast to that, a predicate or a traditional window is a filter on a stream that selects certain events to be passed through. It does not control the suspension of the above operators and keeps them in *busy waiting* state that wastes valuable resources and degrades system performance.
- 2) Our context-driven stream router directs *event stream portions during application contexts* to the appropriate event queries (Section 6.2). In contrast to that, predicates and traditional time constraints (e.g., event sequence within 4

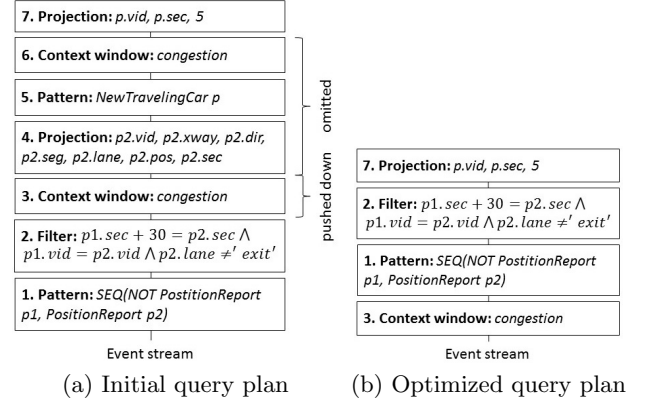

Figure 6: Query plans

hours [34]) typically filter events one by one at the *individual event level*. This is a resource consuming slow process.

Theorem 1 proves that pushing a context window down in a combined query plan leads to lower execution costs than placing it at any other position in the query plan.

THEOREM 1. *Given a query q , let P be the set of all possible query plans for q , $p \in P$ be a query plan for q and $cost(p)$ be the cost of executing the plan p . With the context window pushed down, the new plan, denoted by p' , has cost $cost(p')$. Then $\forall p \in P, p \neq p', cost(p') \leq cost(p)$.*

PROOF. As described in Section 5.1, the cost of the context window operator is constant. That is, it adds constant cost to the overall execution costs of a query plan no matter its position in the query plan. The context window operator completely suspends the execution of all upstream operators while the context is not active. In that case, the cost of a query plan is reduced, i.e., $cost(p) < cost(p')$. In an unlikely case when the context window happens to be always active, the costs of the query plans p and p' are equal. \square

5.3 Context Workload Sharing

Inspired by traditional multi-query optimization, grouping the event queries enables computation sharing among these queries. We observe the opportunity that substantial computational savings can be achieved by executing only one instance of each context deriving query for each context. Without context window grouping, each context processing query has to run its respective context deriving queries separately so to determine its current context to ensure correct execution. If this context analytics is performed on an individual query level, significant computational resources are wasted and system responsiveness suffers.

Sharing query workloads of overlapping context windows is challenging for the following reasons: (1) The duration of context windows may vary and their bounds are unknown at compile time. So, we have to infer whether context windows overlap. (2) Different contexts may contain identical or similar event queries in their query workloads. How to share query workloads driven by contexts is crucial to achieve high performance execution. We now propose an efficient solution that addresses this problem by splitting and grouping overlapping context windows.

For overlapping context windows, a naive solution would be to merge these context windows to form a larger encompassing context window. Inside this large context window,

we can now analyze the associated event query workloads to optimize their executions. However, such solution could do more harm than good in some cases. For example, if all context windows were to be overlapping, then only one huge all encompassing context window would be formed as a result. This would forfeit the purpose of being context-aware. Consequently, redundant computations would be incurred.

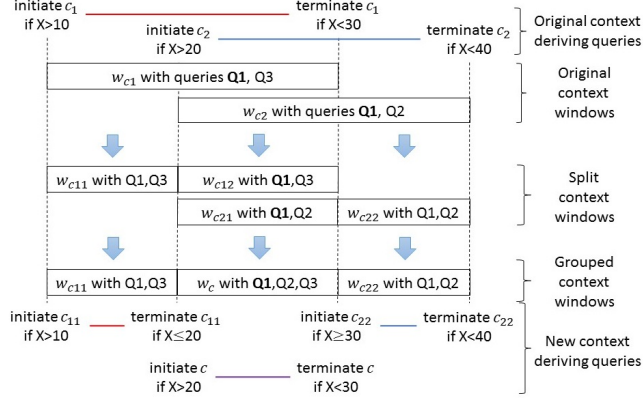

Figure 7: Context Window Grouping

We now propose an effective strategy for splitting the original user-defined *overlapping* context windows into finer granularity context windows and grouping them into *non-overlapping* context windows. For example, the context windows w_{c1} and w_{c2} in Figure 7 overlap. The window w_{c1} is split into w_{11} and w_{12} , while the window w_{c2} is split into w_{21} and w_{22} . Since the windows w_{12} and w_{21} cover the same time interval, the event queries associated with them are merged to form the workload of the *grouped context window* w . The context deriving queries are adjusted accordingly.

```

1 Input: Set  $W$  of user-defined context windows. A window is
   described by start, end and queries.
3 Output: Set  $G$  of grouped context windows
    $G = W.extractNonOverlappingWindows()$ 
5  $W = W.sortByStart()$ 
    $W = W.mergeIdenticalWindows()$ 
7  $Q = \emptyset$ 
   while  $W.hasNextWindowBound()$ 
9      $next = W.getNextWindowBound()$ 
      $S = W.getStartingWindows(next)$ 
      $E = W.getEndingWindows(next)$ 
11    if  $Q.isEmpty()$ 
13        then  $Q = S.queries$ 
     else new window  $w = (previous, next, Q)$ 
15         $G = G \cup w$ 
         $Q = Q - E.queries \cup S.queries$ 
17    end if
      $previous = next$ 
19 end while
for each  $w \in G$ 
21     $w.queries = w.queries.dropDuplicates()$ 
end for each
23 return  $G$ 

```

Listing 1: Context window grouping algorithm

Consider our context window grouping algorithm in Listing 1. It takes a set of user-defined context windows as input. Context windows which do not overlap any other window remain unchanged (line 4). The algorithm sorts the overlapping context windows in increasing order by start time (line 5). Even though the exact start time of context

windows is not known at compile time, the order of their beginning can be determined for overlapping context windows. For example, it is known at compile time that the window w_{c2} in Figure 7 will start at the same time or later than the window w_{c1} . If there are several identical context windows, the algorithm only keeps one by merging the workloads of identical windows (line 6). The core of the algorithm (lines 8-19) forms a new grouped context window for each time interval between two subsequent bounds of original context windows and associates the query workload with it that is appropriate during this time interval. For each grouped context window, the algorithm deletes duplicate event queries (lines 20-22) and returns the set of grouped context windows (line 23). Since several subsequent grouped context windows correspond to one original context window, an event query within a grouped context window may need access to its partial matches in the previous grouped context windows to ensure completeness of its results. In Section 6, we introduce a customized design (called *context history*) to ensure correct grouped context window execution.

The time complexity of the algorithm is $O(n \log(n) * m)$ where n is the number of original user-defined context types that are sorted (line 5) and m is the number of predicates that have to be analyzed while comparing two context types.

Based on the newly produced non-overlapping context windows, we now further exploit traditional multi-query optimization (MQO) techniques [31, 27, 21] to produce an optimized shared query execution plan for each group of event queries. This opens opportunities to share the similar workload within a context which further saves computational costs and reduces query latency. MQO is an NP-Hard problem due to the exponential search space. Thus, the solutions [31, 27, 21] of MQO tend to be expensive.

Our context window grouping solution divides the event query workloads into smaller groups based on their time overlap. Hence, the search space for an optimal query plan within each group is substantially reduced compared to the global space. Any state-of-the-art MQO solution can leverage this idea to return an optimized query plan efficiently.

The search space for multi-query optimization is doubly exponential in the size of the queries (n). The spectrum of possible multi-query groupings ranges from a separate group per each *individual* query (i.e., non-sharing) in the given query workload to a single group for *all queries*. The upper-bound for all possible multi-query groups corresponds to the number of distinct ways of assigning n event queries to one or more groups. The number that describes this value is the Bell number B_n , which represents the number of different groupings of a set of n elements. The Bell number is the sum of Stirling numbers. A Stirling number $S(n, k)$ is the number of ways to partition n elements into k partitions [20]:

$$B_n = \sum_{k=1}^n S(n, k) = \sum_{k=1}^n \left(\frac{1}{k!} \sum_{j=1}^k (-1)^{k-j} \binom{n}{k} j^n \right)$$

By dividing our n queries first into m groups, we subsequently only need to optimize the small shared set one by one and thus reduce the search space to:

$$B'_n = \sum_{k'=1}^{n/m} S(n/m, k') = \sum_{k'=1}^{n/m} \left(\frac{1}{k'!} \sum_{j=1}^{k'} (-1)^{k'-j} \binom{n/m}{k'} j^{n/m} \right)$$

As confirmed by our experimental study in Section 7.2,

the CAESAR optimizer produces a context-aware query plan 2712 times faster than the state-of-the-art context-independent multi-query optimization approaches.

6. CAESAR EXECUTION INFRASTRUCTURE

6.1 Overview of the CAESAR Infrastructure

Figure 8 shows the CAESAR execution infrastructure. The boxes represent the system components.

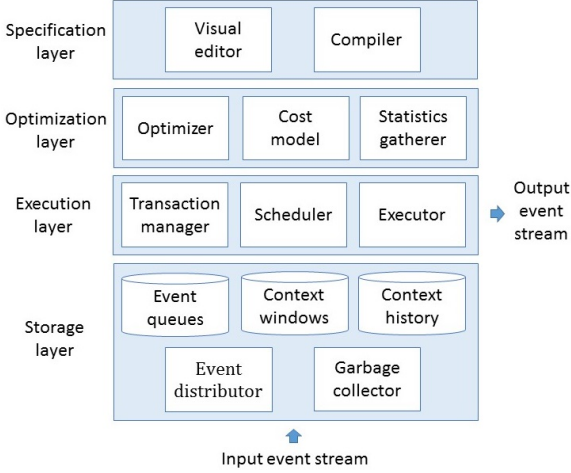

Figure 8: CAESAR infrastructure

Specification Layer. A CAESAR model is specified by the application designer using the visual CAESAR editor [25]. As explained in Section 4, we then translate it into an algebraic query plan.

Optimization Layer. As described in Section 5, the query plan is optimized using several context-aware optimization strategies to produce an execution plan.

Execution Layer. The optimized query plan is forwarded to the transaction manager that forms transactions. These transaction are submitted for execution by the scheduler that guarantees correctness. These components build the core of the CAESAR execution infrastructure. They are described in details in Section 6.2.

Storage Layer. The event distributor buffers the incoming events in the event queues. The current context windows and the context history are compactly maintained in-memory. The garbage collector ensures that only the values which are relevant to the current contexts are kept.

6.2 Core of the CAESAR Infrastructure

The core of the CAESAR execution infrastructure consists of the context derivation, context processing, context-aware stream routing and scheduling of these processes (Figure 9).

Context Derivation. For each stream partition (unidirectional road segment in the traffic management use case), we save which context windows currently hold in the context bit vector W . This vector W has a time stamp $W.time$ and a one-bit entry for each context type, i.e., $W.size = |C|$. The entries are sorted alphabetically by context names to allow for constant time access. The entry 1 (0) for a context c means that the context window w_c holds (does not hold) at the time $W.time$. Since context windows may overlap, multiple entries in the vector may be set to 1.

The context window vector is updated by the context deriving queries. Since *each* event in the stream can potentially

Figure 9: Core of the CAESAR infrastructure

update a context window, the context deriving queries processes all input events. $W.time$ is the application time when the vector W was last updated. Since events arrive in-order by time stamps, only one most recent version of the context bit vector is kept.

Context-aware Stream Routing. Based on the context window vector, the system is aware of the currently active event query workloads. For each current context window w_c , it routes all its events to the query plan associated with the context c . Query plans of all currently inactive context windows do not receive any input. They are suspended to avoid busy waiting, i.e., waste of resources.

Context-aware stream routing is a light-weight process for the following reasons. First, the lookup of all vector entries set to 1 takes constant time. Second, this routing happens for stream batches (multiple subsequent events in the input event stream) rather than for single events.

Context Processing. The CAESAR model allows the application designer to specify the *scope* of event queries in terms of their context windows. When a user-defined context window ends, all event queries associated with it are suspended and thus will not produce new matches until they become activated again. Therefore, their partial matches, called *context history*, can be safely discarded.

When a user-defined context window w_c with its associated query workload Q^c is split into smaller non-overlapping context windows w_{c_1} and w_{c_2} partial matches of the queries Q^c are maintained across these newly grouped windows w_{c_1} and w_{c_2} to ensure correctness of these queries Q^c . Therefore, for each event query we save the grouped context windows across which the results of the query are kept. For example, the event query q_1 in Figure 7 is executed during all 3 grouped context windows. However, when the third window begins, the partial results within the first window expire.

Correct Context Management. Context processing queries are dependent on the results of context deriving queries. Due to bursty input streams, network and processing delays context derivation might not happen on time. To avoid race conditions, these inter-dependencies must be taken into account to guarantee correct execution.

We define a *stream transaction* as a sequence of operations that are triggered by all input events with the same time stamp. The application time stamp of a transaction (and all its operations) coincides with the application time stamp of the triggering events. An algorithm for scheduling read and write operations on the shared context data is *correct* if conflicting operations⁴ are processed sorted by time stamps.

⁴Two operations on the same value such that at least one of

While existing transaction schedulers can be deployed in the CAESAR system, we now describe a time-driven scheduler. For each time stamp t , our scheduler waits till the event distributor progress is larger than t and the context derivation for all transactions with time stamps smaller than t is completed. Then, the scheduler extracts all events with the time stamp t from the event queues, wraps their processing into transactions (one transaction per road segment for the traffic control use case) and submits them for execution.

7. PERFORMANCE EVALUATION

7.1 Experimental Setup and Methodology

Experimental Infrastructure. We have implemented our CAESAR system in Java with JRE 1.7.0_25 running on Linux CentOS release 6.3 with 16-core 3.4GHz QEMU Virtual CPU and 48GB of RAM. We execute each experiment three times and report their average results here.

Linear Road Benchmark. We have chosen this benchmark [9] to evaluate the effectiveness of the CAESAR system for the following reasons: (1) it expresses a variety of application contexts such that the system reactions to an event depends on the current context, and (2) it is time critical since it poses tight latency constraint of 5 seconds.

Event Queries. We focused on a subset of event queries of the benchmark that based on input events derive toll notifications and accident warnings. The queries depicted in Figure 3 are simplified versions of the actual benchmark queries to illustrate the key concepts of our model in the paper only. We simulate low, average and high query workloads by replicating the event queries of the benchmark.

(a) Events per road segment (b) Events per minute

Figure 10: Event streams

Event Streams. Event distribution across road segments varies. Figure 10(a) shows the number of processed and derived events per segment of a randomly chosen unidirectional road⁷. There are more cars in some road segments than in others. In some road segments accidents and traffic jams happen more often than in others. Hence, more toll notifications and accident warnings are triggered for them.

Event distribution across time also varies. Event rate gradually increases during 3 hours of an experiment. Figure 10(b) shows the number of processed and derived events per minute by for a randomly chosen unidirectional road segment⁷ and visualizes the application contexts. Accident warnings are derived only during accidents (minutes 30-50). The benchmark requires zero toll derivation during accidents and clear road conditions (minutes 0-70). During traffic jams, real toll is computed (minutes 70-180).

Real Data Set. In addition to the benchmark, we evaluate our system using the physical activity monitoring real them is a write are called conflicting operations.

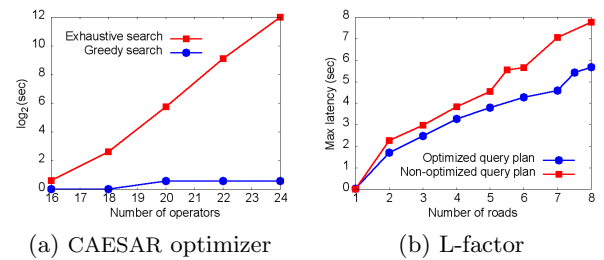

⁷We have observed a similar event distribution for other roads and roads segments.

data set (1.6GB) [26]. It contains physical activity reports from 14 people during 1 hour 15 minutes.

Metrics. We measure two metrics common for stream systems, namely *maximal latency* and *scalability*. Additionally, we measure the *win ratio* of context-aware over context independent event stream analytics in terms of CPU processing time. *Maximal latency* is the maximal time interval elapsed from the event arrival time (i.e., system time when a position report is generated) till the complex event derivation time (i.e., system time when a toll notification or an accident warning is derived based on this position report). As mentioned above, the benchmark restricts the query latency to be within 5 seconds. The *system scalability* is determined by the *L-factor*, the maximal number of roads that are processed without violating this constraint. The *win ratio* of context-aware over context-independent event stream analytics is computed as the maximal latency of context-independent processing divided by the maximal latency of context-aware processing of the same event query workload against the same input event stream.

Methodology. To show the efficiency of our context-aware query optimization, we compare it to the exhaustive search approach by varying the number of operators in a query plan. To measure the effectiveness of our optimized context-aware query plan, we compare the performance of our context-aware query execution plan to the state-of-the-art solution [34, 5]. To demonstrate the effectiveness of our context-aware workload sharing technique, we compare it to our default non-sharing solution. We conduct these comparisons by varying the following parameters: number of operators in a query plan, input event stream rate, number of event queries, data distribution in a context window, length of a context window, number of context windows, number of overlapping context windows, overlapping ratio of context windows, and the shared workload size. Since context windows are derived from the input events, context window related parameters can be varied only through input data manipulation. Thus, for the experiments on real data set we vary the number of event queries.

7.2 Efficiency of CAESAR Optimizer

(a) CAESAR optimizer

(b) L-factor

Figure 11: CAESAR Optimization Techniques

In Figure 11(a), we vary the number of operators in a query plan and measure the CPU time required for the query plan search (logarithmic scale on Y-axis). We compare the context-independent (CI) exhaustive to the context-aware (CA) greedy query plan search. As confirmed by the search space analysis (Section 5.3), the processing time of the exhaustive search grows exponentially with the number of operators in a query plan. In contrast, the CPU time required for our context-aware search stays fairly constant while varying the query plan size. At size 24, CAESAR's optimizer is 2712-fold faster than the exhaustive search. This is due to

the fact that our context window push down and context grouping techniques substantially reduce the search space.

7.3 Efficiency of CAESAR Runtime

Next, we conduct a comprehensive evaluation to demonstrate the efficiency of our CAESAR solution. The baseline approach is the context-independent processing commonly used in most state-of-the-art solutions [34, 5, 32]. We first demonstrate the superiority of our CAESAR’s context-aware event processing compared to the state-of-the-art context-independent approach by strictly following the constraints of the benchmark. Then we evaluate the CAESAR’s context window sharing technique.

7.3.1 Efficiency of Context-Aware Stream Analytics

L-factor. In Figure 11(b), we vary the input stream rate by increasing the number of roads and measure the maximal latency. We compare the latency of the optimized versus non-optimized query plan. As the figure shows, the optimized query plan processes at most 7 roads without violating the latency constraint of 5 seconds. In contrast, the non-optimized query plan can process at most 5 roads under this constraint. Intuitively, our context-aware optimization approach successfully avoids the unnecessary computations by executing different queries only at appropriate time periods (contexts). On the other hand, the state-of-the-art solution suffers from executing all queries all the time.

Next, we compare continuous context-independent stream processing to context-aware solution when some of the involved event query workloads are appropriate only in certain critical contexts and can be suspended in other contexts. Unless stated otherwise, in Figures 12 and 13, we consider 3 roads (1.7GB) and assume that 2 critical non-overlapping context windows of length 3 minutes process 10 event queries each. These queries can be suspended in other contexts.

Evaluating diverse context window distributions. In Figure 13, we vary the number of event queries per context window and measure the maximal latency. We compare three setups, namely, uniform context window distribution versus their Poisson distribution with positive skew (λ is the first second) and with negative skew (λ is the last second). Context window bounds vary across different window distributions. The rest of the stream is identical for these setups.

As expected, when the context windows are at the end of the experiment where the stream rate is high, the maximal latency remains almost constant with the growing event query workload. This is explained by the fact that most queries are irrelevant for these contexts and thus are suspended. In contrast, if these windows are uniformly distributed or are at the beginning of the experiment when the stream rate is low, the maximal latency grows linearly with the number of queries. The maximal latency of 20 event queries with uniform context window distribution is 1.8-fold faster than with Poisson distribution with positive skew and 11-fold slower than with Poisson distribution with negative skew. Thus, to achieve fair results we consider uniform context window distribution in all following experiments.

Scaling event query workload. In Figure 12(a), we vary the number of event queries per context window and measure the maximal latency of context-aware versus context-independent event stream processing. The maximal latency grows linearly in the number of event queries. For an average workload of 10 event queries, we find that the context-aware

processing is 8-fold faster than the context-independent solution using the Linear Road benchmark data (LR). CAESAR achieves the same win using the Physical Activity Monitoring data set (PAM) and 20 event queries. Our system has a clear win in this case because the context-aware event stream analytics suspends those event queries which are irrelevant to the current context.

Varying event stream rates. In Figure 12(b), we vary the number of considered roads. We measure the maximal latency of context-aware versus context-independent processing. The maximal latency grows linearly with an increasing input stream rate (number of roads). For 7 roads, context-aware processing is 9-fold faster than the context independent solution. The results show that the CAESAR system is more robust to the event stream rate increase compared to the context-independent solution.

Varying context window lengths. In Figure 12(c), we vary the length of the context windows and measure the win ratio of the context-aware over context-independent processing. The numbers above the bars indicate the percentage of the input event stream covered by the context windows that allow suspension of complex event query workload. Given that CAESAR only keeps one context active at a time, the win ratio exceeds 3 if such context windows cover more than 80% of the stream. It becomes negligible (almost 1) when they cover less than 50% of the input event stream.

Varying the number of context windows. A similar trend can be observed while varying the number of context windows that allow suspension of irrelevant event queries (Figure 12(d)). Again, we measure the win ratio of the context-aware over context-independent stream processing. The numbers above the bars indicate the percentage of the input event stream covered by the context windows. Similarly, the win ratio exceeds 2 if the context windows cover more than 80% of the input event stream. It becomes negligible (almost 1) when they cover less than 50%.

7.3.2 Efficiency of Context-Aware Workload Sharing

Next, we measure the effect of the shared workload processing of overlapping context windows (Figure 14). Unless stated otherwise, 30 windows of length 15 minutes each overlap by 10 minutes. Each of them processes 4 event queries.

Varying the number of overlapping context windows. In Figure 14(a), we vary the maximal number of overlapping context windows and measure the maximal latency of shared versus non-shared query processing. As expected, the larger the number of overlapping context windows are the more significant is the gain of the event query sharing. If 45 context windows overlap, the workload sharing strategy outperforms the default non-shared solution by factor of 10. The reason is that the CAESAR context window grouping technique exploits the sharing opportunities within overlapping context windows at a fine granularity level by splitting the overlapping context windows into non-overlapping parts and sharing event query processing within them.

Varying the length of context window overlap. In Figure 14(b), we vary the minimal length of context window overlap and measure the maximal latency of shared versus non-shared workload execution. The gain of sharing grows linearly with the length of overlap. If 30 context windows overlap by 15 minutes, our workload sharing strategy performs 6-fold faster than the non-shared solution. This is due to the fact that similar workloads can be shared for a longer

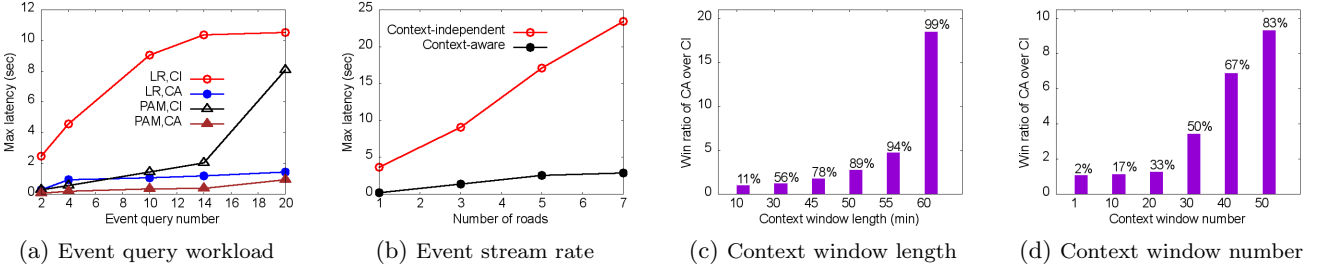

Figure 12: Context-aware event stream analytics

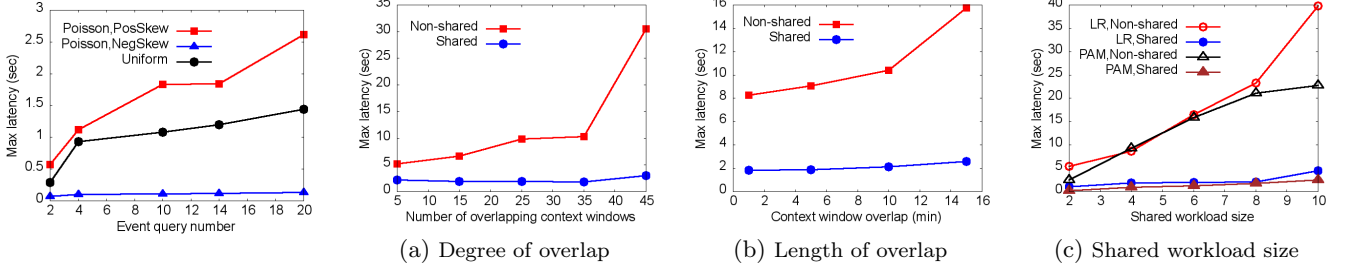

Figure 13: Context window distribution

Figure 14: Shared workload of overlapping context windows

time period, and hence more computational savings can be harvested from the overlapping part of the context windows.

Shared workload size. In Figure 14(c), we vary the number of event queries per context window and measure the maximal latency of shared versus non-shared event query processing. As expected, the more event queries can be shared the more significant is the gain of the event query sharing. If each context window contains 10 queries that can be shared with other context windows, the workload sharing strategy outperforms the default non-shared solution by factor of 9 using the Linear Road benchmark data (LR). A similar trend can be observed with the Physical Activity Monitoring data set (PAM).

8. RELATED WORK

Context-aware Event Stream Models [11, 33] propose a fuzzy ontology to support uncertainty in event queries. Context-aware event queries are rewritten into context-independent and processed in parallel on different stream partitions. Isoyama et al. [18] propose to allocate event queries to event processors so that the state of event processing (i.e., intermediate event query results) is efficiently managed. These ideas are orthogonal to our optimization techniques.

Hermosillo et al. [17] and Proton software prototype [1] feature a model similar to the CAESAR model. However, these approaches lack a formal definition of the event language, optimization techniques and experimental evaluation. The recent emergence of these approaches confirms the importance of the notion of context-aware event queries that has been formally defined by us in [25]. Our current work on CAESAR now is completed by the context-aware optimization strategies and their experimental evaluation.

Event Stream Processing Automata [34, 5, 13] continuously evaluate the *same* set of *single* event queries using traditional windows of *fixed* length. These automata capture single query processing states. Their runs corre-

spond to independent event query instances. In contrast to that, the CAESAR model expresses the semantics of the *whole stream-based application* rather than single isolated event queries. Our model captures application contexts of variable, statically unknown duration. Its runs correspond to interdependent processes traveling through application contexts, triggering appropriate context-aware event queries and incrementally maintaining their results.

Event Query Languages, like CQL [10] and SASE [5, 34], lack explicit support of application contexts. These contexts could possibly be hard-coded by queries deriving events that mark context bounds. However, this approach is cumbersome and error prone. It is neither modular nor human-readable. It requires tedious specification of multiple complex event queries – placing an unnecessary burden on the designer [25]. Inter-dependencies between context deriving and context processing queries would have to be taken into account to avoid re-computations, waste of valuable resources, delayed responsiveness and even incorrect results. Special optimization techniques would have to be developed to enable the benefits of context-awareness – as accomplished by our approach (Section 3.2). Furthermore, workload sharing among overlapping context windows has not been addressed in prior research.

Event Query Optimization Techniques [29] are often based on stream algebras [30, 34, 12]. Operators of these stream algebras work on *events*. In these approaches, *application contexts* are not supported as first-class citizens and thus they are not available for the operators. Hence, these approaches miss the event query optimization opportunities enabled by context-aware stream processing. Application contexts are first class citizens in our CAESAR model. They enable context-aware optimization techniques (Section 5).

Business Process Models [16, 28] explicitly support application contexts in a readable manner and allow to specify context-aware system reactions. However, these models target business process specification. They were not designed

for CEP and neglect its peculiarities. In particular, the event-driven nature of streaming applications and the importance of temporal aspect are not given enough attention. Indeed, context transitions in these models are triggered by conditions and process flow rather than by events [19]. Temporal constraints are specified on clocks rather than on event time stamps [7]. These models do not derive higher level knowledge in form of complex events.

9. CONCLUSIONS

The responsiveness of time-critical decision-making event stream processing applications can be substantially speed-up by evaluating only those event queries which are relevant to the current situation. Inspired by this observation, we propose the first context-aware event stream processing solution, called CAESAR, which is composed of the following key components: (1) To allow for human-readable context-aware event query specification, we propose the CAESAR model that visually captures the application contexts and allows the designer to associate appropriate event queries with each context. (2) To achieve prompt system responsiveness, the model is translated into a query plan composed of the context-aware operators of the CAESAR algebra we propose. This algebra serves as a foundation for the CAESAR optimizer that suspends those event queries which are irrelevant to the current application context and detects workload sharing opportunities of overlapping contexts. (3) We built the CAESAR runtime execution infrastructure that guarantees correct and efficient execution of inter-dependent context deriving and context processing queries. The context-aware processing is shown to perform 8-fold faster on average than the context-independent solution when using the Linear Road stream benchmark and real world data sets.

ABSTRACT

The preservation of privacy when publishing spatiotemporal traces of mobile humans is a field that is receiving growing attention. However, while more and more services offer personalized privacy options to their users, few trajectory anonymization algorithms are able to handle personalization effectively, without incurring unnecessary information distortion. In this paper, we study the problem of *Personalized (K,Δ)-anonymity*, which builds upon the model of (k, δ) -anonymity, while allowing users to have their own individual privacy and service quality requirements. First, we propose efficient modifications to state-of-the-art (k, δ) -anonymization algorithms by introducing a novel technique built upon users' personalized privacy settings. This way, we avoid over-anonymization and we decrease information distortion. In addition, we utilize dataset-aware trajectory segmentation in order to further reduce information distortion. We also study the novel problem of *Bounded Personalized (K,Δ)-anonymity*, where the algorithm gets as input an upper bound the information distortion being accepted, and introduce a solution to this problem by editing the (k, δ) requirements of the highest demanding trajectories. Our extensive experimental study over real life trajectories shows the effectiveness of the proposed techniques.

1. INTRODUCTION

With the rapid development of information and communication technologies, the advent of mobile computing and the increasing popularity of location-aware services, the volume of mobility data

gathered daily by service providers has exploded. It is safe to predict that this trend will continue in the near future. Publishing such information allows researchers to analyze humans' trajectories and extract behavioral patterns from them, in order to support decision-making.

However, publishing datasets consisting of humans' trajectories creates threats regarding the privacy of the individuals involved. This occurs when the spatiotemporal traces that users leave behind are combined with other publicly available information, which can reveal their identity, as well as other sensitive information about them (place of residence, sexual orientation, religious or political beliefs, etc.). Thus, it becomes necessary to develop methods providing privacy-preservation in mobility data publishing, where a sanitized version of the original dataset is published while the maximum possible data utility is maintained. A number of anonymization methods have been proposed so far, with most of them adopting the concept of k -anonymity, the fundamental principle which states that every entry of a published database should be indistinguishable from at least $k-1$ other entries. For example, trajectories are grouped into clusters of at least k members and published as cylindrical volumes which 'conceal' the individual trajectories [1][2], points of trajectories are suppressed so that adversaries with partial knowledge of a trajectory cannot identify a specific one amongst at least $k-1$ others [13], and so on.

Figure 1(a) illustrates an example dataset consisting of 5 trajectories, where each trajectory is associated with its own k -anonymity requirement, whereas Figure 1(b) illustrates the anonymization provided by W4M [2], a state-of-the-art (k, δ) -anonymity algorithm, assuming (a universal) $k = 3$ requirement (i.e., the maximum of the particular requirements). Clearly, the result fails to maintain the trend of the original data. However, if we could have taken into account the specific users' privacy preferences (i.e., the different k 's in Figure 1(a)), two clusters instead of one would have been created, as illustrated in Figure 1(c); *this is the first objective of this paper*. Moreover, if we could have performed an appropriate segmentation of trajectories in sub-trajectories before the anonymization process, the distortion would be even less, as illustrated in Figure 1(d); *this is the second objective of this paper*. (In this example, the δ -parameter effect is not discussed but it is similar to that of k .)

Figure 1: (a) a set of five trajectories along with the anonymization result provided by (b) universal k ; (c) personalized k_i ; (d) segmentation and personalized k_i .

As revealed by the previous example, an important drawback of most of the existing anonymization methods is that they are based on universal (e.g. $k = 3$) rather than user-defined privacy requirements. This lack of personalization may lead to unnecessary anonymization and data utility loss for users whose privacy requirements are overvalued and to inadequate anonymization and violation of privacy for users whose requirements are undervalued. Towards this goal, state-of-the-art techniques, such as [1][2] can be extended to use a user-specific privacy threshold k and uncertainty diameter δ . On the other hand [9] offers personalization by introducing trajectory-specific privacy requirements, however it ignores service quality, as it will be discussed in Section 2. In contrast, the method we propose uses trajectory-specific values to determine each user's specific privacy level and service quality requirements, therefore reducing data utility loss and improving service quality.

An additional shortcoming of the existing anonymization methods that are based on clustering is that they function at the trajectory level. As a result, when dealing with trajectories that are on the whole very different to each other, though they maintain some similar parts, these algorithms fail to recognize this situation and either assign such trajectories to different clusters (i.e., k -anonymity sets) or assign them into the same cluster after considerable spatiotemporal translation. This failure to recognize and make use of similarities between parts of trajectories is counter-intuitive and increases the overall distortion. In our proposal, we deal with this problem by utilizing trajectory segmentation in order to discover similar sub-trajectories and use those as the basis of our clustering process.

In this paper, we present the so-called *Who-Cares-about-Others'-Privacy* (WCOP) suite of methods for publishing spatiotemporal trajectory data using personalized (K, Δ) -anonymity, extending the concept of (k, δ) -anonymity as introduced in [1][2], where, for

each user u_i , k_i dictates the required privacy level of the specific user and δ_i functions as a service quality threshold. In addition, we adopt a privacy-aware trajectory segmentation phase, during which trajectories are partitioned into sub-trajectories. This phase allows the clustering algorithm to discover similarities between the trajectories and assign the respective partitions into clusters, the members of which require the least necessary editing to fulfill (K, Δ) -anonymity, thus keeping distortion as low as possible. Finally, we present an approach aiming at controlling the information loss caused by the anonymization. The most *demanding* trajectories, i.e., the ones corresponding to users who require to be hidden among a large number of other users (hence, high k) in a small region (thus, low δ), are edited in order to be made less demanding, thus decreasing anonymization distortion.

Summarizing, in this paper, we make the following contributions:

- We propose WCOP-CT, an algorithm that extends [1][2] for spatiotemporal trajectory data publication based on the assumption that users have different privacy preferences.
- We extend WCOP-CT to WCOP-SA, by incorporating a trajectory segmentation phase aiming to facilitate the discovery of patterns shared between parts of trajectories, thus decreasing the distortion caused during the anonymization process.
- We propose WCOP-B, an algorithm able to control the level of the anonymization distortion by data assessment and requirements relaxation.
- Finally, we conduct a comprehensive set of experiments over a real trajectory dataset, in order to evaluate our approach.

The rest of the paper is structured as follows: Section 2 presents related work. Section 3 formulates the two problems to be addressed: *Personalized (K, Δ) -anonymity* and *Bounded Personalized (K, Δ) -anonymity*, respectively. Sections 4 and 5 provide effective solutions to the above two problems, respectively. Our experimental study is presented in Section 6. Finally, Section 7 concludes the paper.

2. RELATED WORK

The methods proposed so far in order to tackle the issue of privacy-preserving mobility data publishing mostly adopt the principle of k -anonymity, which was originally proposed for relational databases [12]. In the context of mobility data, trajectories of moving objects are time ordered sequences of (p, t) pairs, where p denotes the place a moving object was located at recorded time t , usually assuming linear interpolation between consecutively recorded locations. Such a trajectory dataset is considered k -anonymized if each trajectory is indistinguishable from at least $k-1$ other trajectories. Given the complicated nature of spatiotemporal data and the dependence of consecutive points in a trajectory, attributes (p, t) are considered both sensitive and quasi-identifiers at the same time. Under this setting, methods similar to those used for relational data can be employed to achieve anonymization.

Hoh and Gruteser's method [6] is an example of data perturbation with a goal of decreasing an adversary's certainty of correctly identifying a user. To do that, the so-called Path Perturbation algorithm creates fake intersection points between couples of non-intersecting trajectories if they are close enough. The crossing points must be generated within a specific time-window and within a user-specified radius, which indicates the maximum allowable perturbation and desired degree of privacy. Terrovitis

and Mamoulis [13] proposed an approach that uses suppression. Trajectories are modeled as sequences of locations where users made transactions and an adversary is assumed to have partial knowledge of users' visited locations and their relative order, therefore an incomplete projection of the dataset. Based on this assumption the algorithm seeks to eliminate the minimum amount of locations from trajectories so that the remaining trajectories are k -anonymous w.r.t. an adversary's partial knowledge. Always Walk with Others (AWO) [11] is a generalization-based approach, which transforms trajectories into series of anonymized regions, while assuming adversary's partial or full knowledge of a trajectory. To achieve anonymity, the algorithm creates groups with representative trajectories and then iteratively adds to them their closest trajectories until they consist of k members. After that, k points from each anonymized region are randomly selected and connected to points similarly generated in adjacent regions in order to form k new trajectories. Monreale et al. [10] propose k -anonymization using spatial generalization of trajectories. In particular, their method finds characteristic points of trajectories and applies spatial clustering to them. The centroids of those clusters are then used for Voronoi tessellation of the area covered in the dataset dividing it into cells with at least k trajectories. Trajectories are formed by segments linking those cells.

Never Walk Alone (NWA) [1] and its extension Wait For Me (W4M) [2], proposed by Abul et al., follow a clustering-based approach which takes advantage of the inherent uncertainty of a moving object's location introducing the concept of (k, δ) -anonymity. An object's location at a given time is not a point, but a disk of radius δ , and the object could be anywhere inside that, so a trajectory is not a polyline, but a cylinder consisting of consecutive such disks. To achieve k -anonymity, each trajectory is assigned to a group of at least $k-1$ other trajectories using a greedy clustering algorithm. Then, the trajectories of each cluster are spatially translated so that they will all lie entirely within the same cylinder (uncertainty area) of radius $\delta/2$. W4M is a variant of NWA that uses the time-tolerant EDR distance function [4] during the clustering phase in order to overcome the limitations of Euclidean distance. Moreover, W4M performs spatio-temporal instead of spatial translation to the trajectories. All the aforementioned approaches offer no degree of personalization since they assume that all users share the same privacy level k which is application-determined.

The most related to our work is the one proposed by Mahdavi et al. [9]. It introduces the idea of non-uniform privacy requirements, where each trajectory is associated with its own privacy level indicating the number of trajectories it should be indistinguishable from. Trajectories are first divided into groups depending on their privacy level. Clusters are then created by randomly selecting a centroid and adding to the cluster the trajectories nearest to it if their EDR distance is lower than a threshold, until the maximum privacy requirement within the cluster is satisfied. If the requirements are not satisfied, groups with lower privacy levels are progressively searched for trajectories to be added to the cluster, until all the privacy requirements are met. Finally, the trajectories of each cluster are anonymized using a matching point algorithm that generates an anonymized trajectory as the cluster's representative. While this approach offers a greater degree of personalization than others, it still leads to a compulsory trade-off between privacy and quality for each user. If a trajectory has a high privacy requirement k , it will very likely be part of a large cluster, thus suffering from increased information loss and low data utility, since the user cannot set a 'quality' requirement.

3. PROBLEM FORMULATION

In this section, we present the formal background and definition of the *Personalized (K, Δ) -anonymity* problem in two variations. We assume that the trajectory τ of a moving object is a polyline in 3-dimensional space represented as a sequence of time-stamped locations: $(p_1, t_1), (p_2, t_2), \dots, (p_n, t_n), t_1 < t_2 < \dots < t_n$. During the non-recorded time periods (t_i, t_{i+1}) , we assume linear interpolation, i.e., the object moves along a straight line from p_i to p_{i+1} with a constant speed.

Following the definition adopted by [1], an uncertain trajectory buffer is defined as a cylindrical volume of diameter δ centered at an object's expected trajectory. Formally:

Definition 1 (uncertain trajectory): Given a trajectory τ defined in $[t_1, t_n]$ and an uncertainty threshold δ , τ^δ is the uncertain counterpart of trajectory τ , defined as follows: for each 3-dimensional point (p, t) in τ , its uncertainty area is the horizontal disk centered at (p, t) with diameter δ . The trajectory volume of τ^δ , denoted by $\text{Vol}(\tau^\delta)$ is the union of all such disks for every $t \in [t_1, t_n]$. A possible motion curve of τ is any continuous function $f_{\text{PMC}}^\tau: \text{Time} \rightarrow \mathbb{R}^2$ defined on the interval $[t_1, t_n]$, such that for any $t \in [t_1, t_n]$, the 3-dimensional point $(f_{\text{PMC}}^\tau(t), t)$ lies inside the uncertainty area at time t . ■

Definition 2 (co-localized trajectories): Two trajectories τ_1, τ_2 , both defined in $[t_1, t_n]$, are considered co-localized w.r.t. δ , if for each point (p_1, t) in τ_1 and (p_2, t) in τ_2 , $t \in [t_1, t_n]$, it holds that the Euclidean distance $d(p_1, p_2) \leq \delta$; we write $\text{Coloc}_\delta(\tau_1, \tau_2)$ omitting the time interval $[t_1, t_n]$. ■

Definition 3 ((k, δ) -anonymous set of trajectories): Given a set of trajectories S , an uncertainty threshold δ , and an anonymity threshold k , S is (k, δ) -anonymous iff $|S| \geq k$ and $\text{Coloc}_\delta(\tau_i, \tau_j)$ for each $\tau_i, \tau_j \in S$. ■

A dataset D of moving object trajectories is considered (k, δ) -anonymous if each of its members belongs to a (k, δ) -anonymity set. If D does not meet this requirement, then it should be transformed into a sanitized version, called D_s , which satisfies the aforementioned condition. Hence:

Definition 4 ((k, δ) -anonymity): Given a dataset D of moving object trajectories, an uncertainty threshold δ , and an anonymity threshold k , (k, δ) -anonymity is satisfied by transforming D to D_s , such that for each trajectory $\tau_s \in D_s$ there exists a (k, δ) -anonymity set $S \subseteq D_s$, $\tau_s \in S$, and the distortion between D and D_s is minimal. ■

One of the possible approaches to transform a dataset to its sanitized version is the spatiotemporal translation of the trajectory points. Distortion usually measures the difference between the original and the sanitized data. A trajectory's distortion is defined as the sum of its point-wise distances to its sanitized version. In case the trajectory is an outlier, thus removed from the anonymized dataset, the distortion is proportional to the number of the distorted moving points of the original trajectory. The total distortion caused by sanitizing the entire database is defined as the aggregation of its individual trajectories' distortion.

Definition 5 (trajectory distortion due to translation): Given a trajectory $\tau \in D$ defined in $[t_1, t_n]$ and its sanitized version $\tau_s \in D_s$, the translation distortion (TD) over τ due to its translation into τ_s is defined as:

$$TD(\tau, \tau_s) = \begin{cases} \sum_{t \in [t_1, t_n]} d(\tau[t], \tau_s[t]) & |\tau_s| > 0 \\ |\tau| \cdot \Omega & |\tau_s| = 0 \end{cases} \quad (1)$$

where $|\tau|, |\tau^s|$ indicate the size (i.e., number of points) of the original and the sanitized trajectory, respectively, and Ω is a constant that penalizes distorted moving points. Summing for all trajectories, the total translation distortion over a trajectory dataset D due to its translation into D_s is defined as:

$$TTD(D, D_s) = \sum_{\tau \in D} TD(\tau, \tau_s) \quad (2)$$

■

Regarding Ω , in our experiments it corresponds to the maximum translation occurred during the anonymization process.

The problem introduced in this paper is that of achieving anonymity of a trajectory dataset, where each trajectory prescribes its own (k_i, δ_i) values, while keeping the total distortion as low as possible. The problem is formulated as follows:

Problem 1 (Personalized (K, Δ) -anonymity problem): Given a dataset D of moving object trajectories, $D = \{\tau_1, \dots, \tau_n\}$, along with their respective anonymity preferences (k_i, δ_i) , and a trash size threshold $trash_{max}$, the Personalized (K, Δ) -anonymity problem, where $K = \{k_1, \dots, k_n\}$ and $\Delta = \{\delta_1, \dots, \delta_n\}$, is to find an anonymized version of D , $D_s = \{\tau_{s_1}, \dots, \tau_{s_m}\}$, $0 \leq n-m \leq trash_{max}$ where τ_{s_i} is a (k_i, δ_i) -anonymity version of τ_i and the total distortion, $TTD(D, D_s)$, is minimal. ■

In the above definition, please note that $m \leq n$, i.e., the cardinality of the output dataset D_s may be lower than that of the input dataset D . This is due to the fact that during the anonymization process some of the original trajectories may be moved to the trash bin, i.e., they are completely removed.

A comment on Problem 1 is that the distortion caused in the original dataset due to anonymization is not controlled since it has to do with the nature of the trajectories, as well as the values of their anonymity preferences (k_i, δ_i) . Therefore, a natural variation of the above problem is that of anonymizing a database of trajectories of moving objects where each object has its own (k_i, δ_i) values, while keeping a control over the overall distortion. This problem is formulated as follows:

Problem 2 (Bounded Personalized (K, Δ) -anonymity problem): Given a dataset D of moving object trajectories, $D = \{\tau_1, \dots, \tau_n\}$, along with their respective anonymity preferences (k_i, δ_i) , a trash size threshold $trash_{max}$, and a distortion threshold $distort_{max}$, the Bounded Personalized (K, Δ) -anonymity problem, where $K = \{k_1, \dots, k_n\}$ and $\Delta = \{\delta_1, \dots, \delta_n\}$, is to find an anonymized version of D , $D_s = \{\tau_{s_1}, \dots, \tau_{s_m}\}$, $0 \leq n-m \leq trash_{max}$ where τ_{s_i} is a (k_i, δ_i) -sanitized version of τ_i and the total distortion, $Distortion(D, D_s) \leq distort_{max}$. ■

The total distortion of the dataset when compared to its sanitized version, $Distortion(D, D_s)$, is a formula consisting of two factors, i.e. the distortion from the translation during the anonymization step, $TTD(D, D_s)$, which is calculated according to Eq.(2) along with the distortion caused from the editing phase, $TE(D)$ (to be introduced in Section 5).

A special case is when the solution D_s of Problem 1 also makes a solution to Problem 2, formally: $Distortion(D, D_s) \leq distort_{max}$; in such case, nothing extra has to be done in order to provide a solution to Problem 2. In the general case, however, where $Distortion(D, D_s) > distort_{max}$, Problem 2 can be solved by relaxing the (k_i, δ_i) constraints of those trajectories that are most responsible for the distortion caused; we call them, the most demanding ones, and a formulation of the demandingness of a trajectory will be defined in Section 5.

4. PERSONALIZED (K, Δ) -ANONYMITY

In this section, we present a suite of methods for publishing spatiotemporal trajectory data using the personalized (K, Δ) -anonymity. In particular, Section 4.1 describes baseline solutions for providing personalized anonymization w.r.t. different users' preferences. In section 4.2, we present an approach that provides personalized (K, Δ) -anonymity based on trajectory segmentation.

4.1 Baseline Solutions

Given a trajectory dataset D along with personalized privacy requirements (k_i, δ_i) for each trajectory τ_i , a baseline solution to Problem 1 consists of exploiting a state-of-the-art (k, δ) -anonymity algorithm, such NWA [1] or W4M [2], using a single, universal value for each k and δ . In order to satisfy every user's privacy requirement, it is the maximum among all k_i and the minimum among all δ_i that are assigned to the universal k and δ variables, respectively. The following algorithm, being the naïve version of our *Who-Cares-about-Others'-Privacy* (WCOP) suite of methods, illustrates this solution. As already discussed, Function $k\text{-}\delta\text{-anonymity}()$ in Line 3 of the algorithm corresponds to a state-of-the-art (k, δ) -anonymity algorithm, such as NWA or W4M.

Algorithm 1. WCOP-NV

Input: (1) a trajectory dataset, $D = \{(\tau_1, k_1, \delta_1), \dots, (\tau_n, k_n, \delta_n)\}$; (2) a trash size threshold, $trash_{max}$, (3) a maximum cluster radius threshold, $radius_{max}$
Output: A sanitized trajectory dataset, $D_s = \{\tau_{s_1}, \dots, \tau_{s_m}\}$

1. $max_k \leftarrow \max_i \{k_i\}$
2. $min_\delta \leftarrow \min_i \{\delta_i\}$
3. $D_s \leftarrow k\text{-}\delta\text{-anonymity}(D, max_k, min_\delta, trash_{max}, radius_{max})$
4. **return** D_s

In order to improve this very crude attempt of satisfying personalized (K, Δ) values, we propose an alternative approach directly using the user-specific privacy requirements and being based on clustering and translation, called WCOP-CT (where 'CT' stands for Clustering and Translation). WCOP-CT follows the general structure of W4M, consisting of two phases: a *greedy clustering phase*, which has been shown in [1] to have the best effectiveness/efficiency ratio, followed by a *spatiotemporal translation phase*, which uses Edit Distance on Real sequence (EDR) distance function [4] in order to modify each cluster to make it an anonymity set. During the first phase, a pivot trajectory is randomly selected and a cluster is formed around it by its $k-1$ unvisited closest neighbors. Then the unvisited trajectory that is farthest away from previous pivots is selected as a new pivot, and the process is repeated until clusters satisfying certain criteria. During the second phase, each cluster formed in the previous phase is transformed into a (k, δ) -anonymity set.

The input of WCOP-CT algorithm is a dataset D consisting of n trajectories τ_i along with their personalized privacy requirements (k_i, δ_i) , a $trash_{max}$ value that bounds the size of trash, which contains the outliers suppressed during the clustering process (phase 1 of the algorithm) in order to improve the quality of the final output and the maximum allowable cluster radius, $radius_{max}$. The output of the algorithm is the personalized (K, Δ) -anonymized dataset D_s .

Algorithm 2. WCOP-CT

Input: (1) a trajectory dataset, $D = \{(\tau_1, k_1, \delta_1), \dots, (\tau_n, k_n, \delta_n)\}$; (2) a trash size threshold, $trash_{max}$, (3) a maximum cluster radius threshold, $radius_{max}$

Output: A sanitized trajectory dataset, $D_s = \{\tau_{s_1}, \dots, \tau_{s_m}\}$

```
1.  $D_s \leftarrow \emptyset$ 
2.  $\gamma \leftarrow WCOP\text{-}Clustering(D, trash_{max}, radius_{max})$ 
   /* Clustering phase */
3. for each cluster  $C \in \gamma$  do
4.    $C_s \leftarrow \emptyset$ 
5.    $\tau_c \leftarrow \text{pivot of } C; \delta_c \leftarrow \min_i \{\delta_i\} \text{ in } C$ 
   /* Translation phase */
6.   for each  $\tau \in C$  do
7.      $\tau_s \leftarrow WCOP\text{-}Translation(\tau, \tau_c, \delta_c)$ 
8.      $C_s \leftarrow C_s \cup \{\tau_s\}$ 
9.   end for
10.   $D_s \leftarrow D_s \cup C_s$ 
11. end for
12. return  $D_s$ 
```

In detail, WCOP-CT works as follows: the operation *WCOP-Clustering* (line 2) extracts a set of clusters γ from the original dataset. Then, for each cluster (represented by the corresponding pivot trajectory), the algorithm defines its own δ value, which is the $\min_i \{\delta_i\}$ among its members (lines 3-5). All trajectories contained on the current cluster are translated by the *WCOP-Translation* operation (lines 6-7). The procedure is repeated until all trajectories of all clusters are anonymized.

The main difference between the proposed WCOP-CT and, e.g. W4M is that, whereas in W4M a pivot is selected and then invariably grouped along with its $k-1$ closest neighbors in order to form a cluster, in WCOP-CT each cluster has its own, non-fixed k value. It can easily be seen that this approach results in clusters of non-fixed size ranging between 2 and $\max_i \{k_i\}$. In the same spirit, the spatiotemporal editing phase of WCOP-CT, called *WCOP-Translation* in Algorithm 2, differs to that of W4M in that there is no universal δ applied to all clusters, but each cluster is edited based on its own δ_c value, which is the $\min_i \{\delta_i\}$ among its members.

The core of WCOP-CT, i.e., the clustering step under the name *WCOP-Clustering*($D, trash_{max}, radius_{max}$) in Algorithm 2 above, is listed in Algorithm 3 below. *WCOP-Clustering* follows the general structure of the respective algorithm of W4M and Greedy Clustering, where W4M is based on. After forming clusters, each of them is separately processed and transformed into a (k, δ) -anonymity set, with (k, δ) being values specific to the cluster. Here we follow the approach proposed in [2], which achieves that by using the cluster's pivot as reference and editing the other trajectories so that they are co-located with it (see Section 3) and also have the same number of points as the pivot. The difference with our method is that each cluster uses its own δ value for co-localization instead of a universal value.

In detail, *WCOP-Clustering* iteratively selects pivot trajectories to function as centers of clusters, with pivots being selected at random from amongst the available active trajectories (Line 4). A pivot's (k_i, δ_i) values serve as the initial (k, δ) requirements of its candidate cluster (Line 6). The algorithm then successively adds to the candidate cluster the nearest unvisited neighbor of the pivot and updates the cluster's k and δ , until the cluster's size is enough to satisfy its k requirement, which equals to the maximum k_i value among its members (Lines 7-11).

Algorithm 3. WCOP-Clustering

Input: (1) a trajectory dataset, $D = \{(\tau_1, k_1, \delta_1), \dots, (\tau_n, k_n, \delta_n)\}$; (2) a trash size threshold, $trash_{max}$, (3) a maximum cluster radius threshold, $radius_{max}$

Output: A set of clusters γ

```
1. repeat
2.   Active  $\leftarrow D$ ; Clustered  $\leftarrow \emptyset$ ; Pivots  $\leftarrow \emptyset$ ; Trash  $\leftarrow \emptyset$ 
3.   while Active  $\neq \emptyset$  do
4.      $\tau_p \leftarrow \text{random}(\tau) \mid \tau \in \text{Active}$ 
5.      $c_{\tau_p}.size \leftarrow 1$ 
6.      $c_{\tau_p}.k \leftarrow \tau_p.k$ ;  $c_{\tau_p}.\delta \leftarrow \tau_p.\delta$ 
7.     while ( $c_{\tau_p}.k > c_{\tau_p}.size$ ) do
8.        $c_{\tau_p} \leftarrow \{\tau_p\} \cup \{\text{NN of } \tau_p \in D - \text{Clustered}\}$ 
9.        $c_{\tau_p}.size \leftarrow c_{\tau_p}.size + 1$ 
10.       $c_{\tau_p}.k \leftarrow \max(c_{\tau_p}.k, \tau_{NN}.k)$ 
11.       $c_{\tau_p}.\delta \leftarrow \min(c_{\tau_p}.\delta, \tau_{NN}.\delta)$ 
12.    end while
13.    if  $\max_{\tau \in c_{\tau_p}} \text{Dist}(\tau_p, \tau) \leq radius_{max}$  then
14.      Active  $\leftarrow \text{Active} - c_{\tau_p}$ 
15.      Clustered  $\leftarrow \text{Clustered} \cup c_{\tau_p}$ 
16.      Pivots  $\leftarrow \text{Pivots} \cup \{\tau_p\}$ 
17.    else
18.      Active  $\leftarrow \text{Active} - \{\tau_p\}$ 
19.    end while
20.    for each  $\tau \in D - \text{Clustered}$  do
21.       $\tau_p \leftarrow \text{argmin}_{\tau' \in \text{Pivots} \mid c_{\tau'}.size \geq \tau.k - 1, c_{\tau'}. \delta \leq \tau.\delta} \text{Dist}(\tau', \tau)$ 
22.      if  $\text{Dist}(\tau_p, \tau) \leq radius_{max}$  then
23.         $c_{\tau_p} \leftarrow c_{\tau_p} \cup \{\tau\}$ 
24.      else
25.        Trash  $\leftarrow \text{Trash} \cup \{\tau\}$ 
26.      end for
27.    increase( $radius_{max}$ )
28.  until  $|\text{Trash}| \leq |\text{Trash}_{max}|$ 
29.  return  $\{c_{\tau_p} \mid \tau_p \in \text{Pivots}\}$ 
```

Once all possible clusters have been formed, the remaining unassigned trajectories are assigned to the cluster of their closest pivot, on condition that their k_i can be satisfied by the cluster's size (including themselves), their δ_i are not smaller than the cluster's current δ , and their addition will not increase the cluster's radius beyond $radius_{max}$ (Lines 20-23). If a trajectory cannot be added to any cluster without violating a condition, it is moved to the trash (Line 25). If the solution found results in trash with size larger than the $trash_{max}$ threshold, the $radius_{max}$ constraint is relaxed and the process starts again from the beginning until a solution is achieved that satisfies the $trash_{max}$ size requirement (Lines 27-28). As output, the algorithm returns only the clusters formed, excluding the suppressed trajectories implicitly (Line 29).

After the clusters have been defined, Algorithm 2 proceeds to the necessary spatiotemporal translation. Since trajectories may not be of the same size, the EDR time-tolerant distance function is responsible to minimize the necessary number of operations so as to make them indistinguishable. The goal of the *editing* operations (i.e. translate points towards pivot, remove deleted points, insert new points) that are performed to a trajectory is to make it more similar to the pivot. Algorithm 4 describes the translation procedure that is followed by WCOP-CT.

Algorithm 4. WCOP-Translation

Input: (1) a trajectory τ , (2) cluster's pivot trajectory τ_c , (3) cluster's uncertainty threshold δ_c

Output: Anonymized trajectory τ_s

```

1. edit ← EDR_op_sequence( $\tau, \tau_c$ )
2.  $\tau_s \leftarrow \langle \rangle$ 
3.  $i, j \leftarrow 1$ 
4. for all  $op \in \text{edit}$  do
5.   if  $op = \text{remove}(\tau_{c,j})$  then
6.      $\tau_s.append(\langle \text{random\_point\_in\_circle}(\tau_{c,j}.x, \tau_{c,j}.y, \delta_c/2), \tau_{c,j}.t \rangle)$ 
7.      $j \leftarrow j+1$ 
8.   else
9.     if  $op = \text{match}(\tau_i, \tau_{c,j})$  then
10.       $\tau_s.append(\langle \text{transl}(\tau_i.x, \tau_i.y, \tau_{c,j}.x, \tau_{c,j}.y, \delta_c/2), \tau_{c,j}.t \rangle)$ 
11.       $i \leftarrow i+1$ 
12.       $j \leftarrow j+1$ 
13.     else
14.       $i \leftarrow i+1$ 
15.   end for
16. return  $\tau_s$ 

```

As a first step, the algorithm reconstructs the sequence of the required operations (Line 1). In case of a point deletion from the pivot trajectory τ_c , the algorithm instead of deleting, it creates a new point randomly inside the circle of radius $\frac{\delta_c}{2}$ around the corresponding point in τ_c (Lines 5-7). Recall that in our case each cluster has its own δ_c equal to $\min_i \{\delta_i\}$ among its members. Differently, when the deletion concerns trajectory τ , the point is permanently removed (Lines 13-14). If a matching between τ and τ_c occurs, then operation *transl* is responsible to ensure that the distance between them will be equal or less than $\frac{\delta_c}{2}$. If the two points match w.r.t. the temporal dimension, then trajectory's point is transferred inside the circle to a point having the minimum distance translation from the original one. Else, the temporal coordinate value of the pivot's point is used and the point is spatially translated again inside the circle with radius equal to or less than $\frac{\delta_c}{2}$ (Lines 9-12).

4.2 Personalized (K, Δ) -Anonymity using Trajectory Segmentation

In this section, we introduce a novel approach to the problem of *Personalized (K, Δ) -anonymity*, which aims to improve upon the baseline solutions presented in the previous section by implementing trajectory segmentation, in order to increase clustering effectiveness and decrease distortion levels. A shortcoming of the two baseline solutions (WCOP-NV and WCOP-CT), which is common in all clustering methods, is that they use the trajectory as the smallest working unit. As a result, when two trajectories have some similar parts, but are significantly different on the whole, the algorithm is unable to discover and make use of those similar elements, leading to an overall increased distortion during clustering. In order to deal with this issue, our approach includes a trajectory segmentation phase, where trajectories are partitioned into sub-trajectories according to a set of privacy-aware criteria. It is these sub-trajectories that are then used as input for the anonymization stage of the algorithm that follows. While this segmentation incurs extra computational cost, it offers a distinct advantage in that it facilitates the discovery of patterns shared between parts of trajectories, which otherwise are significantly different on the whole.

The so-called WCOP-SA (where 'SA' stands for Segmenting and Anonymizing), which is presented in Algorithm 5 below, is the generic two-step method that we propose. Given a dataset D consisting of n trajectories τ_i along with their personalized privacy requirements (k_i, δ_i) , in the first step the algorithm applies a trajectory segmentation process to produce the respective dataset of partitioned sub-trajectories D_p , followed by the second step that anonymizes those sub-trajectories.

Algorithm 5. WCOP-SA

Input: (1) a trajectory dataset, $D = \{(\tau_1, k_1, \delta_1), \dots, (\tau_n, k_n, \delta_n)\}$; (2) a trash size threshold, $trash_{max}$, (3) a maximum cluster radius threshold, $radius_{max}$

Output: A sanitized trajectory dataset, $D_s = \{\tau_{s1}, \dots, \tau_{sm}\}$.

```

1.  $D_p \leftarrow \text{WCOP-Segmenting}(D)$ 
2.  $D_s \leftarrow \text{WCOP-Anonymizing}(D_p, trash_{max}, radius_{max})$ 
3. return  $D_s$ 

```

An example of using WCOP-SA on a dataset partitioned using this method can be seen in Figure 1(d), where segments that are similar in terms of the number of their neighboring trajectories have been identified and grouped into sub-trajectories, which in turn have been assigned to appropriate clusters causing less spatiotemporal translation. WCOP-SA is by purpose generic, in that it does not strictly specify the algorithms used for segmentation and anonymization. Any algorithm of this kind can be used. However, in our experimental study (Section 6) we evaluate WCOP-SA using a trajectory-aware (Traclus [8]) vs. a neighborhood-aware segmentation algorithm (Convoys [7]) for the segmentation step, and WCOP-CT vs. WCOP-B (to be introduced in Section 5) for the anonymization step.

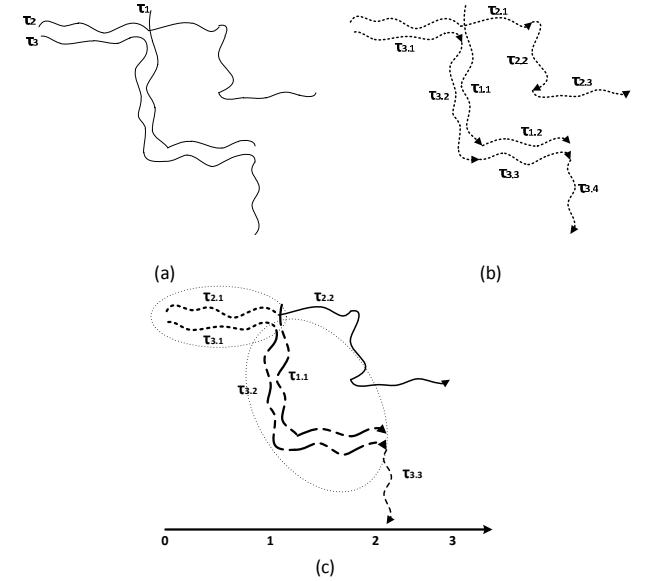

Figure 2: (a) a set of trajectories segmented by (b) Traclus and (c) Convoys partitioning-and-clustering algorithms.

Why Traclus vs. Convoys? Traclus [8] is a well-known and widely-used partitioning and clustering framework that performs density-based clustering on line segments aiming at discovering common sub-trajectories instead of grouping trajectories as a whole. During this process, trajectories are first partitioned on segmentation points representing significant changes of the trajectory's behavior (i.e. direction) by using the minimum description length principle.

Then, the directed line segments previously discovered are clustered with a variant of DBSCAN density-based clustering algorithm. However, the aforementioned approach does not properly incorporate the temporal dimension of trajectories as it spatially segments trajectories w.r.t their direction. A well-known temporal-awareness approach for clustering spatiotemporal trajectories is the one of Convoys [7]. It is a concept that uses different criteria for grouping the trajectories. A *convoy* is defined as a group of objects that has at least m objects, which are density-connected with respect to a distance threshold e , during k consecutive time-instants.

The difference between the two aforementioned approaches is illustrated in Figure 2. Let us assume three trajectories τ_1, τ_2, τ_3 (Figure 2(a)); when Traclus is applied for the segmentation of trajectories, the derived sub-trajectories (illustrated in Figure 2(b)) are constructed based on geometric parameters, actually, significant changes on their own direction. In contrast, Convoys performs segmentation by discovering neighboring trajectories that are moving together during a time period; as illustrated in Figure 2(c), τ_2 and τ_3 are moving together between $t = 0$ and $t = 1$ while τ_1 and τ_3 between $t = 1$ and $t = 2$, thus two convoys are discovered, which are then used for the segmentation of the trajectories to 6 sub-trajectories.

5. BOUNDED PERSONALIZED (K, Δ)-ANONYMITY

In order to deal with the problem of *Bounded Personalized (K, Δ)-anonymity* defined in Section 3, where the requirement is to keep anonymization distortion below a given threshold, we extend the methods presented in the previous sections by introducing dataset assessment and requirement relaxation. Since distortion is due to spatiotemporal translation, a naïve approach would be to anonymize a dataset once, identify the trajectories, which have undergone the most translation and edit them. However, a trajectory τ might be translated not due to its own (k, δ) values, but in order to be assigned to a cluster that includes very demanding members, i.e., τ 's neighbors. Therefore, in order to decrease the overall distortion of a dataset, we argue that the most demanding trajectories should be detected and edited.

By intuition, high values of k and low values of δ make a trajectory demanding. As such, a metric for the demandingness of a trajectory is defined as follows:

Definition 6 (dataset-aware trajectory demandingness): Given a trajectory $\tau \in D$ with privacy requirements (k, δ) , its dataset-aware demandingness, $d_{dem}(\tau, D) \rightarrow [0, 1]$, is defined as:

$$d_{dem}(\tau, D) = w_1 * \frac{\tau.k}{k_{max}} + w_2 * \frac{\delta_{min}}{\tau.\delta} \quad (3)$$

where $k_{max} > 1$ and $\delta_{min} > 0$ correspond to the maximum k and minimum δ values of trajectories in D , respectively, and (k, δ) contribute to the overall value according to some weights, $\sum w_i = 1$.

■

Eq. (3) formulates the intuition that trajectory demandingness is proportional to k and reversely proportional to δ . k_{max} and δ_{min} are used for normalization purposes and the weights w_i are introduced in order for the importance of the two components to be controlled, according to the application scenario. For simplicity, in the rest of the paper, the two components are equally weighted, i.e., $w_1 = w_2 = 1/2$.

As an example, consider a dataset D consisting of 50 trajectories where $k_{max} = 50$ and $\delta_{min} = 20$. Table 1 below lists the top-5 demanding trajectories of the dataset, where their demandingness has been calculated according to Eq. (3). Now assume that the overall distortion caused by the sanitization of the dataset D to D_s exceeds $distort_{max}$ threshold. The two most demanding trajectories, i.e. τ_{21}, τ_5 could be edited in order to decrease the complexity of assigning them to a cluster. Trajectory τ_{21} requires to be hidden among other 49 neighbors within an area of diameter 30 m. Similarly, trajectory τ_5 , less demanding, requires other 29 neighbors within an area of diameter 20 m.

Table 1: An example of editing the most demanding trajectories

τ_i	(k_i, δ_i)	$d_{dem}(\tau_i, D)$
τ_{21}	(50,30)	0.83
τ_5	(30,20)	0.8
τ_{47}	(23,100)	0.33
τ_{15}	(23,220)	0.27
τ_7	(20,200)	0.25

How can we relax these requirements? Actually, we need a measure that indicates the degree of trajectory editing. For this purpose, we define *trajectory edit cost* as the ratio of the (k, δ) -editing required for the particular trajectory over the (k, δ) -editing required for the most demanding one. Note that for a trajectory τ , its dataset-aware demandingness can be reduced by editing its k and/or δ values.

Definition 7 (trajectory edit cost): Given a trajectory $\tau \in D$ with dataset-aware demandingness, d_{dem} , defined over D , and a threshold trajectory τ_{thres} , the edit cost of trajectory τ , $0 \leq cost_{edit} \leq 1$, is defined as:

$$cost_{edit}(\tau, D) = \begin{cases} \frac{d_{dem}(\tau, D) - d_{dem}(\tau_{thres}, D)}{\max_{\tau \in D} d_{dem}(\tau, D) - d_{dem}(\tau_{thres}, D)}, & \text{if } \max_{\tau \in D} d_{dem}(\tau, D) \neq d_{dem}(\tau_{thres}, D) \\ 0, & \text{otherwise} \end{cases} \quad (4)$$

where $\max_{\tau \in D} d_{dem}(\tau, D)$ is the maximum dataset-aware demandingness among the trajectories in D . ■

As a threshold trajectory, τ_{thres} , we refer to the trajectory with the maximum acceptable demandingness in the ranking. All trajectories having a higher ranking (i.e. more demanding) are being edited. Back to Table 1, let us assume that the two most demanding trajectories need to be edited. Trajectory τ_{47} will be the threshold trajectory τ_{thres} . Thus, according to Eq. (4), the edit cost of τ_{21} equals to 1 while for τ_5 it is equal to 0.94.

The distortion caused by an edited trajectory can be measured as the number of its points multiplied by the maximum dataset translation, multiplied by the trajectory's edit cost, which indicates the required editing degree compared to the maximally edited one.

Definition 8 (trajectory distortion due to (k, δ) editing): Given an edited trajectory $\tau \in D$, the contribution of trajectory τ to the overall distortion cost, $distort$, is defined as:

$$distort(\tau, D) = |\tau| \cdot \Omega \cdot cost_{edit}(\tau, D) \quad (5)$$

where $|\tau|$ indicates the size of the trajectory (i.e. the number of its points) and Ω is a constant that penalizes distortion. The overall

editing distortion, DE , over a trajectory dataset D due to trajectory editing, is defined as:

$$DE(D) = \sum_{\tau \in D} distort(\tau, D) \quad (6)$$

Regarding Ω , as in Eq. (2), we define it to be the maximum translation occurred during the anonymization process.

Definition 9 (dataset distortion): The total distortion of a dataset D due to its anonymization to D_s , is defined as the sum of the total distortion due to translation, TTD , and the total distortion due to editing, DE :

$$Distortion(D, D_s) = TTD(D, D_s) + DE(D) \quad (7)$$

WCOP-B ('B' stands for Bounded), which is presented in Algorithm 6 below, shows the generic concept we propose to tackle the *Bounded Personalized (K, Δ)-anonymity problem*, as it was defined in Section 3. Note that, as a first step, a user is able to apply WCOP-CT on the original dataset. The output will be an anonymized dataset along with the distortion caused during the anonymization. The user is then capable to estimate the desired distortion thus determining $distort_{max}$.

Algorithm 6. WCOP-B

Input: (1) a trajectory dataset, $D = \{(\tau_1, k_1, \delta_1), \dots, (\tau_n, k_n, \delta_n)\}$; (2) a trash size threshold, $trash_{max}$; (3) a distortion threshold, $distort_{max}$; (3) an amount of editable trajectories, $step$.

Output: A sanitized trajectory dataset, $D_s = \{\tau_{s_1}, \dots, \tau_{s_m}\}$

```

1. for each  $\tau \in D$  do
2.   Calculate  $d_{dem}(\tau, D)$  // according to Eq. (3)
3. end for
4.  $edit_{size} \leftarrow step$ 
5. SortByDemandingness(D)
6. repeat
7.   ResetTrajectories(D)
8.   Edited  $\leftarrow \emptyset$ ; Trashed  $\leftarrow \emptyset$ ; editcount  $\leftarrow 0$ 
9.    $\tau \leftarrow$  highest scoring trajectory
10.   $\tau_{thres} \leftarrow \tau_{N-edit_{size}-1}$ 
    /*Editing phase*/
11.  while editcount < editsize do
12.    Calculate costedit( $\tau, D$ ) // according to Eq. (4)
13.     $\tau.k \leftarrow \tau_{thres}.k$ 
14.     $\tau.\delta \leftarrow \tau_{thres}.\delta$ 
15.    Edited  $\leftarrow$  Edited  $\cup \{\tau\}$ 
16.    editcount  $\leftarrow$  editcount + 1
17.     $\tau \leftarrow$  next trajectory
18.  end while
    /* Anonymization phase */
19.   $D_s \leftarrow$  WCOP-CT(D, trashmax, radiusmax)
20.  Calculate Distortion(D,  $D_s$ ) // according to Eq. (7)
21.  editsize  $\leftarrow$  editsize + step
22. until (Distortion  $\leq$  distortmax || editsize  $\geq$  |D|)
23. return  $D_s$ 

```

Algorithm WCOP-B-Edit-and-Anonymization works as follows: With the trajectory database and a distortion threshold $distort_{max}$ given as input, the trajectories are first assessed in order for the algorithm to calculate the demandingness of each trajectory according to Eq. (3) (Lines 1-3). Then, the trajectories are sorted according to their demandingness, to facilitate the steps that follow (line 5). Based on the demandingness scores previously calculated, the (k, δ) values of the most demanding trajectories are edited, with $edit_{size}$ determining the amount of editable trajectories (Lines 11-18). In more detail, the goal of the editing process that

follows is to edit the most expensive trajectories so that their editing score will become equal to the threshold trajectory's editing score. Starting with the highest-scoring trajectory and continuing until $edit_{size}$ has been reached, the editing cost of each trajectory is calculated (lines 11-12). Trajectory's k value is then decreased to the corresponding value of the threshold trajectory (lines 13). Next, the trajectory's δ is increased up to threshold trajectory's δ value (Line 14). The trajectory is then marked as 'edited', the edit-counter is updated and the next-highest-ranking trajectory selected (Lines 15-17). After the editing phase is completed, the edited dataset D is given as input to the WCOP-CT algorithm, which produces an anonymized dataset D_s (Line 19). The total distortion of the dataset is then calculated according to Eq.(7) (Lines 20). If the total distortion is below the distortion threshold, $distort_{max}$, the algorithm ends and the anonymized dataset is given as output, otherwise the portion of the dataset that is marked for editing is increased (Line 21) and the editing - anonymization phase is repeated; this loop continues until either the distortion requirement is satisfied or the entire dataset has been edited (Line 22).

It is worth to note that the method is valid for datasets consisting of either whole trajectories or segmented sub-trajectories. Therefore, it is the same algorithm that can be used in combination with either WCOP-CT or WCOP-SA (see line 19 in Algorithm 6).

Since the distortion caused by the anonymization of a dataset is heavily dependent on the original data and the dataset's privacy / quality requirements, it is possible that there will be combinations of strict distortion requirements and very demanding datasets that prohibit the discovery of a solution.

6. EXPERIMENTAL STUDY

In this section, we evaluate the effectiveness of our WCOP suite of methods for addressing the *Personalized (K, Δ)-anonymity problem* and its *Bounded* variation, as defined in Section 3. Namely, our suite consists of four algorithms: WCOP-NV, WCOP-CT, and WCOP-SA that address the first problem and WCOP-B that addresses the second problem.

We describe the experimental settings in Section 6.1. We make a base comparison between all the proposed algorithms in Section 6.2, while in Section 6.3, we briefly discuss the effects of (k, δ) parameter values. In Section 6.4, we examine the results of having first partitioned the trajectories of the dataset into sub-trajectories using dataset-aware criteria. In Section 6.5, we validate the results of using trajectory editing to relax demanding trajectories' requirements so as to decrease anonymization distortion.

6.1 Experimental Setting

In this experimental study we use a real dataset to evaluate the performance of the examined algorithms. In particular, we use a sample of GeoLife dataset [14] reporting the traces of a group of individuals monitored in Beijing, consisting of 238 trajectories.

The dataset used in our experiments is visualized in Figure 3 whereas in Table 2, we report the characteristics of the dataset, namely the number of objects – users, the number of trajectories, $|D|$, the total number of spatiotemporal points composing those trajectories, the derived average speed, the half-diagonal of the minimum bounding box of the entire space that the dataset is covering, $radius(D)$, and the duration of the dataset.

Figure 3: the trajectory dataset used in the experimental study (portion of GeoLife dataset).

Table 2: Statistics of GeoLife dataset

GeoLife	
# objects (users)	72
# trajectories, $ D $	238
# spatiotemporal points	343,129
avg. speed (in m/s)	6.36
half-diagonal of entire space, radius(D) (in m)	51,982
dataset duration (in days)	1,477

δ_{max} parameter is set to 3% of $radius(D)$. $trash_{max}$, i.e., the maximum number of trajectories that can be suppressed, is set to 10% of $|D|$. $radius_{max}$ is set equal to $radius(D)$. Finally, the tolerance thresholds of the EDR, $\Delta = \{dx, dy, dt\}$, are set as heuristic functions of δ_{max} : $\Delta = \{10 * \delta_{max}, 10 * \delta_{max}, 10 * \delta_{max} / avg_speed\}$, where avg_speed is the average speed of all the moving objects in the dataset.

The experiments were performed on an Intel Xeon 2 GHz processor with 4 Gb of RAM and all the proposed algorithms were implemented in C.

6.2 Base Comparison

In this section, a base comparison between the proposed approaches is presented, in order to prove the validity of our personalized approaches. The dataset is used for this experiment with randomly generated (k, δ) requirements for each trajectory, $k \in [2, 100]$, $\delta \in [10, 1400]$. WCOP-NV finds the $\max\{k_i\}$, $\min\{\delta_i\}$ values in the dataset and uses them for all trajectories, ignoring their individual requirements, essentially replicating the way W4M works. WCOP-CT does not take universal (k, δ) values as input, instead it parses each trajectory's specific (k_i, δ_i) requirements from the dataset and uses them throughout the process. Moreover, WCOP-SA algorithms first converts the dataset into a set of sub-trajectories and then WCOP-CT is applied in order to anonymize them w.r.t. user preferences. Finally, WCOP-B improves the overall distortion when the dataset is anonymized with WCOP-CT by editing the most demanding trajectories.

Table 3 displays the results from the experiment previously described. In particular, it lists a number of useful statistics, such as the number of the input (sub-)trajectories, the number of created clusters, the number of trajectories and the number of trajectory points that ended to the trash bin, the discernibility

metric [3], which measures the data quality of the anonymized trajectories, the number of created and deleted points on trajectories, the average spatial and temporal translation per trajectory, the total distortion according to Eq.(2) (for WCOP-B Eq. (7) is used), and the runtime.

In particular, *discernibility* [3] aims at measuring the quality of the sanitized data. Given a set of clusters $C_s = \{C_{s_1}, \dots, C_{s_m}\}$ of D and the trash bin, *Trash*, it is defined as:

$$DM = \sum_{i=1}^n |C_{s_i}|^2 + |Trash| \cdot |D| \quad (6)$$

Lower values of discernibility imply that more data elements are becoming indistinguishable.

Table 3: Comparison of WCOP-NV, WCOP-CT, WCOP-SA (Traclus & Convoys), WCOP-B anonymizing the GeoLife dataset with the same parameters ($k_{max}=5$, $\delta_{max}=250$)

Algor.	WCOP-NV	WCOP-CT	WCOP-SA Traclus	WCOP-SA Convoys	WCOP-B
Stat.					
# (sub-) trajectories	238	238	17,717	272	238
# clusters	21	55	4,412	3	51
# trajectories moved to trash	17	6	83	2	4
# points moved to trash	25,103	9,189	3,634	2,731	5,706
discernibility ($\times 10^3$)	19.7	2.5	1,546	40.4	2.1
# created points	14,995	41,056	176,706	75,785	47,946
# deleted points	56,086	5,118	18,704	26,321	5,509
avg. spatial translation ($\times 10^6$)	453	4,612	48	1,638	525
avg. temporal translation ($\times 10^6$)	31,633	31,244	103	33,752	30,333
total distortion ($\times 10^{12}$)	10.5	8.6	2.5	9.9	8.2
runtime (seconds)	30	30	120	114	414

WCOP-NV causes greater values of distortion when compared to the other approaches. The minimum distortion and the maximum discernibility metric appear when the input is a set of sub-trajectories that are segmented with the use of Traclus algorithm, thus trajectories are assigned to clusters more effectively. Moreover, 7% of the trajectories and 7% of the trajectories' points are trashed when they are anonymized by using universal (k, δ) privacy requirements, in contrast to WCOP-SA Traclus where the corresponding portions reaches 0.4% and 1% respectively. WCOP-B is able to decrease the overall distortion of the dataset by more than 20% when it is anonymized with WCOP-CT via editing the 6 most demanding trajectories (edit step is set to 1). Finally, runtime comparison shows that the approaches that anonymize sub-trajectories are slower than those that anonymize trajectories since a greater number of trajectories is processed. WCOP-B is even slower since every time that trajectories are edited it repeats the anonymization process until the distortion is lower than the threshold.

Based on the visualization of the aforementioned experiments as illustrated in Figure 4, we can conclude that the original trajectory dataset (see Figure 3) was better anonymized by WCOP-CT (Figure 4(b)) than by WCOP-NV (Figure 4(a)).

Clearly, WCOP-NV was not able to maintain the trend of the original trajectories. due to the reduced number of the created clusters. WCOP-CT and WCOP-SA-Convoys (Figure 4(d)) better preserved the pattern of the original trajectories. WCOP-SA-Traclus (Figure 4(c)) reports dense sanitized trajectories due to the segmentation of the original dataset that increased its size by 99%. Thus, we can argue that the result is expected.

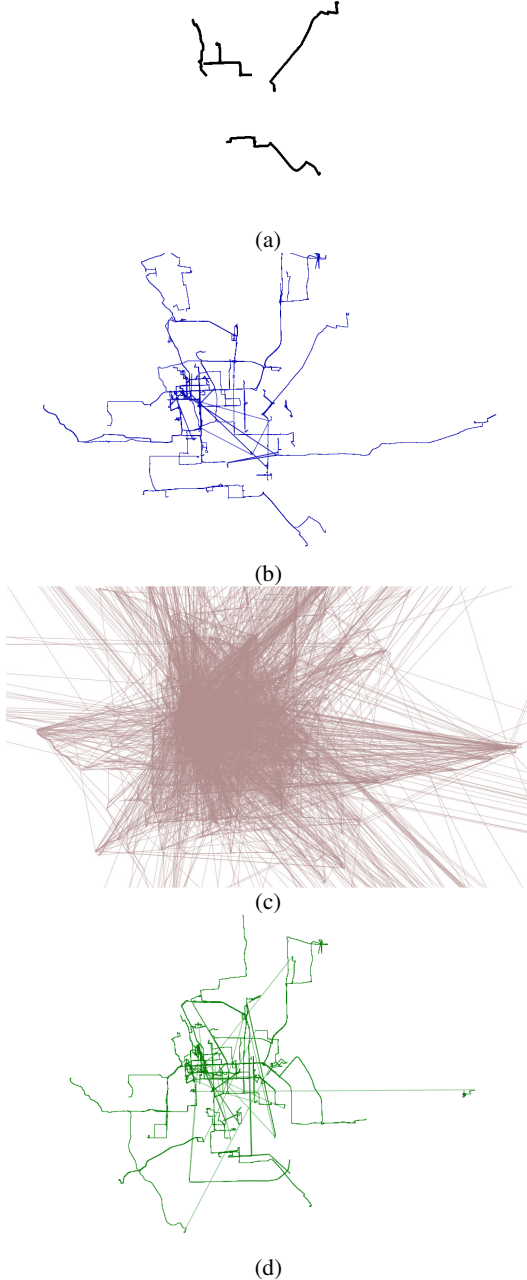

Figure 4: Anonymized trajectories by (a) WCOP-NV; (b) WCOP-CT; (c) WCOP-SA-Traclus; (d) WCOP-SA-Convoys.

6.3 The Effect of (K, δ) Parameters

In this section, we examine the effects of using varying combinations of (K, δ) values with respect to the total information distortion caused by the anonymization. Each trajectory's (k, δ) requirements are randomly generated, with $k \in [2, k_{max}]$, $\delta \in [10, \delta_{max}]$. As mentioned above, δ_{max} parameter has been set to 3% of the dataset bounding rectangle's radius. The k_{max} and δ_{max} variables are varying on each iteration with $k_{max} = \{5, 10, 25, 50, 100\}$ while $\delta_{max} = \{50, 100, 250, 500, 1000, 1400\}$.

Focusing on WCOP-CT, Figures 5(a) and 5(b) provide a visual representation of the total distortion and the discernibility metric, respectively, for different combinations of (k_i, δ_i) . It is clear that WCOP-CT is affected from the changes both in k_{max} and δ_{max} parameters. However, there is a point in Figure 5(a) where while the distortion decreases with the increase of k_{max} , reaching the minimum values when $k=50$, a sudden increase appears when $k=100$. This is due to the fact that the number of the trash size increases up to a point that exceeds $trash_{max}$. When this occurs, $radius_{max}$ is enlarged in order to cluster more trajectories thus the number of the removed trajectories is shrunk but trajectories are spatially translated even more. This trend is obvious at the overall distortion and the discernibility metric when $k_{max}=25$ (Figures 5(a) and 5(b)).

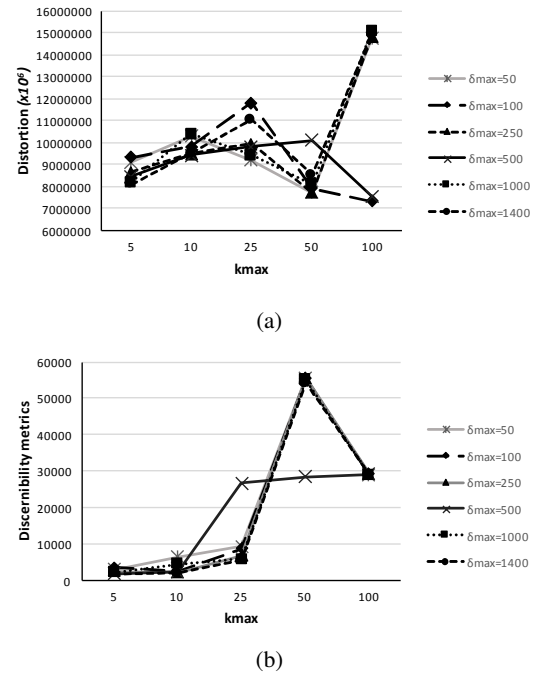

Figure 5: WCOP-CT: (a) total distortion and (b) discernibility for different combinations of (k_{max}, δ_{max}) .

6.4 The Effect of Trajectory Partitioning

In this section, we validate WCOP-SA algorithm. In particular, we compare the effects of using WCOP-CT with two different inputs of the GeoLife dataset, i.e. trajectories after being segmented into sub-trajectories using either Traclus [7] or Convoys [6]. Regarding k and δ , they were again randomly generated with $k \in [2, k_{max}]$ and $\delta \in [10, \delta_{max}]$.

(a)

(b)

Figure 6: total distortion for different combinations of (k_{max} , δ_{max}) using (a) WCOP-SA-Traclus; (b) WCOP-SA-Convoys.

(a)

(b)

Figure 7: discernibility for different combinations of (k_{max} , δ_{max}) using (a) WCOP-SA-Traclus; (b) WCOP-SA-Convoys.

As we observe in the base comparison (see Table 3), partitioning the dataset into sub-trajectories results in very high discernibility, caused by the significantly higher number of clusters. Moreover, the segmentation of trajectories also appears to cause substantially decreased information distortion especially when they were partitioned with the Traclus algorithm. Figures 6(a) and 6(b) illustrate the total distortion in both approaches which rises as the value of k_{max} increases. Discernibility metrics in Figure 7(a) and 7(b) reports that the data quality is maintained either in lower or in higher values of k_{max} . It is worth noting that WCOP-SA with

Traclus manages to increase the average quality by 99% and decrease the average total distortion by 43% compared to the corresponding average values of WCOP-CT. Similarly, WCOP-SA when using the Convoys algorithm increases the average data quality by 31% and decreases the distortion by 2%.

6.5 The Effect of Trajectory Editing

In the final part of our experimental study, we examine the effects of trajectory editing based on the algorithm outlined in Section 5. Two different versions of GeoLife dataset are applied in this set of experiments, using different ranges of randomly assigned (k, δ) values, i.e. [25, 500] and [100, 1400], in order to examine the effect of edit on the final result and how privacy requirements can influence it. Secondly, in order to examine the effects of trajectory editing on datasets of whole trajectories and on datasets consisting of segmented sub-trajectories, we apply WCOP-B in both types of data.

Figure 8(a) illustrates the effects of editing various numbers of trajectories for a dataset that corresponds to medium demanding users. In contrast, Figure 8(b) depicts the respective outcome but for much more demanding users. It is obvious that most of the approaches decreased 10% of their distortion by only editing the top-5 demanding trajectories apart from WCOP-SA-Traclus due to the increased number of sub-trajectories.

(a)

(b)

Figure 8: WCOP-B: distortion for varying edit size values where (a) $k_{max} = 25$ and $d_{max} = 500$; (b) $k_{max} = 100$ and $d_{max} = 1400$.

It is not only that distortion changes in a non-monotone as edit size increases; we also observe that it can actually increase as edit size increases. This is due to the fact that each edited trajectory incurs a distortion penalty, which grows proportionally to the edit-size. However, the distribution of demanding trajectories across

the clusters and the distribution of (k, δ) values in the dataset significantly influence the degree to which relaxing additional trajectories' requirements affect the clustering and anonymization phases. Therefore, higher percentage of edited trajectories does not guarantee decreased distortion, indicating that there exists an 'optimal' edit-size value, where distortion is the minimum possible.

7. CONCLUSIONS

In this paper, we proposed a novel approach for anonymizing trajectories called Personalized (K, Δ) -Anonymity, which uses user-specific privacy requirements. Based on this framework, we have developed WCOP-CT algorithm, which takes advantage of user-specific (k, δ) requirements in order to assign trajectories to clusters of minimal size, so as to avoid over-anonymization, increase data quality and decrease distortion. Expanding upon that framework, we made use of dataset-aware trajectory segmentation, in order to further improve our approach's effectiveness, by partitioning trajectories to sub-trajectories that are more easily assignable to clusters. Additionally, we examined the concept of Bounded (K, Δ) -Anonymity, whereby there is a threshold to the acceptable distortion caused by the anonymization process, and proposed methods for trajectory assessment and editing by relaxing the requirements of the most demanding trajectories without editing the spatiotemporal data.

To show the effectiveness of our methods, we have performed experiments using the GeoLife dataset. Our personalized anonymity approach has been shown to significantly increase to the overall quality and to decrease of the total distortion of the anonymized datasets, while it has also been demonstrated that trajectory segmentation can improve data quality even further. Experimental results also show that our trajectory assessment and editing algorithms perform very well towards the goal of decreasing data distortion without altering the trajectories' spatiotemporal information itself.

Overall, we argue that we have provided a novel approach in mobility data anonymization. Using our WCOP suite of techniques, data analysts are able to preserve the quality of anonymized datasets taking advantage of user-specific privacy requirements combined with methods such as segmentation and trajectory editing. However, there is a number of points, such as sensitivity to (k, δ) values distribution, replacement of greedy clustering with a more sophisticated clustering method, sensitivity to segmentation method and alternative trajectory assessment and editing methods, which deserve further study in order to expand and improve upon the framework presented here.

ABSTRACT

The amount of crowdsourced geospatial content on the Web is constantly increasing, providing a wealth of information for a variety of location-based services and applications. This content can be analyzed to discover interesting locations in large urban environments which people choose for different purposes, such as for entertainment, shopping, business or culture. In this paper, we focus on the problem of identifying and describing Streets of Interest. Given the road network in a specified area, and a collection of geolocated Points of Interest and photos in this area, our goal is to identify the most interesting streets for a specified category or keyword set, and to allow their visual exploration by selecting a small and spatio-textually diverse set of relevant photos. We formally define the problem and we present efficient algorithms, based on spatio-textual indices and filter and refinement strategies. The proposed methods are evaluated experimentally regarding their effectiveness and efficiency, using three real-world datasets containing road networks, POIs and photos collected from several Web sources.

1. INTRODUCTION

A large amount of user-generated content is becoming available on the Web daily, with increasingly large portions of it being associated with geospatial information. Typical examples include maps of road networks and other spatial features available on OpenStreetMap and Wikimapia, information about *Points of Interest* (POIs) from Wikipedia and Foursquare, geotagged photos from Flickr and Panoramio. This creates a valuable resource for discovering and exploring locations and areas of interest, with numerous applications in location-based services, geomarketing, trip planning, and other domains. In this paper, we advocate the use of *street* as the elemental area of interest in modern cities, and tackle two complementary problems, *identifying* and *describing* them.

Regarding the first task, there has been substantial work in identifying a *single POI*, based on spatial and textual criteria. More precisely, spatio-textual similarity queries, aim at retrieving POIs that are both spatially close to a given location and textually relevant to a given set of keywords specifying an information need [9]. Additional metadata associated to the POIs, such as ratings, comments, “likes” or check-ins, can be considered to weigh the *importance*

of each POI when computing the ranking. The proximity of a POI to other relevant POIs has also been considered as a factor indicating importance [5]. Furthermore, in Location-Based Social Networks, information about social connectivity is also considered in determining the importance of POIs (and users) [4, 2].

A line of work more related to our first task deals with discovering a set of nearby and topically related POIs, that designate a *Region of Interest*. This is a more challenging problem, and proposals mainly differ in the way regions are formed. The majority of past research addresses the *maximum range sum problem*, where the region is defined as either a rectangle of fixed length and width [21, 24, 10], or a disk with fixed radius [10], and the objective is to find the one that maximizes an aggregate importance score on the topically relevant POIs it contains. Other works do not enforce a constraint on region shape or size, and rather implement density-based clustering of POIs [20, 19].

All aforementioned works assume that POIs are located in a Euclidean space. However, particularly in urban environments, it is often more realistic and useful to consider the underlying road network. Grouping together nearby POIs makes little sense if the actual travel distance between them is large, e.g., when they are located in opposite banks of a river. Surprisingly, little work is done in this frontier. In [7], the authors look for a connected subgraph of the road network that maximizes an aggregate score on the relevant POIs that are included, subject to a constraint on its total length.

Nonetheless, such an approach also has shortcomings. First, the fact that there is no control on the *subgraph type* may result in returning oddly-shaped regions that are hard to inspect and not particularly meaningful in a user exploration setting. Additionally, the approach favors *POI quantity* over density. More often than not, there exists a single popular street with a high density of POIs. Using the formulation of [7], such a street would be in the result but accompanied by several other smaller adjacent streets that happen to have at least one relevant POI. Similarly, looking for *connected components* may lead to discovering artificial links among important streets for the sole purpose of ensuring connectivity. Another limitation is that [7] assumes POIs are conveniently situated on the road network as vertices. In reality, however, the situation is much different. Figure 1(a) shows the map of a popular corner (Oxford Str. and Regent Str.) in the center of London, and also depicts various types of POIs. It should be apparent that there is no straightforward mapping of POIs to the road network vertices. Instead, it is more natural to “assign” POIs to edges (streets) but not necessarily in an exclusive manner. For example a POI (e.g., the clothing shop in Figure 1(a)) near the corner should be associated with both intersecting streets. Moreover, a POI (e.g., the photo shop in Figure 1(a)) farther from the streets but inside a corner building should also contribute to the importance of the main crossing streets.

Figure 1: Illustrative example for shopping streets in the center of London.

Motivated by these observations, we formulate the problem of *identifying Streets of Interest* (SOIs). Briefly, given some textual information (keywords, categories) the goal is to identify the streets (more accurately the street segments) that have a large density of relevant POIs around them. An example for the center of London is illustrated in Figure 1(b), where the top 20-SOIs are highlighted with red. Notice that the returned streets are not connected via non-interesting streets. Moreover, our ranking approach naturally allows for an exploratory search of the area. To efficiently retrieve a ranked list of SOIs, we propose an algorithm inspired from top- k query processing that operates on top of spatio-textual indices.

Although very helpful, identifying the main SOIs for the user’s keywords is only the first step towards exploring a larger area. Typically, the user then needs to find more information and gain more insights about those results that are discovered and suggested. For this purpose, perhaps the easiest and most effective way is by providing visual information; thus, a valuable source is the numerous relevant photos that can be found in various Web sources, such as Flickr and Panoramio. The challenge that arises then is how to select a small set of results to present, in order to avoid overloading the user, especially when using a mobile device with limited resources in terms of bandwidth, screen size and battery, while still providing enough information. This can be achieved by *diversifying* the results to present, so that more and different information can be conveyed with fewer results.

To that end, the second task we address in this paper refers to the selection of a concise and spatio-textually diverse set of relevant photos for describing the discovered SOIs. We follow the general diversity principles from information retrieval [16, 8], and formulate a *spatio-textual SOI diversification* problem. In particular, we introduce spatial and textual measures of *relevance* and *diversity*, and seek to extract a small set of photos that act as an informative summary of a given SOI (see the example in Figure 1(c) for a 4-photo summary of Oxford Str). As this is a computationally hard problem, we turn into heuristic methods supported by appropriate spatio-textual indices.

The main contributions of our work can be summarized as follows:

- We formally define the top- k SOI query, and we present an efficient algorithm for its evaluation.
- We present spatio-textual relevance and diversity criteria for selecting subsets of available photos to describe SOIs, and we propose an efficient approximation algorithm for their computation.
- We present the results of an experimental evaluation of our proposed methods, using real-world datasets containing road

networks, POIs and photos from several major Web sources, covering the areas of three different European capital cities.

The rest of the paper is organized as follows. Section 2 discusses related work. Section 3 formally introduces the problem of finding k -SOIs, and presents an efficient algorithm for their computation. Section 4 presents measures for spatio-textual relevance and diversity, and an efficient approximation algorithm for selecting diversified subsets of relevant photos to describe SOIs. Finally, Section 5 presents the results of our experimental evaluation, while Section 6 concludes the paper.

2. RELATED WORK

This section reviews existing approaches for spatio-textual POI retrieval and diversification.

2.1 Ranking Points and Areas of Interest

Numerous works have focused on discovering and ranking points or areas of interest, based on various definitions and criteria. The main differences involve the following aspects: (a) whether the focus is on single POIs or whole areas, i.e. sets of POIs; (b) whether the problem involves nearby search around a given query location or rather browsing and exploration within a whole area; (c) whether the aim is to maximize the number or the total score (e.g. relevance or importance) of the POIs enclosed in the discovered area or to minimize some cost function (e.g. distance or travel time) on a set of POIs that suffice for covering the query keywords.

The majority of existing works focuses on the ranking of single POIs. Location-aware top- k text retrieval queries have been studied in [11]. Given the user location and a set of keywords, this query returns the top- k POIs ranked according to both their spatial proximity and their textual relevance to the query. For the efficient evaluation of such queries, a hybrid indexing approach was proposed, integrating the inverted file for text retrieval and the R-tree for spatial proximity querying. Further variations on spatio-textual queries and indexes have been extensively studied [9]. Top- k spatial keyword queries have been studied also in [23], with distances being calculated on the road network instead of the Euclidean space. A different perspective for ranking POIs is taken in [5], where the importance of a POI takes into account the presence of other relevant nearby POIs.

Queries involving sets of spatio-textual objects have been investigated in [6, 27]. Given a set of keywords and, optionally, a user location, the goal is to identify sets of POIs that collectively satisfy the query keywords while minimizing the maximum distance or the sum of distances between each other and to the query.

More recently, other works have focused on discovering regions

of interest w.r.t. a specified category or set of keywords, where the importance of a region is determined based on the number or the total weight of relevant POIs it contains. In [19], density-based clustering is applied to identify regions with high concentration of POIs of certain categories, collected and integrated from several Web sources. A method for extracting scenic routes from geo-tagged photos uploaded on sites such as Flickr and Panoramio is presented in [3]. Discovering and recommending regions of interest based on user-generated data is also addressed in [20]. The quality of a recommended area is determined based on the portion of the contained POIs that can be visited within a given time budget. Other variations of queries for discovering interesting regions include the subject-oriented top- k hot region query [21] and the maximizing range sum query [10]. The region is defined by a rectangle or circle with a maximum size constraint, and the goal is to maximize the score of the relevant POIs contained in it.

The most closely related work to our approach is [7], which proposes the length-constrained maximum-sum region query. Given a set of POIs in an area and a set of keywords, this query computes a region that does not exceed a given size constraint and that maximizes the score of the contained POIs that match the query keywords. The query assumes an underlying road network, in which the POIs are included as additional vertices, and the returned region has the form of a connected subgraph of this network with arbitrary shape. The problem is shown to be NP-hard, and approximation algorithms are proposed.

This problem is similar to our setting; in both cases, the goal is to discover interesting parts of a road network that are associated with large number of POIs relevant to a given set of keywords. However, in [7], the result is a single connected subgraph of the road network, maximizing the score of contained points, while our method returns a ranked list of streets that are not necessarily connected and are ordered according to their density w.r.t. POIs relevant to the query. Moreover, we additionally consider the problem of describing these discovered streets by means of a diversified set of photos, which is not addressed in [7] or any of the other works mentioned before.

Finally, in a different line of research, other works have applied probabilistic topic modeling on user-generated spatio-textual data and events to associate urban areas with topics and patterns of user mobility and behavior [18, 15].

2.2 Search Results Diversification

Information retrieval engines often try to improve the utility of the search results by taking into account not only their relevance to the user's query, but also their dissimilarity, offering thus a range of alternatives, which comes handy in situations where the true intent of the user is unknown or many highly similar objects exist. Stated in an abstract manner, the content-based diversification problem is to determine a set of objects that maximizes an objective function with two components, the relevance and the diversity.

While there exist many different formulations (refer to [16, 13] for classification), the most well-known is the MaxSum problem, where the goal is to maximize the weighted sum of two components, the total relevance of objects, and the sum of pairwise diversities among the objects. Similar to other diversification problems, MaxSum is NP-hard as it is related to the dispersion problem [22]. Therefore, various greedy heuristics are proposed. Typically, they incrementally construct the diversified result set by choosing at each step the object that maximizes a certain scoring function. The most well-known function is the *maximal marginal relevance* (*mmr*) [8]. An evaluation of various object scoring functions and different heuristics can be found in [26].

Since [8], several works addressed other diversification prob-

lems, such as taxonomy/classification-based diversification [1], [25] or multi-criteria diversification [12]. Another related work is the coverage problem [14], where the goal is to select a set of diverse objects that cover the entire database.

3. IDENTIFYING STREETS OF INTEREST

We first formulate the problem of identifying interesting streets, and then present our proposed approach.

3.1 Problem Definition

A road network is a directed graph $G = (\mathcal{V}, \mathcal{L})$, where the set of vertices \mathcal{V} contains street intersections or breakpoints in streets, and the set of links \mathcal{L} contains street segments (between intersections or breakpoints) represented as line segments. Each vertex $v \in \mathcal{V}$ is associated with its coordinates (x_v, y_v) . The length $len(\ell)$ of a segment $\ell \in \mathcal{L}$ is computed as the Euclidean distance between its endpoints. We also consider the set of streets \mathcal{S} , where each street $s \in \mathcal{S}$ comprises a set of consecutive segments (a simple path on G). Each segment $\ell \in \mathcal{L}$ belongs to a unique street s , and we denote this relationship by $\ell \in s$. The length $len(s)$ of street s is the sum of the length of its segments.

Moreover, we define an additional data source \mathcal{P} , being a set of POIs. Each POI $p \in \mathcal{P}$ is defined by a tuple $p = \langle (x_p, y_p), \Psi_p \rangle$, where (x_p, y_p) are the coordinates of the POI, and Ψ_p is a set of keywords describing this POI (e.g., keywords derived from its name, description, tags). The distance $dist(p, \ell)$ of a POI p to a line segment ℓ is defined as the minimum Euclidean distance between POI location (x_p, y_p) and any point on ℓ . Accordingly, the distance of POI p to a street s is the minimum distance of p to any segment of s , i.e., $dist(p, s) = \min_{\ell \in s} dist(p, \ell)$.

To measure the interest of a street segment w.r.t. a given set of keywords, we use the notion of *mass*, which refers to the number of relevant POIs that exist in its proximity. Then, we rank segments according to their *mass density*, to account also for the different lengths of each segment. We formally define these concepts below.

DEFINITION 1 (SEGMENT MASS). *For a given set of keywords Ψ and a distance threshold ϵ , the mass of segment ℓ is the number of POIs within distance ϵ that contain at least one keyword from Ψ :*

$$mass(\ell | \Psi, \epsilon) = |\{p \in \mathcal{P} : dist(p, \ell) \leq \epsilon \ \& \ \Psi_p \cap \Psi \neq \emptyset\}|.$$

Note that this definition can be straightforwardly adapted in the case that POIs have different weights.

DEFINITION 2 (SEGMENT INTEREST). *The interest of segment ℓ is its mass density, i.e., the ratio of ℓ 's mass over the size of the area within distance ϵ around ℓ :*

$$int(\ell | \Psi, \epsilon) = \frac{mass(\ell | \Psi, \epsilon)}{2\epsilon len(\ell) + \pi\epsilon^2}.$$

Given this definition for the interest of a segment, there exist several alternatives for defining the interest of an entire street. Here, we use a simple definition, as stated below.

DEFINITION 3 (STREET INTEREST). *Given Ψ and ϵ , the interest of a street s is the maximum interest among its segments, i.e.:*

$$int(s | \Psi, \epsilon) = \max_{\ell \in s} int(\ell | \Psi, \epsilon). \quad (1)$$

Based on these definitions, a k -SOI query returns the k most interesting streets.

Problem 1. [k -SOI] Assume a set of streets \mathcal{S} , forming a road network G , and a set of POIs \mathcal{P} . The k -Streets of Interest (k -SOI)

query $q = \langle \Psi, k, \epsilon \rangle$, where Ψ is a set of keywords, k a positive integer, and ϵ a distance threshold, returns a set of k streets S^k such that for each $s' \notin S^k$ it holds that $\text{int}(s' | \Psi, \epsilon) \leq \min_{s \in S^k} \text{int}(s | \Psi, \epsilon)$.

3.2 The SOI Algorithm

In what follows, we present the SOI (Streets Of Interest) algorithm. We assume a given query $q = \langle \Psi, k, \epsilon \rangle$; for brevity, Ψ and ϵ are omitted when it is clear from the context.

3.2.1 Methodology and Indices

The SOI algorithm for processing k -SOI queries operates in a manner reminiscent of top- k processing algorithms [17]. It progressively examines segments of streets and POIs until it can establish that the k -SOI can be determined solely from the information already collected. Specifically, SOI maintains a *seen lower bound* LB_k on the interest of the k best streets encountered so far, and an *unseen upper bound* UB on the interest of any street for which no segment has been encountered yet. As more segments are considered, LB_k progressively increases, while UB progressively decreases. When LB_k becomes not smaller than UB , the examination stops, since the k -SOIs are those streets with interest not smaller than LB_k .

Under the aforementioned strategy, there are two issues to address: (1) how to compute the seen lower bound LB_k and the unseen upper bound UB , and (2) how to expedite the termination condition, $LB_k \geq UB$.

We address the former first, as its solution gives intuition about the latter. Based on the definition of street interest (Equation 1), we can compute bounds on the interest of a street s by considering directly the segments. The following lemma suggests a method to compute LB_k and UB ; their exact definition is presented later.

LEMMA 1. Consider a subset of segments $\mathcal{L}_{seen} \subseteq \mathcal{L}$. Then, for a street s it holds that:

$$\begin{aligned} \text{int}(s) &\geq \max_{\ell \in s \cap \mathcal{L}_{seen}} \text{int}(\ell), & \text{if } s \cap \mathcal{L}_{seen} \neq \emptyset \\ \text{int}(s) &\leq \max_{\ell \in \mathcal{L} \setminus \mathcal{L}_{seen}} \text{int}(\ell), & \text{if } s \cap \mathcal{L}_{seen} = \emptyset. \end{aligned}$$

PROOF. For the first case observe that $s \cap \mathcal{L}_{seen} \subseteq s$, and thus $\max_{\ell \in s \cap \mathcal{L}_{seen}} \text{int}(\ell) \leq \max_{\ell \in s} \text{int}(\ell) = \text{int}(s)$. For the second case observe that $\mathcal{L} \setminus \mathcal{L}_{seen} \supseteq s$, and thus $\max_{\ell \in \mathcal{L} \setminus \mathcal{L}_{seen}} \text{int}(\ell) \geq \max_{\ell \in s} \text{int}(\ell) = \text{int}(s)$. \square

Consider a seen street s , meaning that one of its segments has been encountered, i.e., $s \cap \mathcal{L}_{seen} \neq \emptyset$. The first case of Lemma 1 implies that a lower bound on the interest of s can be extracted from the largest interest of its seen segments, or, more practically, from the largest lower bound on the interest of any of its seen segments.

On the other hand, consider an unseen street s , i.e., $s \cap \mathcal{L}_{seen} = \emptyset$. The second case of Lemma 1 implies that an upper bound on the interest of s can be extracted from the largest possible interest among unseen segments, or, more practically, from an upper bound on the largest possible interest among unseen segments.

In other words, Lemma 1 directly addresses the former issue. However, it also suggests how to address the latter. Suppose we have encountered a set of segments \mathcal{L}_{seen} . What segments should it contain so as to increase the chances of satisfying the termination condition? To obtain a high seen lower bound LB_k , the first case of Lemma 1 suggests putting in \mathcal{L}_{seen} segments with high interest. Moreover, to obtain a small unseen upper bound UB , the second case of Lemma 1 suggests leaving out from \mathcal{L}_{seen} segments with

low interest. Therefore, the algorithm should try to visit segments with large interest first.

As it is impractical to directly retrieve segments by interest (that would require precomputation for all possible k -SOI queries, i.e., for arbitrary ϵ, Ψ), we need a way to identify promising segments having large interest. To this end, we employ the following data structures.

- A *spatial grid index* with arbitrary cell size storing all POIs. Within each cell c , there is a *local inverted index* on the set of keywords among the cell POIs. The entry for keyword ψ is a list of POIs sorted increasingly on POI id.
- A *global inverted index* on the set of all keywords. The entry for keyword ψ is a list of $\langle c, \text{numPOIs} \rangle$ entries sorted decreasingly on numPOIs , which is the number of POIs within cell c that contain keyword ψ .
- A *cell-to-segment map* that stores for each grid cell the segments that pass through it. At query time when ϵ is known, the map is augmented to contain for each cell all segments that are within distance ϵ . We denote the augmented list for cell c as $\mathcal{L}_\epsilon(c)$.
- A *segment-to-cell map* that stores for each segment the grid cells that it intersects. At query time when ϵ is known, the map is augmented to contain for each segment all cells that are within distance ϵ . We denote the augmented list for segment ℓ as $\mathcal{C}_\epsilon(\ell)$.
- A *list of segments* sorted increasingly on their length.

Note that since street segments and POIs are relatively static, these data structures can be created and maintained offline.

3.2.2 Algorithm Description

In what follows, we discuss the case of a query specifying a single keyword, i.e., $\Psi = \{\psi\}$. Intuitively, we look for segments that have large *mass* and small *len*. Thus, given the above data structures, we look for segments that (1) are close (within distance ϵ) to cells with large number of relevant POIs (satisfying ψ), (2) are close to many cells, and (3) have small *len*. The first two factors combined contribute to the *mass*, while the third directly to *len*. Therefore, the algorithm considers segments according to the following three ranked source lists constructed, in part, at query time.

SL_1 : Contains all cells sorted decreasingly on the number of POIs with keyword ψ . This is essentially the list of the global inverted index for keyword ψ .

SL_2 : Contains all segments sorted decreasingly on the number of cells within distance ϵ to them (the cells each segment intersects when enlarged by ϵ).

SL_3 : Contains all segments, sorted increasingly on their length.

The algorithm proceeds iteratively, considering in each iteration either the next cell from SL_1 or the next segment from SL_2 or SL_3 . Each source list can be accessed in a round robin fashion; the correctness of our method is not affected by the access strategy. In practice, we alternate between SL_1 and SL_3 , trying to balance the number of segments considered from each source; each cell access results in the access of multiple segments, while each segment access causes the visit of multiple cells. We only access segments via the second source SL_2 in the case that a few segments with a large number of neighboring cells exist.

During the processing of k -SOI, a segment can be in three possible states. Initially, a segment is *unseen*, meaning that the algorithm

has not considered it via any source. An efficient algorithm would leave many segments in the unseen phase. Then, when a segment is first retrieved, it is put into the *partial* state, meaning that some, but not all, POIs near it that satisfy the query have been accounted for. For each partial segment ℓ , we maintain two pieces of information: (1) the count $mass^-(\ell)$ of relevant POIs seen so far that satisfy the query, and (2) a list $toVisit$ indicating which neighboring cells (and consequently their POIs) to visit. Based on these, we can compute a lower bound on ℓ 's interest as:

$$int(\ell) \geq int^-(\ell) = \frac{mass^-(\ell)}{2\epsilon len(\ell) + \pi\epsilon^2}.$$

Once all relevant POIs have been processed (equivalently, all neighboring cells have been visited), the segment is in the *final* state, where its exact interest is known.

Algorithm 1 presents the pseudocode for the SOI algorithm. During initialization, SOI prepares the three source lists. Particularly, it builds SL_1 by examining the global inverted index (lines 1–3); for the simple case of one keyword ψ , SL_1 is essentially the inverted list $I[\psi]$. Moreover, source list SL_3 corresponds to the list of segments, while SL_2 is extracted from the augmented segment-to-cell map (lines 4–7).

Then, SOI proceeds to the main filtering phase (lines 8–24), where segments from the source lists are examined until the termination condition $LB_k \geq UB$ holds; initially LB_k and UB are set to zero and infinity, respectively (line 9).

Assume that cell c via source list SL_1 is to be accessed (lines 11–15). For this cell we examine the segments that are within distance ϵ (lines 13–14), and for each segment we determine the number of POIs with keyword ψ that are within distance ϵ so as to update their interest score given the contents of cell c . Specifically, we employ the cell-to-segment map to determine all segments $\mathcal{L}_\epsilon(c)$ that are within distance ϵ to cell c (line 13). For each such segment ℓ , we invoke the procedure `UpdateInterest` (line 14), whose pseudocode is also depicted. After the procedure returns, we set the next source list to consider according to round robin (line 15).

Procedure `UpdateInterest` first checks whether cell c has been visited for ℓ and immediately returns if so. Otherwise, it removes c from the $toVisit$ list. Then it visits the local inverted index of cell c and retrieves the list for keyword ψ . For each POI p in the list, `UpdateInterest` checks whether it is within distance ϵ to segment ℓ , and if true increments $mass^-(\ell)$ by one.

Now, assume that segment ℓ is to be accessed (lines 16–21), either via source list SL_3 or SL_2 . Its exact interest will be determined, changing its state to final. Using the segment-to-cell map, we visit sequentially all neighboring cells of ℓ , and invoke procedure `UpdateInterest` (lines 18–19). A cell visited during some segment access, may be again visited due to another segment's access or via a direct cell access via source list SL_1 . The next step is to properly set the next source list to consider (lines 20–21).

After each access, cell or segment, algorithm SOI checks whether the termination condition applies. It first computes an upper bound UB on the interest of any *unseen* segment (line 22). Let $top(SL_1)$, $top(SL_2)$, $top(SL_3)$ denote the top items in the corresponding sources lists that are to be accessed next. Due to the second case of Lemma 1, it computes the unseen interest upper bound as:

$$UB = \frac{top(SL_1) \cdot top(SL_2)}{2\epsilon top(SL_3) + \pi\epsilon^2}.$$

SOI also computes a lower bound LB_k on the interest of the k -SOIs based on the first case of Lemma 1 (lines 23–24). It maintains all seen segments in a ranked list \mathcal{L}_{seen} sorted decreasingly on the interest lower bound $int^-(\cdot)$. Let $\mathcal{L}_{seen}[i]$ denote the first i items

Algorithm 1: Algorithm SOI

Input: network G , streets S , query $q = \langle \Psi, k, \epsilon \rangle$
Output: k -SOIs S^k

24 $LB_k \leftarrow int^-(\ell_\mu)$
 \triangleright refinement phase
25 **foreach** $\ell \in \mathcal{L}_{seen}$ **do**
26 **foreach** $c \in \mathcal{C}_\epsilon(\ell)$ **do** $\triangleright \ell$ within distance ϵ to c
27 \triangleright UpdateInterest(ℓ, c, Ψ)
28 **return** $S^k \leftarrow$ extract k -SOIs from \mathcal{L}_{seen}

Procedure UpdateInterest(ℓ, c, Ψ)

1 **if** $c \notin \ell.toVisit$ **then return** $\triangleright c$ is already visited for ℓ
2 remove c from $\ell.toVisit$
 \triangleright traverse lists $c.I(\psi), \forall \psi \in \Psi$ synchronously
3 **foreach** $p \in \bigcup_{\psi \in \Psi} c.I(\psi)$ **do**
4 $mass^-(\ell) \leftarrow mass^-(\ell) + 1$

in the list. Then, LB_k is set to the interest lower bound of the μ -th ranked segment ℓ_μ provided that μ is the smallest index such that the segments of $\mathcal{L}_{seen}[\mu]$ belong to k distinct streets, i.e.,

$$LB_k = int^-(\ell_\mu), \text{ for } \mu = \min_i : |\{s \mid \exists \ell \in \mathcal{L}_{seen}[i], \ell \in s\}| = k.$$

The accesses on source lists stop as soon as $UB \leq LB_k$. At that point, it is guaranteed that the result to k -SOI can be extracted from the segments in \mathcal{L}_{seen} . To identify the streets with the top- k interest, a refinement phase begins (lines 25–28). The exact interest of each segment in \mathcal{L}_{seen} is computed by invoking `UpdateInterest` as necessary. The extraction of the streets with the highest interest, i.e., the k -SOI, is then straightforward.

A final note concerns the case of multiple keywords Ψ in the query. The SOI algorithm changes in only two places. The first is when source list SL_1 is built. It is necessary to account for POIs that have any keyword among those in Ψ . SOI looks within the global inverted index, for each entry $I[\psi][c]$ corresponding to the entry for cell c in the list for keyword ψ . This entry contains the count of POIs in cell c that have keyword ψ . Adding these counts for all keywords provides an upper bound to the number of POIs within c that have any keyword among Ψ . The minimum of this number and the total number $|\mathcal{P}_c|$ of POIs in the cell (line 2) is then inserted into SL_1 . The second change is in the `UpdateInterest` procedure. To compute for segment ℓ the exact number of POIs within cell c that satisfy Ψ , lists $c.I[\psi]$ for each $\psi \in \Psi$ are tra-

versed in parallel; recall that the lists are sorted by POI id. For each encountered POI, the mass of ℓ is incremented.

4. DESCRIBING STREETS OF INTEREST

Having identified the k -SOIs in the road network, the next step is to provide summarized information to describe them. Section 4.1 formalizes the problem, while Section 4.2 describes our solution.

4.1 Problem Definition

We begin by formalizing the problem, and then present details about the measures considered.

4.1.1 Problem Statement

In the following, we assume an additional data source \mathcal{R} , being a set of geo-tagged photos. Each photo $r \in \mathcal{R}$ is defined by a tuple $r = \langle (x_r, y_r), \Psi_r \rangle$, specifying its location and a set of keywords (its tags); the distance of a photo to a segment or a street is defined as in the case of a POI.

To describe a SOI, we exploit its related photos. For each street s , these are the photos that are located within distance ϵ , i.e. $\mathcal{R}_s = \{r \in \mathcal{R} : \text{dist}(r, s) \leq \epsilon\}$. However, the size of \mathcal{R}_s can typically be quite large. Thus, the problem is to select a relatively small subset of k photos ($k \ll |\mathcal{R}_s|$) to present as an overview for the street s . To avoid redundancy and repetition, we formulate the problem as a MaxSum diversification problem, where a subset of items is selected from a set in such a way as to maximize both their relevance to a given need and their pairwise dissimilarity. More formally, the problem can be defined as a bi-criteria optimization problem, aiming at optimizing an objective function \mathcal{F} that comprises a *relevance* component and a *diversity* component [16, 26].

Let R^k be a subset of \mathcal{R}_s of size k , and let $\text{rel}(R^k)$ and $\text{div}(R^k)$ be two functions that measure, respectively, the relevance and the diversity of the contents of R^k . Then, the problem is to select among all possible subsets R^k the one that maximizes the function \mathcal{F} defined as follows:

$$\mathcal{F}(R^k) = (1 - \lambda) \cdot \text{rel}(R^k) + \lambda \cdot \text{div}(R^k) \quad (2)$$

where $\lambda \in [0, 1]$ is a parameter determining the tradeoff between relevance ($\lambda = 0$) and diversity ($\lambda = 1$).

Problem 2. [SOI Diversification] Given a street s with an associated set of photos \mathcal{R}_s , where each photo has a geolocation and a set of keywords, select a subset R^k of \mathcal{R}_s containing k photos such that the objective function \mathcal{F} is maximized, i.e.:

$$R^k = \arg \max_{R \subseteq \mathcal{R}_s, |R|=k} \mathcal{F}(R) \quad (3)$$

We proceed to define the functions $\text{rel}(R^k)$ and $\text{div}(R^k)$ for our problem. Note that the value of k throughout this section refers to the number of photos describing a street, and is thus unrelated to the value of k in Section 3 which refers to the number of SOIs.

4.1.2 Spatio-Textual Relevance and Diversity

The function \mathcal{F} described above provides a generic criterion for selecting a subset of items that are both relevant and diverse w.r.t. a given query. In our context, this needs to take into account both the spatial and the textual description of a street. In particular, the *spatial aspect* of a street s is determined by the locations of its associated photos \mathcal{R}_s . The *textual aspect* of s is captured by a keyword frequency vector Φ_s , which describes the strength of each keyword associated with s ; we denote as Ψ_s the set of keywords with non-zero frequency in Φ_s . Note that there are many ways

to derive the keyword frequency vector of a street; for example, we can extract it directly from a textual description, or from the keywords of its neighboring POIs and/or photos.

The relevance and diversity functions of a set R^k of photos should thus capture both aspects. Assuming a weight parameter $0 \leq w \leq 1$ between the two aspects, we define:

$$\text{rel}(R^k) = \frac{w}{k} \sum_{r \in R^k} \text{spatial_rel}(r) + \frac{1-w}{k} \sum_{r \in R^k} \text{textual_rel}(r) \quad (4)$$

and

$$\begin{aligned} \text{div}(R^k) = & \frac{2w}{k(k-1)} \sum_{r, r' \in R^k} \text{spatial_div}(r, r') \\ & + \frac{2(1-w)}{k(k-1)} \sum_{r, r' \in R^k} \text{textual_div}(r, r'). \end{aligned} \quad (5)$$

Notice that the relevance of set R^k is defined as the sum of the spatial and textual relevance of each photo $r \in R^k$, whereas the diversity of R^k is the sum of the pairwise spatial and textual diversity over all photo pairs $r, r' \in R^k$. To balance the different number of summands in $\text{rel}(R^k)$ and $\text{div}(R^k)$, we normalize them using the fractions $\frac{1}{k}$ and $\frac{2}{k(k-1)}$, respectively. Next, we define the four functions that account for spatio-textual relevance and diversity.

Spatial relevance and diversity. For a point query, the spatial distance of an item to the query point would typically constitute a natural way to measure relevance. However, in our case, ranking the photos of a street according to their distance from it does not generally provide an indicative criterion for judging relevance. Thus, we select instead a different criterion, based on spatial coverage. The intuition is that high density of photos in an area can be considered as an indication of “importance”; thus, the selection of photos should be biased towards those areas. Accordingly, we define the spatial relevance of a photo based on the number of other photos contained in its neighborhood. Furthermore, we divide this number to the total number of photos associated with the street, in order to obtain a normalized value in the range $[0, 1]$.

DEFINITION 4 (SPATIAL RELEVANCE). Assuming a radius ρ for the neighborhood of a photo r , we define the spatial relevance of r w.r.t. the street s as:

$$\text{spatial_rel}(r) = \frac{|\{r' \in \mathcal{R}_s : \text{dist}(r, r') \leq \rho\}|}{|\mathcal{R}_s|}. \quad (6)$$

The spatial diversity of a pair of photos r, r' can be defined by means of their spatial distance. For normalization, we divide the distance of the pair with $\text{maxD}(s)$, which is the largest possible distance between any two photos associated with s . Value $\text{maxD}(s)$ is computed as the length of the diagonal of the minimum bounding rectangle, extended with a buffer of size ϵ , that encloses s . Thus:

DEFINITION 5 (SPATIAL DIVERSITY). We define the spatial diversity of two photos r, r' associated with street s as:

$$\text{spatial_div}(r, r') = \frac{\text{dist}(r, r')}{\text{maxD}(s)}. \quad (7)$$

Textual relevance and diversity. The textual relevance of a photo r measures the similarity of its textual description Ψ_r to the textual aspect of street s as captured by its keyword frequency vector Φ_s .

DEFINITION 6 (TEXTUAL RELEVANCE). *The textual relevance of a photo r to street s is defined as:*

$$\text{textual_rel}(r) = \frac{\sum_{\psi \in \Psi_r} \Phi_s(\psi)}{\|\Phi_s\|_1}, \quad (8)$$

where $\|\Phi_s\|_1 = \sum_{\psi \in \Psi_s} \Phi_s(\psi)$ is a normalization term.

Finally, we define textual diversity by means of the Jaccard distance.

DEFINITION 7 (TEXTUAL DIVERSITY). *We define the textual diversity of two photos r, r' as the Jaccard distance of their sets of keywords, i.e.:*

$$\text{textual_div}(r, r') = 1 - \frac{|\Psi_r \cap \Psi_{r'}|}{|\Psi_r \cup \Psi_{r'}|}. \quad (9)$$

4.2 The ST_Rel+Div Algorithm

Next, we present the ST_Rel+Div (Spatio-Textual Relevance and Diversity) algorithm. We first describe the methodology and index used, and then we present how the algorithm selects the diversified subset of photos more efficiently.

4.2.1 Methodology and Indices

The ST_Rel+Div algorithm follows the standard greedy methodology for solving MaxSum diversification problems. It builds the diversified set R^k iteratively, selecting at each step the photo that maximizes the maximum marginal relevance function mmr (see Section 2). Suppose that set R has been constructed, where $|R| < k$. Then, the photo from $\mathcal{R}_s \setminus R$ to be inserted next is the one that maximizes the function:

$$mmr(r) = (1 - \lambda) \cdot \text{rel}(r) + \frac{\lambda}{k - 1} \cdot \sum_{r' \in R} \text{div}(r, r'). \quad (10)$$

Functions $\text{rel}(r)$ and $\text{div}(r)$ are as defined in Section 4.1.2 taking into account the spatial and textual aspects.

The main issue with applying this heuristic methodology in our context is the computational complexity of mmr . A naïve implementation would compute a large number of spatial and textual photo-to-street relevances and photo-to-photo diversities. In particular, computing mmr at each iteration, requires $O(|\mathcal{R}_s|)$ computations for its first component, and $O(|R||\mathcal{R}_s|)$ for the second. Even though some of these computations need not be repeated across iterations, the total computational cost can be prohibitive, especially when the set \mathcal{R}_s is large.

Consequently, the goal of ST_Rel+Div is to efficiently evaluate each component of the objective function mmr towards retrieving the best candidate at each iteration. For this purpose, we construct an index as described in the following. We use an index structure that combines a spatial grid with inverted indices in each cell. Each cell $c_{i,j}$ in the grid has side length $\frac{\theta}{2}$, and contains the following information:

- a list of the photos in the cell, denoted as $c_{i,j}.\mathcal{R}$
- an inverted index $c_{i,j}.I$, where the terms are the keywords appearing in the photos in this cell, and each postings list $c_{i,j}.I[\psi]$ contains those photos that have the keyword ψ (we denote as $c_{i,j}.\Psi$ the set of keywords present in $c_{i,j}.I$)
- the maximum ($c_{i,j}.\psi_{max}$) and minimum ($c_{i,j}.\psi_{min}$) number of keywords for the photos in this cell.

Next, we show how this index is used to derive lower and upper bounds for each of the components of the objective function mmr . Note that the described index, although similar to the grid index used in Section 3.2, is distinct, indexing a different dataset, i.e. the set of photos instead of POIs.

4.2.2 Computing Bounds

Using the index, we can derive, for any of the photos within a cell, upper and lower bounds for each of the components of the mmr function. The ST_Rel+Div algorithm exploits these bounds while computing the mmr function in order to iterate over the cells instead of individual photos and to prune the search space more quickly, identifying the next candidate that optimizes the mmr criterion. In particular, we need to derive lower and upper bounds for the following: (a) spatial and textual relevance of a cell to a street and (b) spatial and textual diversity of a cell to a photo. We elaborate on each below.

Cell spatial relevance. Consider a cell $c_{i,j}$. The spatial relevance of a photo r w.r.t. street s is defined according to Equation 6. Moreover, recall that the length of each side of a cell in the spatial grid is $\frac{\theta}{2}$. Hence, each photo $r \in c_{i,j}.\mathcal{R}$ covers at least all other photos in the same cell and at most all photos that are no more than two cells away. Accordingly, we derive the following lower and upper bounds for the cell-to-street spatial relevance:

$$\text{spatial_rel}^-(c_{i,j}) = \frac{|c_{i,j}.\mathcal{R}|}{|\mathcal{R}_s|}, \quad (11)$$

$$\text{spatial_rel}^+(c_{i,j}) = \frac{\sum_{\Delta i, \Delta j \in [-2, 2]} |c_{i+\Delta i, j+\Delta j}.\mathcal{R}|}{|\mathcal{R}_s|}. \quad (12)$$

Cell textual relevance. Consider a cell c . The textual relevance of a photo $r \in c.\mathcal{R}$ w.r.t. street s is defined according to Equation 8. We seek to construct keyword sets $\Psi^-(c|s), \Psi^+(c|s)$, which are subsets of $c.\Psi$, such that when they substitute set Ψ_r in Equation 8, the obtained values bound the textual relevance of any photo $r \in c.\mathcal{R}$. In other words, we obtain the following bounds of $\text{textual_rel}(r)$:

$$\text{textual_rel}^-(c) = \frac{\sum_{\psi \in \Psi^-(c|s)} \Phi_s(\psi)}{\|\Phi_s\|_1}, \quad (13)$$

$$\text{textual_rel}^+(c) = \frac{\sum_{\psi \in \Psi^+(c|s)} \Phi_s(\psi)}{\|\Phi_s\|_1}. \quad (14)$$

We next describe how to build the keyword sets $\Psi^-(c|s), \Psi^+(c|s)$. Based on the information stored in the index, each photo $r \in P(c)$ may contain at least $c.\psi_{min}$ and at most $c.\psi_{max}$ keywords. Hence, sets $\Psi^-(c|s), \Psi^+(c|s)$ should obey these cardinality constraints.

For set $\Psi^-(c|s)$, we should choose the fewest possible keywords from $c.\Psi$, i.e., $c.\psi_{min}$, and make sure they have as low frequencies in Φ_s as possible. Therefore, we select up to $c.\psi_{min}$ keywords from $c.\Psi$ that do not appear in Ψ_s , and, if necessary (so as to satisfy the minimum cardinality constraint), we additionally select keywords from $c.\Psi$ with the lowest frequencies in Φ_s .

On the other hand, for set $\Psi^+(c|s)$, we select up to $c.\psi_{max}$ keywords from $c.\Psi$ that also appear in Ψ_s , and if necessary (so as to satisfy the minimum cardinality constraint), we arbitrarily choose additional keywords from $c.\Psi$.

Cell-to-photo spatial diversity. Assume a grid cell c and a photo r . The lower and upper bounds of the spatial diversity between r and any photo $r' \in c.\mathcal{R}$ are determined by respective bounds on the distance of r and cell c . Therefore, we have:

$$spatial_div^-(c, r) = \frac{mindist(r, c)}{maxD(s)}, \quad (15)$$

$$spatial_div^+(c, r) = \frac{maxdist(r, c)}{maxD(s)}, \quad (16)$$

where functions $mindist(r, c)$ and $maxdist(r, c)$ return the minimum and maximum distance, respectively, between r and any point within cell c .

Cell-to-photo textual diversity. Assume a grid cell c and a photo r . We determine the lower and upper bounds of the textual diversity between r and any other photo $r' \in c.\mathcal{R}$. We follow a similar rationale as for the cell textual relevance, and construct keyword sets $\Psi^+(c|r)$, $\Psi^-(c|r)$ so that when they substitute $\Psi_{r'}$ in Equation 9 they provide a lower and an upper bound, respectively, on the textual diversity of any photo $r' \in c.\mathcal{R}$.

For the lower bound for the textual diversity, we construct set $\Psi^+(c|r)$ maximizing the common keywords with Ψ_r . Specifically, we insert in $\Psi^+(c|r)$ up to $c.\psi_{max}$ common keywords, and if necessary, we additionally insert keywords from $c.\Psi$ until we obtain at least $c.\psi_{max}$ keywords in $\Psi^+(c|r)$. Therefore, the textual diversity of any $r' \in c.\mathcal{R}$ is lower bounded by:

$$textual_div^-(c, r) = 1 - \frac{|\Psi^+(c|r) \cap \Psi_r|}{|\Psi^+(c|r) \cup \Psi_r|} = \begin{cases} 1 - \frac{|c.\Psi \cap \Psi_r|}{|\Psi_r| + c.\psi_{min} - |c.\Psi \cap \Psi_r|}, & \text{if } |c.\Psi \cap \Psi_r| < c.\psi_{min} \\ 1 - \frac{\min(|c.\Psi \cap \Psi_r|, c.\psi_{max})}{|c.\Psi|}, & \text{if } |c.\Psi \cap \Psi_r| \geq c.\psi_{min} \end{cases} \quad (17)$$

For the upper bound for the textual diversity, we construct set $\Psi^-(c|r)$ minimizing the common keywords with Ψ_r . Specifically, we insert in $\Psi^-(c|r)$ up to $c.\psi_{min}$ keywords from $c.\Psi$ that are not in Ψ_r , and if necessary, we insert additional keywords from $c.\Psi$ until we obtain at least $c.\psi_{min}$ keywords. Therefore, the textual diversity of any $r' \in c.\mathcal{R}$ is upper bounded by:

$$textual_div^+(c, r) = 1 - \frac{|\Psi^-(c|r) \cap \Psi_r|}{|\Psi^-(c|r) \cup \Psi_r|} = \begin{cases} 1 - \frac{c.\psi_{min} - |c.\Psi \setminus \Psi_r|}{|c.\Psi| + |c.\Psi \setminus \Psi_r|}, & \text{if } |c.\Psi \setminus \Psi_r| < c.\psi_{min} \\ 1, & \text{if } |c.\Psi \setminus \Psi_r| \geq c.\psi_{min} \end{cases} \quad (18)$$

4.2.3 Algorithm Description

Algorithm 2 shows the pseudocode for the ST_Rel+Div algorithm, which incrementally builds the result set R^k by adding, at each step, the next best photo, denoted as $next_r$, that maximizes the objective function mmr defined in Equation 10. However, the distinguishing factor of ST_Rel+Div, compared to a naïve algorithm that directly computes the mmr function for each photo, is that instead of evaluating individual photos, it first considers entire grid cells. Specifically, at each step, in the filtering phase (lines 4–9), it iterates over the cells and computes for each cell the lower and upper bound of the objective function mmr (lines 5–7), by applying the corresponding bounds presented in 4.2.2.

Then, any cell having an upper bound that is lower than the lower bound of another cell is discarded (line 9). The remaining cells are organized in a priority queue ordered descending on their mmr upper bound. Only the photos belonging to the remaining cells are

Table 1: Datasets used in the evaluation.

Dataset	Num of segm.	Min segm. length (m)	Max segm. length (m)	Num of POIs
London	113,885	0.93	5,834.71	2,114,264
Berlin	47,755	0.06	6,312.96	797,244
Vienna	22,211	1.35	9,913.42	408,712

processed in the refinement phase (lines 10–17). For each examined photo, its exact value for the objective function is calculated (line 13). During this process, if the upper bound of a cell is lower than the value computed for an examined photo, this cell is also discarded (lines 14–17). The process continues until the priority queue contains no cells.

5. EXPERIMENTAL EVALUATION

We have conducted an experimental evaluation using real-world data comprising road networks, POIs and photos. The datasets cover the areas of three European capital cities, London, Berlin and Vienna, and were collected from various Web sources, in particular: (a) road networks from OpenStreetMap, (b) POIs from DBpedia, OpenStreetMap, Wikimapia and Foursquare, and (c) photos from Flickr and Panoramio. Table 1 presents statistics about the datasets. All algorithms were implemented in Java and experiments were run on a machine with an Intel Core i7 2400 CPU and 8GB RAM.

The primary focus of this paper is to propose efficient algorithms for the tasks of identifying and describing SOIs, as defined in Sections 3.1 and 4.1. A detailed *performance* study is presented in Section 5.2. Nonetheless, it is also very important to gauge the *effectiveness* of our methods in achieving their goals. Therefore, in Section 5.1, we present the results of an empirical study of both tasks, identification and description.

5.1 Effectiveness Study

The goal of this section is to highlight the effectiveness of our methods in identifying and describing streets of interest.

5.1.1 Identifying Streets of Interest

We focus on a particular SOI retrieval scenario: determine streets in Berlin that are interesting for “shopping”. As ground truth, we

Figure 2: Main shopping sites in Berlin and their most important streets.

Table 2: Comparison of identified top SOIs for “shops” in Berlin.

Top-10 SOIs	Source #1	Source #2
1. Neue Schönhauser Straße	Tauentzienstraße	Kurfürstendamm
2. Rosenthaler Straße	Fasanenstraße	Tauentzienstraße
3. Mäusetunnel	Friedrichstraße	Potsdamer Platz
4. Münzstraße	Alte/Neue Schönhauser Straße	Friedrichstraße
5. Potsdamer Platz Arkaden	Münzstraße	Alte/Neue Schönhauser Straße
6. Friedrichstraße		
7. Mulackstraße		
8. Alte Schönhauser Straße		
9. Weinmeisterstraße		
10. Tauentzienstraße		

assume two authoritative Web sources about top shopping destinations in Berlin^{1 2}. Each source provided a (non-ranked) list of 5 streets, displayed in the two last columns in Table 2.

In our SOI algorithm, we set the query parameters to $\Psi=\{\text{“shop”}\}$, $k=10$, $\epsilon=0.0005^\circ \approx 55m$, i.e., looking for the top 10 streets that have a large concentration of “shop”-related POIs within 55 meters from them. The ranked list is shown in the first column of Table 2. Streets that are common among the 10-SOIs and the two sources are shown in bold. For both sources, we retrieve 4 out of 5 streets; therefore, our method has a recall (at rank 10) of 0.8.

A closer inspection of the results though, suggests that our method has actually better recall (and precision). All streets included in Table 2 belong to one of four main shopping sites in Berlin, near Alte/Neue Schönhauser Straße, near Kurfürstendamm, near Friedrichstraße, and near Potsdamer Platz. Figure 2 illustrates the first three areas on the map (the last one is a public square that has no important adjacent shopping streets) and highlights the streets included in Table 2. Green color indicates that the street is in the 10-SOIs and in at least one of the source lists (true positives); orange means it is in the 10-SOIs but not in any source (false positives); blue indicates it is in a source but not in the 10-SOIs (false negatives).

It should be apparent that all orange streets near Alte/Neue Schönhauser Straße are actually valid results as they are adjacent to the main streets in the respective area, and further have lots of little shops in their vicinity. Similarly, the orange street near Friedrichstraße is also valid as it is a pedestrian underground tunnel with shops. Regarding the blue streets in the Kurfürstendamm site (which is analogous to Champs-Élysées in Paris), we should note that Kurfürstendamm appears in the 20-SOIs. The reason they are ranked lower is that in their vicinity the density of shops is lower, as they essentially house big luxury brands. This could be addressed by exploiting additional metadata to assign different weights to the POIs.

5.1.2 Describing Streets of Interest

To study the effectiveness of our method in selecting appropriate photos for describing a particular SOI, we focus on the popular Oxford Street in London and seek for 3 photos. Since deriving the ground truth from the collected crowd-sourced data is not possible, we choose to empirically test the result of our method against simpler techniques that select photos based on spatial, textual information or their combination, and consider relevance, diversity, or their combination. More precisely, we compare our method ST_Rel+Div that combines spatio-textual relevance and diversity, against 8 other techniques depicted in Table 4. Symbols S and T denote, respectively, that spatial and textual information is considered, while Rel and Div indicate, respectively, that relevance and diversity are taken into account; our method considers all factors and information, hence its name ST_Rel+Div.

For a visual inspection of the results, Figure 3 shows the 3-photo summary of Oxford Street, according to methods S_Rel, T_Rel and ST_Rel+Div, respectively. In the first method, all selected photos are located outside HMV, an entertainment retailing company, and are in fact near-duplicates. The reason for this seems to be that the particular location attracts a large number of photos, due to the release of popular movies, music albums and other similar events, thus creating a high density spot. For the second method, all results are photos from a particular demonstration that took place along Oxford Street. This bias was introduced due to the high frequency of the corresponding tags, thus resulting in a higher rank for photos having those tags. On the other hand, observe that in our method (Figure 3(c)) the result comprises different kinds of photos, achieving both high relevance and diversity: one photo outside HMV, another from the aforementioned demonstration, and a third photo showing a view of the street undergoing construction work.

For a quantifiable measure of effectiveness, we use the objective function of Equation 2 ($\lambda=0.5$, $w=0.5$), that provides a balanced score reflecting the relevance and diversity of both spatial and textual information included in the photo summary. For the top SOI in the considered cities, Table 3 presents the scores achieved by each method; the value is normalized with respect to that of the

¹<http://www.tripadvisor.com/Travel-g187323-s405/Berlin:Germany:Shopping.html>

²<http://www.globalblue.com/destinations/germany/berlin/top-five-shopping-streets-in-berlin>

Table 3: Objective scores (Equation 2 after normalization).

Method	London	Berlin	Vienna
S_Rel	0.831	0.726	0.508
S_Div	0.923	0.982	0.961
S_Rel+Div	0.982	0.953	0.911
T_Rel	0.708	0.367	0.219
T_Div	0.831	0.811	0.895
T_Rel+Div	0.949	0.848	0.919
ST_Rel	0.776	0.367	0.279
ST_Div	0.913	0.986	0.961
ST_Rel+Div	1.000	1.000	1.000

ST_Rel+Div method. In all cities, our method achieves the highest normalized score (shown with bold), often by a large margin (up to 4.5x). It is worth mentioning that there is no clear runner-up, as S_Rel+Div is second best for London, while ST_Div is for Berlin and Vienna (second highest values shown with italics).

5.2 Performance Study

We next evaluate the efficiency of the proposed methods.

5.2.1 Identifying Streets of Interest

Methods. First, we evaluate the performance of our proposed SOI algorithm for solving k -SOI. To the best of our knowledge, no approaches have been proposed in previous works for the specific problem addressed (see Problem 1). Hence, we compare the performance of SOI to a baseline implementation, denoted as BL. Specifically, BL uses only the spatial grid index to efficiently compute the interest of every segment, and then determines the k -SOIs.

Parameters. Throughout our experiments, we set the distance threshold ϵ to a fixed value ($\epsilon = 0.0005^\circ \approx 55m$). We study the effect of the number k of SOIs requested, and the number $|\Psi|$ of keywords in the query. To construct the keyword set, we select the first $|\Psi|$ keywords among $\{\textit{religion}, \textit{education}, \textit{food}, \textit{services}\}$. The resulting accumulated number of relevant POIs is shown in Table 4. In each experiment, we vary one parameter while setting the other to its default value ($k = 50$, $|\Psi| = 3$).

Table 4: Relevant POIs according to $|\Psi|$.

Dataset	$ \Psi = 1$	$ \Psi = 2$	$ \Psi = 3$	$ \Psi = 4$
London	10,445	32,682	113,211	202,127
Berlin	1,969	10,506	47,950	78,310
Vienna	1,678	7,660	25,695	41,484

Metrics. The objective of our evaluation is to analyze the performance of SOI compared to BL. Therefore, we measure the total execution time of both methods. For SOI we further break it down into time spent during list construction, filtering, and refinement.

Results. Figure 4 presents the evaluation results on the three datasets for all settings considered. Note that the bars for SOI are divided into the time spent in each of the three phases discussed.

The value of k has a small effect on all algorithms. Particularly for SOI the execution time slightly increases with k . SOI outperforms BL by a factor around 2.1–3.2 for London, 1.6–2.1 for Berlin, and 1.1–2.5 for Vienna. An important observation is that our method is more efficient for larger datasets, such as London (see Table 1).

The value of $|\Psi|$ has no effect in BL. On the other hand, the execution time of SOI increases with $|\Psi|$ as more POIs become relevant (see Table 4) and thus more cells and segments have to be visited. For example in London, the number of cells SOI visits increases from 5% to 13% of the total cells. As a result, SOI outperforms BL by a factor that varies from 1.1 up to 18.

(a) Spatial relevance (S_Rel).

(b) Textual relevance (T_Rel).

(c) Spatio-textual relevance and diversity (ST_Rel+Div).

Figure 3: Selected photos under different criteria.

Note that the selected keywords are quite general; they only serve for benchmark purposes in extreme settings. For example, when $|\Psi|=4$, we are essentially trying to rank streets that have churches, schools, restaurants or various services within their neighborhood. As a result, around 60% of all street segments are relevant (SOI manages to prune half of them). In practice, the user would pose more selective keywords.

5.2.2 Describing Streets of Interest

Methods. Next, we evaluate the performance of the ST_Rel+Div algorithm compared to a baseline method (BL) which, similarly to ST_Rel+Div, constructs the diversified result set iteratively, but examining all photos in each iteration instead of operating on the grid cells and using the bounds presented in Section 4.2.

Parameters. We fix the values of the distance parameters to $\epsilon = 0.0005^\circ$ and $\rho = 0.0001^\circ$, and we vary: (a) the number k of photos requested (default $k=20$), (b) the weight λ between relevance and diversity (default $\lambda=0.5$), and (c) the weight w between the spatial and textual components (default $w=0.5$). For each dataset, we randomly selected one of the returned k -SOIs in the previous experiments. The number of nearby photos for the cases of London, Berlin and Vienna was, respectively, 6572, 788, and 1584.

An interesting discussion concerns the selection of an appropriate value for parameter λ .³ We can think of the relevance-diversity trade-off as follows. In order to increase the diversity of the result set (the *return*), we have to sacrifice its relevance (the *investment*). Typically, diversity starts to increase quickly in the beginning (when relevance is still high), but its rate slowly decreases, meaning that a greater reduction in relevance is required to achieve

³The other parameter in Equation 2, w , is application dependent.

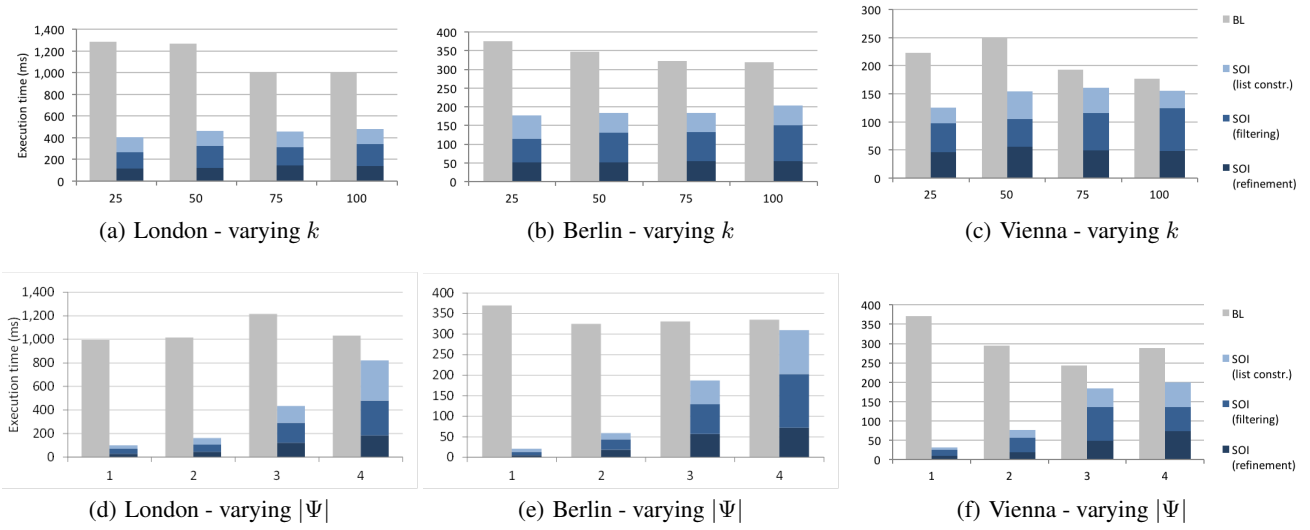

Figure 4: Experimental results for the SOI algorithm.

Figure 5: Trade-off between relevance and diversity ($w = 0.5$).

the same increase in diversity. So the goal is to figure out an acceptable investment that is “value for money”.

Figure 5 depicts the normalized relevance (Equation 4) and diversity (Equation 5) scores of the constructed photo summary for the top SOI in the three cities for various values of λ ; note that the relevance axis is reversed. As we go from bottom left to top right, the value λ increases from 0 to 1 in increments of 0.25, and thus relevance decreases while diversity increases. The larger marker indicates the value $\lambda = 0.5$. In all cities, λ values around 0.5 achieve the best relevance-diversity trade-off. For example, in Vienna $\lambda = 0.5$ suggests that by sacrificing 0.22 units of normalized relevance we achieve a diversity of 0.87 normalized units. These findings justify our selection of 0.5 as the default value for λ .

Metrics. As previously, we compare the total execution time of the ST_Rel+Div algorithm and the BL method.

Results. The results are shown in Figure 6. The pruning achieved by ST_Rel+Div via bounds computed for the grid cells drastically reduces the execution time in all experiments. ST_Rel+Div outperforms BL by a factor that varies from 2 up to 64.

Moreover, it is worth noticing that ST_Rel+Div has response times of less than a second, in contrast to the BL method that typically requires several seconds to compute the results, thus being unsuitable for online exploration. In fact, the execution time is much higher for London, due to the fact that the selected segment in that case has a much higher number of associated photos, while the inverse holds for Berlin.

For both algorithms, execution time increases with k , as more iterations are performed; however, ST_Rel+Div shows much better scalability due to the pruning. These differences in performance also remain consistent when varying the parameters λ and w .

6. CONCLUSIONS

In this paper, we have addressed the problem of finding and exploring *Streets of Interest* based on Points of Interest and photos characterized by geolocation and keywords. The problem addressed is twofold. Given a set of keywords, we first rank streets according to relevant nearby POIs. To that end, we define an interest score for a street, and we present an efficient algorithm that returns the top- k interesting streets. Then, we select for each discovered street a small, diversified set of photos. We formulate this as a diversification problem for spatio-textual objects, and we present an efficient algorithm that performs a greedy search using a spatio-textual grid to speed up the selection of candidates. Our experimental results on real-world data from several Web sources show that the proposed algorithms drastically reduce the computation time, allowing for online discovery and exploration of interesting parts of the road network. In the future, we plan to enhance the diversification criteria with visual features extracted from the photos, as well as to provide route recommendations based on the discovered streets of interest.

ABSTRACT

Indoor tracking data is being amassed due to the deployment of indoor positioning technologies. Analysing such data discloses useful insights that are otherwise hard to obtain. For example, by studying tracking data from an airport, we can identify the shops and restaurants that are most popular among passengers. In this paper, we study two query types for finding frequently visited Points of Interest (POIs) from symbolic indoor tracking data. The snapshot query finds those POIs that were most frequently visited at a given time point, whereas the interval query finds such POIs for a given time interval. A typical example of symbolic tracking is RFID-based tracking, where an object with an RFID tag is detected by an RFID reader when the object is in the reader's detection range. A symbolic indoor tracking system deploys a limited number of proximity detection devices, like RFID readers, at preselected locations, covering only part of the host indoor space. Consequently, symbolic tracking data is inherently uncertain and only enables the discrete capture of the trajectories of indoor moving objects in terms of coarse regions. We provide uncertainty analyses of the data in relation to the two kinds of queries. The outcomes of the analyses enable us to design processing algorithms for both query types. An experimental evaluation with both real and synthetic data suggests that the framework and algorithms enable efficient and scalable query processing.

1. INTRODUCTION

Indoor spaces such as shopping malls, office buildings, libraries, metro stations, and airports serve as the settings of significant parts of people's daily lives. The indoor movements of people are increasingly datafied due to advances in indoor positioning [1]. As a result, a new type of data—indoor tracking data—is being accumulated in a variety of formats determined by the particular indoor positioning technologies used.

As in the case for outdoor tracking data [3], analyzing indoor tracking data can reveal how different parts of an

indoor space are used by its inhabitants, e.g., the number of visits to a particular part of space over time can be determined. The findings are potentially useful in practical scenarios. For example, the lease prices of different shop locations in a large shopping mall may be set according to the numbers of people passing by the location. As another example, information on the behavior of past visitors to a museum with multiple exhibitions may be used for making recommendations to new visitors and for planning. These and other example scenarios may benefit from flow counting using indoor tracking data.

Flow counting is non-trivial in indoor spaces, where new, unique technical challenges exist that are different from those in outdoor contexts. These in turn call for novel data management techniques.

First of all, indoor positioning systems differ fundamentally from GPS that is prevalent outdoors but that generally does not work indoors. Having to use wireless technologies such as Wi-Fi, Bluetooth, and RFID that originally are designed for data communication, indoor positioning systems work according to different principles and offer positioning accuracies that are below that of GPS. For example, in an RFID based system, an object with an RFID tag is detected by an RFID reader only when the object is in the reader's detection range. Due to their costs, a limited number of readers are deployed, covering only part of the host indoor space. Consequently, the tracking data is inherently uncertain and only enables the discrete capture of the trajectories of indoor moving objects in terms of coarse regions. Such uncertainty renders flow counting techniques based on GPS data unsuitable for indoor spaces.

Further, indoor spaces are characterized by entities like doors, rooms, and hallways that enable and constrain the movements of indoor objects. Compared to outdoor Euclidean or spatial network space, indoor spaces have more complex topologies. When counting flows in indoor spaces, their complex topologies must be taken into account.

This paper considers flow counting based on symbolic indoor tracking data where object locations are captured as circular regions centered at pre-selected indoor locations. Such circular regions correspond to the detection ranges of proximity detection devices, e.g., RFID readers. We define appropriate ways of counting flows based on the uncertain tracking data. Our definitions capture probabilistically how frequently indoor POIs are visited by tracked visitors. Based on the definitions of indoor flow counting, we define two query types for finding indoor POIs that are visited frequently at a given time point and during a given time range,

respectively. We analyze carefully the data uncertainty with respect to the query types, which enables us to design algorithms for both query types. We use synthetic and real data to evaluate the proposals experimentally. The experimental results show that our proposals are efficient and scalable.

We make the following contributions in this paper.

- We define indoor flow counting methods on symbolic indoor tracking data, and we formulate two types of queries for finding frequently visited indoor POIs.
- We derive query related object uncertainty regions by analysing the relationship between the queries and the tracking data.
- We make use of the uncertainty analysis results to design algorithms for the two query types.
- We perform extensive experiments to evaluate the proposed techniques.

The remainder of the paper is organized as follows. Section 2 presents the format of symbolic indoor tracking data and formulates the research problems. Section 3 derives uncertainty regions for objects. Section 4 details the query processing algorithms. Section 5 reports on the experimental studies. Section 6 reviews the related work, and Section 7 concludes and discusses research directions.

2. PROBLEM FORMULATION

We formulate the research problems in this section. Section 2.1 details the symbolic indoor tracking data, and Section 2.2 gives the problem definitions. Table 1 lists notation used throughout the paper.

Symbol	Meaning
p	An indoor POI
P	A set of indoor POIs
o	An indoor moving object
O	A set of indoor moving objects
t	A time point
rd	An indoor tracking record
$\Phi_t(p)$	The flow of p at time t
$\Phi_{t_s, t_e}(p)$	The flow of p during interval $[t_s, t_e]$
V_{max}	The maximum speed of indoor moving objects

Table 1: Notation

2.1 Symbolic Indoor Tracking Data

In symbolic indoor object tracking, raw position readings are reported in the format $\langle objectID, deviceID, t \rangle$. Such a 3-tuple means that the object identified by *objectID* is seen by the device *deviceID* at time t . As the positioning works at a configured sampling frequency, an object is typically seen in multiple, consecutive raw readings by the same device. Such consecutive raw readings are merged [10] to form a tracking record of the form $\langle ID, objectID, deviceID, t_s, t_e \rangle$. Such a tracking record means that the object is continuously seen by the device from time t_s to time t_e , i.e., t_s is the start time for the continuous detection and t_e is the end time. An object tracking table (OTT) is used to store such historical tracking records, as exemplified in Table 2, where attribute *ID* is a record identifier.

<i>ID</i>	<i>objectID</i>	<i>deviceID</i>	t_s	t_e
rd_1	o_1	dev_4	t_1	t_2
rd_2	o_2	dev_4	t_1	t_2
rd_3	o_1	dev_2	t_5	t_6
rd_4	o_2	dev_1	t_7	t_8
rd_5	o_1	dev_1	t_9	t_{10}
rd_6	o_1	dev_{12}	t_{15}	t_{16}
rd_7	o_2	dev_{13}	t_{20}	t_{21}
rd_8	o_1	dev_{13}	t_{21}	t_{22}
rd_9	o_2	dev_{13}	t_{29}	t_{30}
...

Table 2: Object Tracking Table (OTT)

2.2 Problem Definitions

We assume that each indoor POI p has some fixed extent modeled by a polygon, and for simplicity, we equate a POI p with its polygon. As an entire indoor space is typically not fully covered by proximity detection devices like RFID readers due to economic constraints, there are considerable time intervals during which an object is not seen at all. Consequently, flow counting is not straightforward in the setting of uncertain indoor tracking data. Since object locations are uncertain, exact counting of objects does not make sense. Instead, we estimate how many objects that appeared in an indoor POI's range at a particular past time point or during a past time range. For that purpose, we need to determine an indoor moving object's *uncertainty region* that tells where the object can possibly be located. We differentiate between snapshot and interval uncertainty regions.

Given an object o , we use $UR(o, t)$ to denote o 's *snapshot uncertainty region* at time point t . In particular, $UR(o, t)$ captures an indoor region in which object o can possibly be at time t . Next, we use $UR(o, [t_s, t_e])$ to denote o 's *interval uncertainty region* during time interval $[t_s, t_e]$. Here, $UR(o, [t_s, t_e])$ captures the indoor region in which object o can possibly be during time interval $[t_s, t_e]$. We describe how to derive these uncertainty regions in Section 3. Based on the uncertainty regions, we define the following concepts for flow counting.

First, we consider an object o 's presence in the range of an indoor POI p . The presence stipulates how we "count" objects for a POI p .

DEFINITION 1 (OBJECT PRESENCE). *During a given time interval $[t_s, t_e]$, an object o 's interval presence in a POI p is*

$$\phi_{t_s, t_e, p}(o) = \frac{\text{area}(UR(o, [t_s, t_e]) \cap p)}{\text{area}(p)}. \quad (1)$$

Similarly, $\phi_{t, p}(o)$ is defined by replacing $UR(o, [t_s, t_e])$ with $UR(o, t)$. The idea of object presence is to capture the intersection between the object's uncertainty region and the POI's range. Intuitively, the larger the intersection, the more likely it is that the object was in the POI. For an arbitrary object o and an arbitrary POI p , it is apparent that $0 \leq \phi_{t, p}(o) \leq 1$ and $0 \leq \phi_{t_s, t_e, p}(o) \leq 1$. Therefore, o 's object presence can be regarded as the probability that o is in POI p at t or during $[t_s, t_e]$.

Next, we define the concept of flow for indoor POIs.

DEFINITION 2 (FLOW). Suppose O is the set of all objects in an indoor space of interest. Given an indoor POI p and a time interval $[t_s, t_e]$, p 's interval flow is defined as

$$\Phi_{t_s, t_e}(p) = \sum_{o \in O} \phi_{t_s, t_e, p}(o). \quad (2)$$

Similarly, $\Phi_t(p)$ is defined by replacing $\phi_{t_s, t_e, p}(o)$ with $\phi_{t, p}(o)$. The flow definitions perform weighted counting of objects that stay in POI p at time t or during time interval $[t_s, t_e]$, and the weight assigned to each object is its object presence.

With the above definitions, we formulate two types of queries that return the top- k frequently visited indoor POIs.

PROBLEM 1 (SNAPSHOT TOP- k INDOOR POIS QUERY). Given a set P of indoor POIs, a time point t , and an integer k ($0 < k \leq |P|$), return a k -subset P_T of P such that $\forall p \in P_T (\forall p' \in P \setminus P_T (\Phi_t(p) \geq \Phi_t(p')))$.

PROBLEM 2 (INTERVAL TOP- k INDOOR POIS QUERY). Given a set P of indoor POIs, a time interval $[t_s, t_e]$, and an integer k ($0 < k \leq |P|$), return a k -subset P_T of P such that $\forall p \in P_T (\forall p' \in P \setminus P_T (\Phi_{t_s, t_e}(p) \geq \Phi_{t_s, t_e}(p')))$.

These queries return the indoor POIs that are visited by the largest number of visitors at a time point or during a time interval. This functionality has many applications. For example, it can be used to identify the most popular shops in a shopping mall. Shop rental fees can take such information into account. As another example, it can be used to identify possible bottlenecks that slow down movement in an airport.

3. DERIVING UNCERTAINTY REGIONS

We elaborate on how to derive uncertainty regions for an given object and specified time parameters. Section 3.1 presents the basic terminology, including uncertainty regions for snapshot queries. Section 3.2 focuses on uncertainty regions for interval queries. Section 3.3 addresses how to finalize the uncertainty regions in a given indoor space.

3.1 Basic Terminology

We first cover basic terminology adopted from previous work [10, 17, 25] that is necessary for understanding the paper's contributions.

3.1.1 Tracking States

Given a time point t , an object o may be in either an active state or an inactive state [25]. Specifically, if there is a tracking record rd_{cov} for o in OTT (see Table 2 in Section 2.1) covering time t , we say o is in an *active state* at t . We use rd_{pre} to refer to rd_{cov} 's predecessor record in OTT . If no tracking record for o exists in OTT covering time t , object o is in an *inactive state* at t . In this case, we identify two relevant tracking records. Record rd_{pre} is the tracking record for o immediately before o becomes inactive. Record rd_{suc} is the tracking record for o immediately after o leaves the inactive state, i.e., rd_{suc} is the first tracking record when o becomes active again after time t . Note that $rd_{pre}.t_e < t < rd_{suc}.t_s$ if object o is inactive at time t .

Object o_1 's tracking records in Table 2 are plotted along the time axis in Figure 1 (originally from [17]). It is in an active state at time t_5 , and it is in an inactive state at time t_{19} . Relevant particular tracking records are also marked in

Figure 1: States in Symbolic Object Tracking

the figure. For simplicity, we use dev_{pre} (dev_{cov} or dev_{suc}) to refer to rd_{pre} 's (rd_{cov} 's or rd_{suc} 's) device.

An object is either in an active or an inactive state at a time point t , whereas it may change state during a time interval $[t_s, t_e]$. In Figure 1, object o_1 changes state five times during $[t_5, t_{19}]$.

3.1.2 Snapshot Uncertainty Regions

Two cases exist for the snapshot uncertainty region of an object o at a time point t [17]. We suppose that V_{max} is the maximum speed that object o can move at in the given indoor space.

Case 1: Object o is in an active state at t . In this case, $UR(o, t) = Ring(dev_{pre}, V_{max} \cdot (t - rd_{pre}.t_e)) \cap dev_{cov}.Range$. I.e., o 's uncertainty region is the intersection of dev_{cov} 's detection range and the ring in which o can be after leaving dev_{pre} 's detection range. Specifically, this ring is determined by dev_{pre} 's range and the maximum distance o can move from $rd_{pre}.t_e$ to t . This case is illustrated in Figure 2(a).

Figure 2: Snapshot Uncertainty Regions

Case 2: Object o is in an inactive state at t . In this case, $UR(o, t) = Ring(dev_{pre}, V_{max} \cdot (t - rd_{pre}.t_e)) \cap Ring(dev_{suc}, V_{max} \cdot (rd_{suc}.t_s - t))$. Here, $UR(o, t)$ is the intersection of two rings: one involves rd_{pre} and is the same as that in Case 1; the other involves rd_{suc} and the same distance o can move from t to $rd_{suc}.t_s$. This case is illustrated in Figure 2(b).

3.1.3 Uncertainty Region Involving Two Consecutive Readings

Without loss of generality, let rd_i and rd_j be two consecutive tracking records for object o . Records rd_i and rd_j involve devices dev_i and dev_j , respectively. For time intervals $[rd_i.t_s, rd_i.t_e]$ and $[rd_j.t_s, rd_j.t_e]$, object o is in dev_i 's and dev_j 's detection range, respectively. For time interval $[rd_i.t_e, rd_j.t_s]$, object o 's location can be constrained by an

¹ $Ring(dev, \rho)$ denotes the ring whose inner circle is device dev 's detection circle and whose outer circle extends the inner circle's radius by ρ .

extended ellipse [10] whose two foci are two points on the boundaries of the two detection ranges (see the two circular regions in dark in Figure 3). Furthermore, the length of the ellipse's major axis is $2a = V_{max} \cdot (rd_j.t_s - rd_i.t_e)$. Such an extended ellipse is illustrated in Figure 3. Object o 's uncertainty region for a time interval is represented by the extended ellipse excluding the two circular regions for the two proximity detection devices. The details of deriving such an extended ellipse can be found in the literature [10, 19]. We use $\Theta(dev_i, dev_j, rd_i.t_e, rd_j.t_s)$ to refer to the complete region covered by the ellipse, which will be used in our subsequent discussions.

Figure 3: Uncertainty Region Examples

3.2 Interval Uncertainty Regions

In order to derive the uncertainty region of object o in a given time interval $[t_s, t_e]$, we need to find all its relevant tracking records in OTT . Temporally, all those records form a chain of detections of object o . In particular, we need to find the start record, the end record, and all the records in-between for object o . We use rd_s and rd_e to refer to the start (first in the chain) and end (the last) records, respectively. Although there may be multiple in-between records, we use rd_b to refer to a concrete record between rd_s and rd_e when it is of particular interest in our discussion. Table 3 gives the start and end records for all cases regarding object o 's state at t_s and t_e .

$t_s \backslash t_e$	Active		Inactive	
	rd_s	rd_e	rd_s	rd_e
Active	$rd_{cov}(t_s)$	$rd_{cov}(t_e)$	$rd_{cov}(t_s)$	$rd_{suc}(t_e)$
Inactive	$rd_{pre}(t_s)$	$rd_{cov}(t_e)$	$rd_{pre}(t_s)$	$rd_{suc}(t_e)$

Table 3: Start and End Records for $[t_s, t_e]$

Next, we derive $UR(o, [t_s, t_e])$, object o 's uncertainty region during $[t_s, t_e]$, for the four cases given in Table 3.

Case 1: Object o is active at both t_s and t_e , i.e., $rd_s = rd_{cov}(t_s)$ and $rd_e = rd_{cov}(t_e)$. Without loss of generality, we assume that there are two records in-between. An illustration is shown in Figure 4, where dev_s is $rd_s.deviceID$ and dev_e is $rd_e.deviceID$. Object o 's uncertainty region is then the union of the ellipse regions associated with the consecutive tracking records from rd_s to rd_e . Formally, $UR(o, [t_s, t_e]) = \bigcup_{i=1..|R|-1} \Theta(dev_i, dev_{i+1}, rd_i.t_e, rd_{i+1}.t_s)$,

where rd_i is a tracking record from sequence $R = \langle rd_{cov}(t_s), rd_{b1}, \dots, rd_{cov}(t_e) \rangle$ and $dev_i = rd_i.deviceID$.

Figure 4: Interval Uncertainty Region for Case 1

Case 2: Object o is inactive at t_s but active at t_e , i.e., $rd_s = rd_{pre}(t_s)$ and $rd_e = rd_{cov}(t_e)$. As for Case 1, an illustration is shown in Figure 5. Here, we need to pay particular attention to the time interval $[t_s, rd_{b1}.t_s]$ before object o becomes detected by device dev_{b1} . For this interval, due to the maximum speed constraint, the object can only be in the intersection of the ellipse region $\Theta_s = \Theta(dev_s, dev_{b1}, rd_s.t_e, rd_{b1}.t_s)$ and the ring captured as $Ring_s = Ring(dev_{b1}, V_{max} \cdot (rd_{b1}.t_s - t_s))$.

As a result, object o 's uncertainty region for the entire interval $[t_s, t_e]$ is this intersection unioned with the union of all other ellipse regions associated with all other consecutive tracking records from rd_{b1} to $rd_e = rd_{cov}(t_e)$. Formally, $UR(o, [t_s, t_e]) = (\Theta_s \cap Ring_s) \cup \bigcup_{i=1..|R|-1} \Theta(dev_i, dev_{i+1}, rd_i.t_e, rd_{i+1}.t_s)$, where rd_i is a tracking record from sequence $R = \langle rd_{b1}, \dots, rd_{cov}(t_e) \rangle$ and $dev_i = rd_i.deviceID$.

Figure 5: Interval Uncertainty Region for Case 2

Case 3: Object o is active at t_s but inactive at t_e , i.e., $rd_s = rd_{cov}(t_s)$ and $rd_e = rd_{suc}(t_e)$. An illustration is shown in Figure 6. In this case, we need to pay particular attention to the time interval $[rd_{b2}.t_e, t_e]$ after object o is last seen by device $rd_{b2}.deviceID$. For this interval, due to the maximum speed constraint, the object can only be in the intersection of the ellipse region $\Theta_e = \Theta(dev_{b2}, dev_e, rd_{b2}.t_e, rd_e.t_s)$ and the ring $Ring_e = Ring(dev_{b2}, V_{max} \cdot (t_e - rd_{b2}.t_e))$.

As a result, object o 's uncertainty region for the entire interval $[t_s, t_e]$ is the above intersection unioned with the union of all other ellipse regions associated with all other consecutive tracking records from $rd_s = rd_{cov}(t_s)$ to rd_{b2} . Formally, $UR(o, [t_s, t_e]) = (\Theta_e \cap Ring_e) \cup \bigcup_{i=1..|R|-1} \Theta(dev_i, dev_{i+1}, rd_i.t_e, rd_{i+1}.t_s)$, where rd_i is a tracking record from sequence $R = \langle rd_{cov}(t_s), rd_{b1}, \dots, rd_{b2} \rangle$ and $dev_i = rd_i.deviceID$.

Figure 6: Interval Uncertainty Region for Case 3

Case 4: Object o is inactive at both t_s and t_e , i.e., $rd_s = rd_{pre}(t_s)$ and $rd_e = rd_{suc}(t_e)$. An illustration is shown in Figure 7. This case combines the handling of the beginning and end from Cases 2 and 3, respectively. Therefore, object o 's uncertainty region in $[t_s, t_e]$ is $UR(o, [t_s, t_e]) = (\Theta_s \cap Ring_s) \cup (\Theta_e \cap Ring_e) \cup \bigcup_{i=1..|R|-1} \Theta(dev_i, dev_{i+1}, rd_i.t_e, rd_{i+1}.t_s)$, where rd_i is a tracking record from sequence $R = \langle rd_{b1}, \dots, rd_{b2} \rangle$ and $dev_i = rd_i.deviceID$.

Figure 7: Interval Uncertainty Region for Case 4

3.3 Indoor Topology Check

Our coverage so far does not consider the topology of the indoor space. Specifically, we need to check $UR(o, t)$ against the given indoor space and exclude all parts of the space that are not accessible to object o at time t . Also, we need to check $UR(o, [t_s, t_e])$ against the given indoor space and exclude all parts of the space that are not accessible to object o from time t_s and t_e without exiting $UR(o, [t_s, t_e])$. For each type of uncertainty region, the part that remains after the indoor topology check is object o 's uncertainty region.

Examples are shown in Figure 8, where the shaded parts must be excluded from the object's uncertainty regions. In Figure 8(a), an object o is inactive at time point t . Suppose that it was detected by device 1 at time $t_1 < t$ and then by device 3 after t . According to the discussion illustrated in Figure 2(b), o 's snapshot uncertainty region $UR(o, t)$ is the intersection of the two large circular regions constrained by the maximum speed V_{max} . However, the shaded part should be excluded as it is too far away for object o to be able to reach it at time point t . After leaving device 1's detection range, object o must go through door 2 to enter the shaded part, which would yield an indoor walking distance that exceeds the maximum Euclidean distance o can move from t_1 to t , i.e., $V_{max} \cdot (t - t_1)$. Therefore, this part should be excluded from $UR(o, t)$. If the topology check is skipped in this example, the object would be "counted" for room 2

whose flow in turn would be increased incorrectly. Such a miscalculation can result in room 2 entering a top- k query result as a false positive.

It is worth noting that if room 2 had had a door in the region given by the intersection of the two large circular regions (see Figure 8(a)), further checking would be needed to exclude parts of space that are too far away for an object in those parts to be able to move from one device to the other via the door. Based on the maximum speed V_{max} , we can calculate the earliest time t_2 ($t_1 < t_2 < t$) for an object to reach the assumed door. Then, moving from the door, the possible region for the object to reach before t is constrained by the distance $V_{max} \cdot (t - t_2)$. Any part of space beyond that distance from the assumed door should be excluded from the object's uncertainty region.

Figure 8: Indoor Topology Check

In Figure 8(b), an object o is detected by devices 1, 4, and then 2. Due to the maximum speed constraint, the object cannot have entered the shaded regions (in rooms 4 and 5). Therefore, these regions should be excluded from object o 's interval uncertainty region $UR(o, [t_s, t_e])$. Otherwise, the flows of rooms 4 and 5 would be incorrectly increased and they may enter the top- k result as false positives.

In our framework, we do such indoor topology checks to capture the uncertainty regions for indoor moving objects better. Specifically, after an uncertainty region UR is obtained, we divide it into several disconnected parts according to the indoor topology. For each such part, we check its indoor distance from the involved devices. If the indoor distance exceeds the corresponding maximum Euclidean distance, the part is excluded. For simplicity, we use $UR(o, t)$ and $UR(o, [t_s, t_e])$ to refer to the object's uncertainty region also after the topology check in the following.

Remark For the sake of conciseness in our presentation, we implicitly assume that the detection ranges of proximity detection devices do not overlap. Overlapping detection ranges can be accommodated by making only slight changes in the corresponding low-level geometric computations; no changes are needed to the overall process of deriving the uncertainty regions for objects. Therefore, the uncertainty analysis presented in this section and the algorithms to be presented in the next section are able to accommodate overlapping detection ranges. We omit the low-level details here in order to keep our discussion concentrated and concise.

4. TOP-K INDOOR POI ALGORITHMS

We proceed to design query processing algorithms by making use of the uncertainty regions derived in Section 3. Section 4.1 presents the indexes we use for query processing.

Sections 4.2 and 4.3 detail the algorithms for snapshot and interval queries, respectively.

4.1 Indexes

We use two R-tree [4] based indexes for the data to facilitate query processing—one for the tracking data and one for the indoor POIs.

The object tracking table (*OTT*) (refer to Table 2) is indexed by an augmented 1D R-tree named A1R-tree [17] on the temporal attributes as follows. Let rd_c be a tracking record for object o in *OTT*. Such a record rd_c is indexed by an A1R-tree leaf entry of the form (t^-, t^+, Ptr_p, Ptr_c) . Specifically, Ptr_c is a pointer to record rd_c , and Ptr_p points to record rd_p that is o 's previous record in *OTT*, i.e., rd_p is rd_c 's predecessor for the same object. In addition, we set $t^- = rd_p.t_e$ and $t^+ = rd_c.t_e$. We call (t^-, t^+) (i.e., $(rd_p.t_e, rd_c.t_e)$) an augmented tracking time interval. A non-leaf entry in an A1R-tree is of the form (t^-, t^+, cp) , where cp is a pointer to a child node and $[t^-, t^+]$ is the minimum bounding interval that contains all time intervals in the child node.

With an A1R-tree, we are able to efficiently obtain all the tracking records relevant to the uncertainty region determination described in Section 2. For a snapshot uncertainty region at query time t , a point query with t as the parameter via the A1R-tree will return a leaf entry $le = (t^-, t^+, Ptr_p, Ptr_c)$ where (t^-, t^+) covers t . If $le.Ptr_p.t_e < t < le.Ptr_c.t_s$, the object is inactive at time t , and $le.Ptr_p$ ($le.Ptr_c$) points to rd_{pre} (rd_{suc}) (see Figures 1 and 2(b)). Otherwise, the object is active at time t ($le.Ptr_c.t_s \leq t \leq le.Ptr_c.t_e$), and $le.Ptr_c$ points to the rd_{cov} (see Figures 1 and 2(a)).

For the uncertainty region in a query time interval $[t_s, t_e]$, a range query with $[t_s, t_e]$ as the parameter via the A1R-tree returns a series of leaf entries such that the first leaf entry's augmented tracking time interval covers t_s and that of the last leaf entry covers t_e . Furthermore, the first (last) leaf entry contains the pointer to the particular first (last) tracking record needed for the four cases presented in Section 3.2, depending on the case encountered. All in-between tracking records, if any, are accordingly obtained through those in-between leaf entries.

The set of indoor POIs is indexed by another R-tree, called R_P . For simplicity, we consider one floor and therefore use a 2D R-tree to index all indoor POIs in our implementation. Nevertheless, our analysis of uncertainty regions as well as the query processing techniques can be extended to multi-floor cases.

4.2 Snapshot Query Algorithms

4.2.1 Iterative Algorithm

A straightforward approach to compute the snapshot query (Problem 1) is to compute the snapshot flow value for each POI p in the query and then return the k POIs with the highest flow values. This iterative algorithm is formalized in Algorithm 1.

The iterative algorithm uses a hash table *flows* to keep flow values for all POIs (lines 1–2). Using a point query on the A1R-tree R_O on the *OTT* (line 3), the algorithm obtains all the relevant leaf entries whose augmented tracking time interval contains the query time t , as described in Section 4.1. For each object o thus obtained from the *OTT*

(lines 4–5), the algorithm derives the uncertainty region $UR(o, t)$ for either an inactive state (lines 6–9) or an active state (line 11). Then all POIs that intersect $UR(o, [t_s, t_e])$ are found (line 12). For each such POI p , its flow value is increased by the current object o 's presence in p (lines 13–14). Finally, the top- k POIs are returned (line 15).

Algorithm 1 *iterativeSnapshot*(R-tree R_P for indoor POIs, A1R-tree R_O for *OTT*, time point t , integer k)

```

1: initialize a hash table flows :  $\{POI\} \rightarrow [0, +\infty]$ 
2: for each POI  $p$  do flows[ $p$ ]  $\leftarrow 0$ 
3: LeafEntrySet les  $\leftarrow R_O.PointQuery(t)$ 
4: for each leaf entry  $le \in les$  do
5:    $o \leftarrow le.Ptr_c.objectID$ 
6:    $ring_1 \leftarrow Ring(le.Ptr_p.deviceID, V_{max} \cdot (t - le.Ptr_p.t_e))$ 
7:   if  $le.Ptr_p.t_e < t < le.Ptr_c.t_s$  then  $\triangleright$  The object is in an
     inactive state
8:      $ring_2 \leftarrow Ring(le.Ptr_c.deviceID, V_{max} \cdot (le.Ptr_c.t_s - t))$ 
9:      $UR(o, t) \leftarrow ring_1 \cap ring_2$ 
10:  else  $\triangleright$  The object is in an active state
11:     $UR(o, t) \leftarrow ring_1 \cap le.Ptr_c.deviceID.Range$ 
12:  ps  $\leftarrow R_P.IntersectionQuery(UR(o, t))$ 
13:  for each POI  $p \in ps$  do
14:     $flows[p] \leftarrow flows[p] + \frac{Area(UR(o, t) \cap p)}{Area(p)}$ 
15: return the top- $k$  from flows.keys with the highest values

```

4.2.2 Join Algorithm

The iterative algorithm suffers from two limitations. It iterates over all objects and relevant POIs, which may be inefficient. Also, it needs to compute a considerable number of uncertainty regions. This may not pay off, as some POIs may finally get very low overall flow values while having incurred complex uncertainty region computations. Motivated by these observations, we design a more efficient join based method that is formalized in Algorithm 2.

The join algorithm consists of three phases. The first (lines 1–11) builds an in-memory aggregate R-tree R_I for all objects whose augmented tracking interval covers query time t . These objects are again obtained by a point query on the A1R-tree (line 2). If an object o is inactive at t (line 5), we obtain the minimum bounding rectangles (MBRs) of the two (*pre* and *suc*) proximity detection devices' detection ranges, and extend each of them by the corresponding maximum possible distance (lines 6–7). The two extended MBRs are then merged to form the object's MBR (line 8). Otherwise, the MBR of device dev_{cov} 's range is used for the active state (lines 10). After the MBR is determined, the object o is inserted into tree R_I , where each node entry is augmented with a field *count* that is the number of all objects in the corresponding sub-tree.

The second phase (lines 12–18) is the initialization for joining the POI R-tree R_P and the aggregate object R-tree R_I . Here, the algorithm initializes a priority queue Q that gives higher priority to R_P node entries (groups of POIs) that potentially have higher flow values. In particular, each R_P entry e_P is associated with a join list of R_I entries whose MBRs overlap e_P 's MBR. Note that for any POI p in e_P 's sub-tree, those objects that can contribute to p 's flow value can only come from such R_I entries. When the two tree roots are joined (line 13–18) initially, the *count* values in the R_I entries are used to upper bound the flow values as an object's presence in any POI never exceeds 1 (Definition 1).

The third phase carries out the join (lines 19–48). The

Algorithm 2 joinSnapshot(R-tree R_P for indoor POIs, A1R-tree R_O for OTT , time t , integer k)

```

1: initialize an in-memory aggregate R-tree  $R_I$ 
2: LeafEntrySet  $les \leftarrow R_O.PointQuery(t)$ 
3: for each leaf entry  $le \in les$  do
4:    $o \leftarrow le.Ptr_c.objectID$ 
5:   if  $le.Ptr_p.te < t < le.Ptr_c.ts$  then ▷ Inactive state
6:      $mbr_1 \leftarrow \text{extend MBR}(le.Ptr_p.deviceID.Range)$  by  $V_{max} \cdot (t - le.Ptr_p.te)$ 
7:      $mbr_2 \leftarrow \text{extend MBR}(le.Ptr_c.deviceID.Range)$  by  $V_{max} \cdot (le.Ptr_c.ts - t)$ 
8:      $mbr \leftarrow \text{MBR}(mbr_1, mbr_2)$ 
9:   else
10:     $mbr \leftarrow \text{MBR}(le.Ptr_c.deviceID.Range)$ 
11:   insert  $(o, mbr)$  into  $R_I$ 
12: initialize a priority queue  $Q$ 
13: for each entry  $e_P$  in  $R_P.root$  do
14:    $ubFlow \leftarrow 0$ ;  $list \leftarrow \emptyset$ 
15:   for each entry  $e_I$  in  $R_I.root$  do
16:     if  $e_P.mbr$  intersects  $e_I.mbr$  then
17:        $ubFlow \leftarrow ubFlow + e_I.count$ ;  $list \leftarrow list \cup \{e_I\}$ 
18:    $Q.enqueue((e_P, list, ubFlow))$ 
19:  $result \leftarrow \emptyset$ ; initialize a hash table  $H_U$ 
20: while  $Q$  is not empty do
21:    $(e_P, list) \leftarrow Q.dequeue()$ 
22:   if  $e_P$  is a leaf entry then
23:     if  $list$  is null then
24:       add POI  $e_P.object$  to  $result$ 
25:       if  $result = k$  then return  $result$ 
26:     else
27:       if  $list$  contain leaf entries then
28:          $flow \leftarrow 0$ 
29:         for each entry  $e_I \in list$  do
30:           if  $H_U[e_I.object] = \emptyset$  then
31:              $H_U[e_I.object] \leftarrow UR(e_I.object, t)$ 
32:              $flow \leftarrow flow + \phi_{t, e_P.object}(e_I.object)$ 
33:           if  $flow \neq 0$  then  $Q.enqueue((e_P, null, flow))$ 
34:       else
35:         expandList( $e_P, list$ )
36:   else
37:     if  $list$  contain leaf entries then
38:       for each sub-entry  $e'_P$  in  $e_P.node$  do
39:          $ubFlow \leftarrow 0$ ;  $list2 \leftarrow \emptyset$ 
40:         for each entry  $e'_I \in list$  do
41:           if  $e'_P.mbr$  intersects  $e'_I.mbr$  then
42:              $ubFlow \leftarrow ubFlow + 1$ 
43:              $list2 \leftarrow list2 \cup \{e'_I\}$ 
44:         if  $list2 \neq \emptyset$  then
45:            $Q.enqueue((e'_P, list2, ubFlow))$ 
46:       else
47:         for each sub-entry  $e'_P$  in  $e_P.node$  do
48:           expandList( $e'_P, list$ )

```

join order is controlled by priority queue Q (lines 20–21). If the current R_P entry e_P is a leaf entry, it is processed as follows. If e_P 's join list is empty, which means its concrete flow value has been calculated and the value is higher than those yet to be calculated, it is added to the result (line 24), and if the result contains k POIs, the algorithm terminates (line 25). Otherwise, the join list may contain leaf entries or non-leaf entries from R_I . In the former case (line 27), the flow value of e_P is calculated by deriving the uncertainty region and presence for each object in the join list (lines 28–32). If the flow value is non-zero, the POI in e_P is pushed back to Q with an empty join list (line 33). To avoid deriving uncertainty regions repeatedly for objects that appear

in multiple join lists, we use a hash table H_U (lines 19 and 30–31) to store the uncertainty regions for objects. If e_P 's join list contains non-leaf entries, procedure expandList (Algorithm 3) is called to join e_P with sub-entries from the join list. The procedure ensures that e_P is only associated with those R_I entries whose MBRs intersect e_P 's (line 4), and it uses the *count* values in the R_I entries to estimate the upper bound of e_P 's flow value (line 5).

Algorithm 3 expandList(Entry e_P in R-tree R_P for indoor POIs, List $list$ of entries in R-tree R_I)

```

1:  $ubFlow \leftarrow 0$ ;  $list2 \leftarrow \emptyset$ 
2: for each entry  $e_I \in list$  do
3:   for each sub-entry  $e'_I$  in  $e_I.node$  do
4:     if  $e_P.mbr$  intersects  $e'_I.mbr$  then
5:        $ubFlow \leftarrow ubFlow + e'_I.count$ 
6:        $list2 \leftarrow list2 \cup \{e'_I\}$ 
7: if  $list2 \neq \emptyset$  then
8:    $Q.enqueue((e_P, list2, ubFlow))$ 

```

If the current R_P entry e_P is a non-leaf entry, it is processed as follows. If the join list contains leaf entries (line 37), the join algorithm overestimates the flow value for each of e_P 's sub-entries when joining them with the relevant entries in the join list (lines 38–43). Only sub-entries with a non-empty join list are pushed back into the priority queue (lines 44–45). Otherwise, procedure expandList is called for each of e_P 's sub-entries (lines 47–48).

4.3 Interval Query Algorithms

4.3.1 Iterative Algorithm

Algorithm 4 offers a straightforward way of computing the interval query (Problem 2). Overall, it follows the same iter-

Algorithm 4 iterativeInterval(R-tree R_P for indoor POIs, A1R-tree R_O for OTT , time interval $[t_s, t_e]$, integer k)

```

1: initialize a hash table  $flows : \{POI\} \rightarrow [0, +\infty]$ 
2: for each POI  $p$  do  $flows[p] \leftarrow 0$ 
3: LeafEntrySet  $les \leftarrow R_O.RangeQuery([t_s, t_e])$ 
4: initialize a hash table  $H$ 
5: for each leaf entry  $le \in les$  do
6:   append  $le.S$  to  $H[le.objectID]$ 
7: for each key  $objectID \in H.keys$  do
8:   get  $(rd_s, \dots, rd_e)$  from  $H[objectID]$ 
9:   calculate  $UR(objectID, [t_s, t_e])$  from  $(rd_s, \dots, rd_e)$ 
10:   $ps \leftarrow R_P.IntersectionQuery(UR(objectID, [t_s, t_e]))$ 
11:  for each POI  $p \in ps$  do
12:     $flows[p] \leftarrow flows[p] + \frac{Area(UR(o, [t_s, t_e]) \cap p)}{Area(p)}$ 
13: return the top- $k$  from  $flows.keys$  with the highest values

```

ative paradigm as does Algorithm 1 for the snapshot query. It uses a range query on the A1R-tree to obtain the relevant leaf entries and objects whose augmented tracking time interval overlap the query time interval $[t_s, t_e]$ (line 3), as described in Section 4.1. An interval query may involve a sequence of tracking records of an object, and therefore the algorithm uses a hash table to form the sequences for all objects obtained (lines 4–6). The uncertainty region of each object is calculated (lines 8–9) according to the discussion in Section 3.2.

4.3.2 Join Based Algorithm

Basic framework. Like for snapshot query processing, we have a join based algorithm for interval query processing. As formalized in Algorithm 5, it also contains three phases: aggregate object R-tree R_I construction (lines 1–9), join initialization (lines 10–16), and join processing (lines 17–46). The differences here lie mainly in the first phase and in the details of deriving the uncertainty regions for objects in a join list in the third phase.

Algorithm 5 joinInterval(R-tree R_P for indoor POIs, AIR-tree R_O for OTT , time interval $[t_s, t_e]$, integer k)

```

1: initialize a hash table  $H$ 
2: LeafEntrySet  $les \leftarrow R_O.RangeQuery([t_s, t_e])$ 
3: for each leaf entry  $le \in les$  do
4:   append  $le.S$  to  $H[le.objectID]$ 
5: initialize an in-memory aggregate R-tree  $R_I$ 
6: for each key  $objectID \in H.keys$  do
7:   get  $(rd_s, \dots, rd_e)$  from  $H[objectID]$ 
8:    $mbr \leftarrow MBR(objectID, [t_s, t_e])$ 
9:   insert  $(objectID, mbr)$  into  $R_I$ 
10: initialize a priority queue  $Q$ 
11: for each entry  $e_P$  in  $R_P.root$  do
12:    $ubFlow \leftarrow 0$ ;  $list \leftarrow \emptyset$ 
13:   for each entry  $e_I$  in  $R_I.root$  do
14:     if  $e_P.mbr$  intersects  $e_I.mbr$  then
15:        $ubFlow \leftarrow ubFlow + e_I.count$ ;  $list \leftarrow list \cup \{e_I\}$ 
16:    $Q.enqueue((e_P, list, ubFlow))$ 
17:  $result \leftarrow \emptyset$ ; initialize a hash table  $H_U$ 
18: while  $Q$  is not empty do
19:    $\langle e_P, list \rangle \leftarrow Q.dequeue()$ 
20:   if  $e_P$  is a leaf entry then
21:     if  $list$  is null then
22:       add POI  $e_P.object$  to  $result$ 
23:       if  $result = k$  then return  $result$ 
24:     else
25:       if  $list$  contain leaf entries then
26:          $flow \leftarrow 0$ 
27:         for each entry  $e_I \in list$  do
28:           if  $H_U[e_I.object] = \emptyset$  then
29:              $H_U[e_I.object] \leftarrow UR(e_I.object, [t_s, t_e])$ 
30:              $flow \leftarrow flow + \phi_{t_s, t_e, e_P.object}(e_I.object)$ 
31:           if  $flow \neq 0$  then  $Q.enqueue((e_P, null, flow))$ 
32:       else
33:          $expandList(e_P, list)$ 
34:     else
35:       if  $list$  contain leaf entries then
36:         for each sub-entry  $e'_P$  in  $e_P.node$  do
37:            $ubFlow \leftarrow 0$ ;  $list2 \leftarrow \emptyset$ 
38:           for each entry  $e'_I \in list$  do
39:             if  $e'_P.mbr$  intersects  $e'_I.mbr$  then
40:                $ubFlow \leftarrow ubFlow + 1$ 
41:                $list2 \leftarrow list2 \cup \{e'_I\}$ 
42:           if  $list2 \neq \emptyset$  then
43:              $Q.enqueue((e'_P, list2, ubFlow))$ 
44:       else
45:         for each sub-entry  $e'_P$  in  $e_P.node$  do
46:            $expandList(e'_P, list)$ 

```

Although this basic framework still works for interval query processing, preliminary experimentation suggests that it can be improved significantly. In the following, we identify the performance bottleneck and present improvements to the design of the join based algorithm.

Improvements. The uncertainty regions for an interval query are much larger than those for a snapshot query. If a single MBR is used for an interval uncertainty region, the

MBR can cover considerable dead space. This is the case in Algorithm 5 that uses a coarse MBR estimation, especially when an overall MBR is created for all tracking records of an object during the query interval (line 8). To alleviate this problem, we introduce several improvements.

Instead of using a single, large MBR to represent an object's trajectory during $[t_s, t_e]$, we use a series of much tighter MBRs, each of which is created based on a pair of consecutive tracking records. Suppose that an object o 's relevant tracking records during $[t_s, t_e]$ are $\langle rd_1, \dots, rd_m \rangle$. For each pair (rd_i, rd_{i+1}) , we create a small MBR mbr_i for the extended ellipse (Section 3.1.3) defined by the two tracking records.

After we create all such $m - 1$ smaller MBR mbr_i s, we create the overall MBR mbr for all of them. When we insert mbr into the aggregate R-tree R_I , we create additional information at the leaf node level for all such smaller mbr_i s for mbr . In particular, we insert a pointer from the entry for mbr to the list of mbr_i s, such that we can easily access these when we visit mbr 's node.

Next, we modify the procedure that expands the join list (Algorithm 3). Instead of simply checking whether two MBRs intersect, we do additional checks when a leaf node entry e'_I is taken from R-tree R_I (line 3 in Algorithm 3). In particular, if e'_I is a leaf node entry and its MBR intersects e_P 's (line 4), we continue to check e_P 's MBR against the smaller MBRs covered by e'_I as described above. We include e'_I into the join list only if at least one such smaller MBR intersects e_P 's MBR. These finer-grained checks are expected to eliminate many false positives in the join list that would otherwise result from the large, dead space-dominant MBR of e'_I . This arrangement reduces the join list size for e_P and reduces also the subsequent join cost.

In similar fashion, we apply the additional MBR intersection checks to Algorithm 5 when it process leaf entries from R_I (line 39). This is also expected to reduce the join list and the join cost.

An example of the improvements is shown in Figure 9. Object o 's overall MBR, whose dead space is indicated by

Figure 9: Less Coarse MBR Checks

the shaded parts, overlaps a POI p , and therefore o is included in p 's join list initially. Later, o 's complex uncertainty region $UR(o)$ is derived to calculate its presence in p . It turns out that the complex calculation does not contribute to the query result because $UR(o)$ does not intersect with p . Specifically, object o 's single, large MBR can be replaced by three smaller MBRs. As shown in the figure, each of the three smaller MBRs bounds the ellipse corresponding

to a pair of consecutive tracking records. Using the smaller MBRs, object o will be excluded from p 's join list, and the calculation of $UR(o)$ will be skipped since none of the three smaller MBRs intersects with p . We only implement the improved framework in the experimental comparisons.

5. EXPERIMENTAL STUDIES

This section reports on the experimental studies of our research. Section 5.1 presents the experimental settings. Sections 5.2 and 5.3 cover the experiments on synthetic and real data, respectively.

5.1 Experimental Settings

All algorithms are implemented in Java and run on a computer with Windows 7 Enterprise edition, an Intel Core i7-2620M 2.70GHz CPU, and 8.0GB main memory.

Synthetic data set: We use a floor plan with about 100 rooms that are all connected by doors to a hallway. We place a total of 143 RFID readers by doors and along the hallways. We generate object movements using the random waypoint model [11]. All objects move with a fixed speed of 1.1 m/s, which is also used as the maximum speed V_{max} .

We vary multiple parameters when generating the data, as shown in Table 4 where default values are in bold. We vary $|O|$, i.e., the number of objects in the OTT from 10 K to 50 K. We vary the RFID detection range, the radius of the circular region covered by an RFID reader, from 1m to 2.5m. For the complete synthetic data set, the number of the OTT tracking records falls in the range from 140 K to 2,000 K.

Parameters	Settings
$ O $	10K, 20K, ..., 50K
Detection Range (meter)	1, 1.5 , 2, 2.5
$ P $ (% of all indoor POIs)	2%, 4% , 6%, 8%, 10%
k	1, 2, 3, 4, 5 , ..., 10, ... 15
$t_e - t_s$ (minutes)	10, 20, 30 , ..., 60

Table 4: Parameter Settings in Experiments

Real-world data set: We use a real data set collected from Copenhagen International Airport (CPH) where passengers with Bluetooth-enabled mobile phones are tracked by deployed Bluetooth radios. We extract the data for a period of 7 months with the most tracking records. Our OTT contains approximately 600K records for about 10K passengers. We do not vary the detection range in the experiments on the real data set because we have no access to change the configurations in the real deployment. We use the same V_{max} as in the synthetic data.

Query parameters: We also vary query parameters according to Table 4. Specifically, k (the number of top ranked indoor POIs to be returned) is varied from 1 to 15. The query POI set is determined as follows. For both synthetic and real data, 375 POIs are determined in the indoor space at distinctive locations and with different areas. Multiple POIs may come from the same large room that is divided into multiple uses. We control the number of query POIs ($|P|$) as a percentage (2% to 10%) of the total number of indoor POIs. Given a percent, the query POI set is determined as a random subset of the total 375 POIs. We start from 2% to make sure there are sufficient query POIs for

returning the top- k results. On the other hand, we do not include more than 10% of all POIs in a query because, intuitively, not all indoor POIs are interesting and frequently visited, so query issuers like building officers may query a subset of all indoor POIs. Furthermore, $t_e - t_s$ is the query time interval used in the interval top- k indoor POI query. We vary it from 10 to 60 minutes.

5.2 Experiments on Synthetic Data

5.2.1 Results for Snapshot Queries

We first evaluate the performance of the snapshot query by varying parameters k , $|P|$, and the detection range. We do not change parameter $|O|$ for the snapshot query because the number of moving objects retrieved at a given time point is fairly random, and is smaller than and independent of $|O|$.

The results of varying k , $|P|$, and the detection range are presented in Figures 10 and 11(a). As a general observation, the join algorithm outperforms the iterative algorithm. This is because the former is able to prune more objects when their uncertainty regions do not overlap with the regions of POIs.

The effect of varying k is shown in Figure 10(a). As can be observed, varying k has only little influence on both algorithms. This indicates that both algorithms are stable with respect to query parameter k . The relatively high cost for both algorithms at $k = 1$ is due to the intensive initial computation of the uncertainty regions for many objects, which, however, does not pay off for a simple top-1 query.

The effect of varying $|P|$ is shown in Figure 10(b). As the number of query POIs increases, the running time increases slightly. This is because more query POIs occupy larger areas, and thus more moving objects are present in POIs. Thus, more object uncertainty regions intersect POIs, which yields longer processing times.

Figure 10: Snapshot Query on Synthetic Data Set

Figure 11(a) presents the effect of varying the detection range of RFID readers. When the detection range increases, the uncertainty region increases as well. Therefore, more computation time is needed to estimate the areas of uncertainty regions. Hence, the running time is the largest when the detection range is set to 2.5m. The slight decrease at 2 meters is attributed to the fluctuation of the OTT size.

5.2.2 Results for Interval Queries

The performance of the interval query algorithms is reported in Figures 11(b) and 12. In this experiment, we vary all five parameters listed in Table 4. Similar to the experiments for snapshot queries, the join algorithm runs faster than the iterative algorithm in almost all settings, which we attribute to its effective pruning strategy.

Figure 11: Effect of Detection Range

As shown in Figure 12(a), varying k does not significantly impact the performance of the algorithms except for $k = 1$. Overall, both algorithms are stable with respect to query result size except when $k = 1$. The longer running time for $k = 1$ occurs because the considerable computations on the uncertainty regions do not pay off for the very small top-1 query results. The performance improves when k increases because neither algorithm works in an incremental manner with respect to k . The relatively high cost at $k = 1$ is not observed in the counterpart experiments on the real data set (see Figure 14(a)), which is attributed to the considerably smaller size of the real data.

The effect of varying $|P|$ is presented in Figure 12(b). When increasing $|P|$, the running time of the iterative algorithm increases, while the join algorithm stays stable. Both algorithms have longer running times when compared to their snapshot query counterparts. This is understandable, as uncertainty regions in the snapshot setting are much smaller than those in the interval setting.

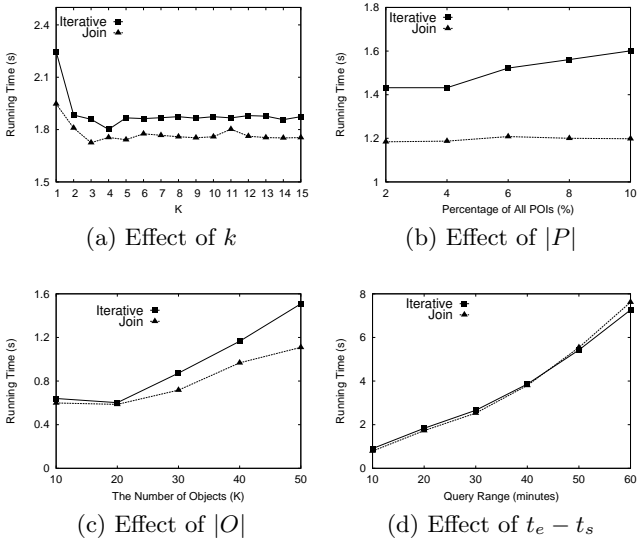

Figure 12: Interval Query on Synthetic Data Set

Figure 12(c) shows that the running time of both algorithms increases as $|O|$ increases. Nevertheless, the join algorithm remains more efficient. This indicates that the join algorithm is most scalable.

As the query time interval $t_e - t_s$ increases, the running time of the two algorithms increases accordingly, as presented in Figure 12(d). Longer query intervals tend to yield larger and more complex uncertainty regions that require more time to process.

As presented in Figure 11(b), when the detection range increases, the running time of both algorithms tends to decrease. This trend is opposite to the observation in the experiment for snapshot queries where the detection range is changed. In the interval setting, the algorithms compute on moving objects trajectories in a given time interval and thus involve a series of tracking records and devices. When the detection ranges of the devices increase, an object's uncertainty regions between pairs of consecutive devices shrink. As a result, objects' overall uncertainty regions tend to be smaller and thus take less time to process. At the outlier of 2 meters, the OTT is small, and the tracking data is sparse, which offsets the benefit of a larger detection range.

5.3 Experiments on Real Data

Results for snapshot queries are reported in Figure 13. Clearly the join algorithm outperforms the iterative algorithm. Both algorithms are fairly stable with respect to varying k , as shown in Figure 13(a). When the number of query POIs is increased, both algorithms' running times increase moderately and almost linearly, as shown in Figure 13(b). These results indicate that our designs are stable and scalable for snapshot queries in real indoor settings.

Figure 13: Snapshot Query on CPH Data Set

Interval query performance results are reported in Figure 14. It is clear that the join algorithm outperforms the iterative algorithm for all settings in these experiments.

The effect of varying k is shown in Figure 14(a). The join algorithm is more efficient and slightly more stable when varying k . This indicates that our strategy of finer MBRs for interval uncertainty regions pays off.

The effect of varying the number of query POIs is shown in Figure 14(b). The more stable performance of the join algorithm is again attributed to the use of finer MBRs for interval uncertainty regions. Smaller MBRs can help prune objects (and their uncertainty regions) more effectively even when there are more POIs and those POIs collectively occupy larger areas.

The effect of varying the query interval length is shown in Figure 14(c). Longer intervals yield longer object trajectories and larger uncertainty regions. This explains the increase in the running times of both algorithms. Nevertheless, the join algorithm is still more efficient thanks to the use of finer MBRs.

6. RELATED WORK

We briefly review related work in this section. Section 6.1 covers the research on indoor-space moving objects, and Section 6.2 covers the density queries in outdoor spaces.

6.1 Indoor-Space Moving Objects

Figure 14: Interval Query on CPH Data Set

Due in part to their different topology, indoor spaces are modeled [10, 13, 16, 21, 22] differently than outdoor spaces. Moreover, indoor moving objects are tracked by means different than outdoor GPS and thus generate different tracking data.

Assuming a generic setting of symbolic indoor tracking, Yang et al. study continuous range monitoring queries [25] and probabilistic k nearest neighbor queries [26] on indoor moving objects. Uncertain query results are returned as objects' locations are unknown when they are outside any detection range. Yu et al. [28] propose a particle filter based method to infer undetected locations under RFID tracking, which thus improves query result quality. Unlike these works that concern the current locations of indoor moving objects, this paper works on historical indoor tracking data.

Lu et al. [17] define spatio-temporal joins over indoor moving objects whose historical locations are captured in the same format as the symbolic tracking data assumed in this paper. However, while we compute flows for static indoor POIs according to historical tracking data, Lu et al. compute pairs of indoor moving objects that were in the same location according to historical data.

Xie et al. [23, 24] study indoor distance-aware spatial queries over online indoor moving objects whose positions are reported as probabilistic samples rather than using RFID detection ranges. Therefore, the proposed techniques are unsuitable for the problems we consider in this paper.

Recently, Ahmed et al. [2] define indoor density queries based on historical RFID indoor tracking data. Their density definition differs from our definition of flow. Moreover, we analyze the inherent uncertainties in the data and design uncertainty-aware solutions, whereas Ahmed et al. do not consider uncertainty.

6.2 Density Queries in Outdoor Spaces

Most existing research works on the querying of object flow and density are for outdoor Euclidean spaces or spatial road networks.

Tao et al. [20] use an aggregate RB-tree (aRB-tree) for indexing spatio-temporal objects in a Euclidean space and propose algorithms to count objects in a given spatial window during a given time interval. The proposed solution considers no location uncertainty and the aRB-tree cannot handle the complex indoor topology. Therefore, that solution cannot be used for the problems addressed in this paper.

Employing micro-clustering [29], Li et al. [15] propose techniques that cluster moving objects and dynamically up-

date the clusters as the objects move linearly. The proposed techniques do not apply in our setting, where indoor object movements can not be captured by linear models but are reported based on discrete detection ranges. Yiu and Mamoulis [27] propose density based and hierarchical methods to partition and cluster static objects on a spatial network. Their proposal uses network distances between static positions and therefore does not solve our problems on indoor moving objects.

Hadjieleftheriou et al. [5] study threshold density region queries that find outdoor regions with more objects than a given threshold. Their solution assumes that the objects move according to known linear functions and are indexed by uniform space-time grids. Jensen et al. [9] study snapshot dense region queries in a Euclidean plane where objects move linearly and are indexed by a B⁺-tree [8]. With the same linear motion assumption, Hao et al. [6] study continuous density queries by using a quad-tree to index moving objects. To improve density query results, Ni and Ravishankar [18] redefine the density and use small square neighborhoods to approximate arbitrary outdoor regions. These proposals [5, 6, 9, 18] are unsuitable for our problems, a key reason being that objects in indoor spaces cannot be modeled well by linear functions.

Huang and Lu [7] define online density region queries on moving objects that are observed by sensors at fixed positions in a geographical area. The proposed solution assumes that object locations are captured as certain points in a 2D Euclidean space. This assumption renders the solution unsuitable for our problems where indoor moving object locations are captured as uncertainty regions.

Li et al. [14] devise techniques to return traffic density-based hot routes from historical trajectories in a road network. Cai et al. [12] design a clustering based technique for continuously monitoring dense road segments. Different from these works, we target indoor spaces where objects' historical movements are captured as detection ranges associated with time intervals.

7. CONCLUSION AND FUTURE WORK

In this paper, we study how to find the top- k frequently visited indoor Points of Interest (POIs) using symbolic indoor tracking data that captures object movements indoors. We define two types of queries in this regard. A snapshot query finds those indoor POIs that were visited by the most tracked objects (e.g., people) at a given time point, whereas an interval query finds such POIs for a given time interval. As symbolic indoor tracking data can only capture trajec-

tories with a considerable degree of uncertainty, we define appropriate ways to quantify how frequently an indoor POI is visited by probabilistically counting objects' presences in the POI. Subsequently, we conduct a detailed analysis on the uncertainty regions of objects in the settings of the two types of queries. Based on the uncertainty analysis, we design algorithms for both query types. We use both synthetic and real data sets to evaluate the query processing algorithms, and the performance results show that our proposed join-based algorithms are capable of significantly outperforming straightforward baselines and are much more scalable in terms of data set size and query interval length.

Several directions exist for future research. First, it is relevant to consider an object's dwell time when calculating its interval presence in a POI. The interval-related definitions in the paper can be extended for that purpose. In particular, an object's interval uncertainty region can be extended to also reflect the temporal aspect in addition to the spatial aspect. Second, it is of interest to extend the uncertainty analysis to support multiple floors. The new challenge is to track object movement between floors appropriately and to derive the uncertainty regions accordingly. Third, it is of interest to investigate how to solve the problems addressed in the paper using other types of indoor tracking data. To this end, it can be considered whether the proposed techniques can be applied to, or adapted for, other data types. Fourth, it is relevant to develop techniques for finding the currently crowded indoor POIs by using tracking data. Fifth, it is of interest to evaluate the query results against real indoor POIs in order to see how effective the proposed query types are at finding frequently visited indoor POIs. For that purpose, ground truth data on popular indoor POIs is needed.

ABSTRACT

The database research community has been building methods to store, access, and update data for more than four decades. Throughout the evolution of the structures and techniques used to access data, *access methods* adapt to the ever changing hardware and workload requirements. Today, even small changes in the workload or the hardware lead to a redesign of access methods. The need for new designs has been increasing as data generation and workload diversification grow exponentially, and hardware advances introduce increased complexity. New workload requirements are introduced by the emergence of new applications, and data is managed by large systems composed of more and more complex and heterogeneous hardware. As a result, it is increasingly important to develop application-aware and hardware-aware access methods.

The fundamental challenges that every researcher, systems architect, or designer faces when designing a new access method are how to minimize, i) read times (R), ii) update cost (U), and iii) memory (or storage) overhead (M). In this paper, we conjecture that when optimizing the read-update-memory overheads, optimizing in any two areas negatively impacts the third. We present a simple model of the RUM overheads, and we articulate the *RUM Conjecture*. We show how the RUM Conjecture manifests in state-of-the-art access methods, and we envision a trend toward RUM-aware access methods for future data systems.

1. INTRODUCTION

Chasing Access Paths. Picking the proper physical design (through static autotuning [14], online tuning [13], or adaptively [31]) and access method [27, 49] have been key research challenges of data management systems for several decades. The way we physically organize data on storage devices (disk, flash, memory, caches) defines and restricts the possible ways that we can read and update it. For example, when data is stored in a heap file without an index, we have to perform costly scans to locate any data we are interested in. Conversely, a tree index on top of the heap file, uses additional space in order to substitute the scan with a more lightweight index probe. Over the years, we have seen a plethora of exciting and innovative proposals for data structures and algorithms, each

one tailored to a set of important workload patterns, or for matching critical hardware characteristics. Applications evolve rapidly and continuously, and at the same time, the underlying hardware is diverse and changes quickly as new technologies and architectures are developed [1]. Both trends lead to new challenges when designing data management software.

The RUM Tradeoff. A close look at existing proposals on access methods¹ reveals that each is confronted with the same fundamental challenges and design decisions again and again. In particular, there are three quantities and design parameters that researchers always try to minimize: (1) the read overhead (R), (2) the update overhead (U), and (3) the memory (or storage) overhead (M), henceforth called the *RUM overheads*. Deciding which overhead(s) to optimize for and to what extent, remains a prominent part of the process of designing a new access method, especially as hardware and workloads change over time. For example, in the 1970s one of the critical aspects of every database algorithm was to minimize the number of random accesses on disk; fast-forward 40 years and a similar strategy is still used, only now we minimize the number of random accesses to main memory. Today, different hardware runs different applications but the concepts and design choices remain the same. New challenges, however, arise from the exponential growth in the amount of data generated and processed, and the wealth of emerging data-driven applications, both of which stress existing data access methods.

The RUM Conjecture: Read, Update, Memory – Optimize Two at the Expense of the Third. An ideal solution is an access method that always provides the lowest read cost, the lowest update cost, and requires no extra memory or storage space over the base data. In practice, data structures are designed to compromise between the three RUM overheads, while the optimal design depends on a multitude of factors like hardware, workload, and user expectations.

We analyze the lower bounds for the three overheads (read - update - memory) given an access method which is perfectly tailored for minimizing each overhead and we show that such an access method will impact the rest of the overheads negatively. We take this observation a step further and propose the RUM Conjecture: *designing access methods that set an upper bound for two of the RUM overheads, leads to a hard lower bound for the third overhead which cannot be further reduced.* For example, in order to minimize the cost of updating data, one would use a design based on differential structures, allowing many queries to consolidate updates and avoid the cost of reorganizing data. Such an approach, however, increases the space overhead and hinders read cost as now queries need to merge any relevant pending updates during processing. Another example is that the read cost can be minimized by

¹Access methods: *algorithms and data structures for organizing and accessing data* [27].

storing data in multiple different physical layouts [4, 17, 46], each layout being appropriate for minimizing the read cost for a particular workload. Update and space costs, however, increase because now there are multiple data copies. Finally, the space cost can be minimized by storing minimal metadata and, hence, pay the price of increased search time when reading and updating data.

The three RUM overheads form a competing triangle. In modern implementations of data systems, however, one can optimize up to some point for all three. Such optimizations are possible by relying on using inherently defined structure instead of storing detailed information. A prime example is the block-based clustered indexing, which reduces both read and memory overhead by storing only a few pointers to pages (only when an indexed tuple is stored to a different page than the previous one), hence building a very short tree. The reason why such an approach would give us good read performance is the fact that data is clustered on the index attribute. Even in this ideal case, however, we have to perform additional computation in order to calculate the exact location of the tuple we are searching for. In essence, we use computation and knowledge about the data in order to reduce the RUM overheads. Another example, is the use of compression in bitmap indexes; we still use additional computation (compression/decompression) in order to succeed in reducing both read and memory overhead of the indexes. While the RUM overheads can be reduced by computation or engineering, their competing nature manifests in a number of approaches and guides our roadmap for RUM-aware access methods.

RUM-Aware Access Method Design. Accepting that a perfect access method does not exist, does not mean the research community should stop striving to improve; quite the opposite. The RUM Conjecture opens the path for exciting research challenges towards the goal of creating RUM-aware and RUM-adaptive access methods.

Future data systems should include versatile tools to interact with the data the way the workload, the application, and the hardware need and not vice versa. In other words, the application, the workload, and the hardware should dictate how we access our data, and not the constraints of our systems. Such versatile data systems will allow the data scientist of the future to dynamically tune the data access methods during normal system operation. Tuning access methods becomes increasingly important if, on top of big data and hardware, we consider the development of specialized systems and tools to cater data, aiming at servicing a narrow set of applications each. As more systems are built, the complexity of finding the right access method increases as well.

Contributions. In this paper we present for the first time the RUM Conjecture as a way to understand the inherent tradeoffs of every access method. We further use the conjecture as a guideline for designing access methods of future data systems. In the remainder of this paper we charter the path toward RUM-aware access methods:

- Identify and model the RUM overheads (§2).
- Propose the RUM Conjecture (§3).
- Document the manifestation of the RUM Conjecture in state-of-the-art access methods (§4).
- Use the RUM Conjecture to build access methods for future data systems (§5).

Each of the above points serves as inspiration for further research on data management. Finding a concise yet expressive way to identify and model the fundamental overheads of access methods requires research in data management from a theory perspective. Similarly, proving the RUM Conjecture will expand on this line of research. Documenting the manifestation of the RUM Conjecture entails a new study of access methods with the RUM overheads

in mind when modeling and categorizing access methods. Finally, the first three steps provide the necessary research infrastructure to build powerful access methods.

While we envision that this line of research will enable building powerful access methods, the core concept of the RUM Conjecture is, in fact, that there is no panacea when designing systems. It is not feasible to build the universally best access method, nor to build the best access method for each and every use case. Instead, we envision that the RUM Conjecture will create a trend toward building access methods that can efficiently morph to support changing requirements and different software and hardware environments. The remainder of this paper elaborates one by one the four steps toward RUM-aware access methods for future data systems.

2. THE RUM OVERHEADS

Overheads of Access Methods. When designing access methods it is very important to understand the implications of different design choices. In order to do so, we discuss the three fundamental overheads that each design decision can affect. Access methods enable us to read or update the main data stored in a data management system (hereafter called *base data*), potentially using auxiliary data such as indexes (hereafter called *auxiliary data*), in order to offer performance improvements. The overheads of an access method quantify the additional data accesses to support any operation, relative to the base data.

Read Overhead (RO). The RO of an access method is given by the data accesses to auxiliary data when retrieving the necessary base data. We refer to RO as the read amplification: the ratio between the total amount of data read including auxiliary and base data, divided by the amount of retrieved data. For example, when traversing a B^+ -Tree to access a tuple, the RO is given by the ratio between the total data accessed (including the data read to traverse the tree and the base data) and the base data intended to be read.

Update Overhead (UO). The UO is given by the amount of updates applied to the auxiliary data in addition to the updates to the main data. We refer to UO as the write amplification: the ratio between the size of the physical updates performed for one logical update, divided by the size of the logical update. In the previous example, the UO is calculated by dividing the updated data size (both base and auxiliary data) by the size of the updated base data.

Memory Overhead (MO). The MO is the space overhead induced by storing auxiliary data. We refer to MO as the space amplification, defined as the ratio between the space utilized for auxiliary and base data, divided by the space utilized for base data. Following the preceding example, the MO is computed by dividing the overall size of the B^+ -Tree by the base data size.

Minimizing RUM overheads. Ideally, when building an access method, all three overheads should be minimal, however, depending on the application, the workload, and the available technology they are prioritized. While access time, optimized by minimizing read overhead, often has top priority, the workload or the underlying technology sometimes shift priorities. For example, storage with limited endurance (like flash-based drives) favors minimizing the update overhead, while the slow speed of main memory and the scarce cache capacity justifies reducing the space overhead. The theoretical minimum for each overhead is to have the ratio equal to 1.0, implying that the base data is always read and updated directly and no extra bit of memory is wasted. Achieving these bounds for all three overheads simultaneously, however, is not possible as there is always a price to pay for every optimization.

In the following discussion we reason about the three overheads and their lower bounds using a simple yet representative case for

base data: an array of integers. We organize this dataset consisting of N ($N \gg 1$) fixed-sized elements in blocks, each one holding a *value*. Every block can be identified by a monotonically increasing ID, *blkID*. The workload is comprised of point queries, updates, inserts, and deletes. We purposefully provide simple examples of data structures in order to back the following hypothesis. The generality of these examples lies in their simplicity.

Hypothesis. *An access method that is optimal with respect to one of the read, update, and memory overheads, cannot achieve the optimal value for both remaining overheads.*

Minimizing Only RO. In order to minimize *RO* we organize data in an array and we store each *value* in the block with $\text{blkID} = \text{value}$. For example, the relation $\{1, 17\}$ is stored in an array with 17 blocks. The first block holds value 1, the last block holds value 17, and every block in-between holds a null value. *RO* is now minimal because we always know where to find a specific value (if it exists), and we only read useful data. On the other hand, the array is sparsely populated, with unbounded *MO* since, in the general case, we cannot anticipate what would be the maximum value ever inserted. When we insert or delete a value we only update the corresponding block. When we change a value we need to update two blocks: empty the old block and insert the new value in its new block, effectively, increasing the worst case *UO* to two physical updates for one logical update.

Prop. 1 $\min(\text{RO}) = 1.0 \Rightarrow \text{UO} = 2.0$ and $\text{MO} \rightarrow \infty$

Minimizing Only UO. In order to minimize *UO*, we append every update, effectively forming an ever increasing log. That way we achieve the minimum *UO*, which is equal to 1.0, at the cost of continuously increasing *RO* and *MO*. Notice that any reorganization of the data to reduce *RO* would result in an increase of *UO*. Hence, for minimum *UO*, both *RO* and *MO* perpetually increase as updates are appended.

Prop. 2 $\min(\text{UO}) = 1.0 \Rightarrow \text{RO} \rightarrow \infty$ and $\text{MO} \rightarrow \infty$

Minimizing Only MO. When minimizing *MO*, no auxiliary data is stored and the base data is stored as a dense array. During a selection, we need to scan all data to find the values we are interested in, while updates are performed in place. The minimum $\text{MO} = 1.0$ is achieved. The *RO*, however, is now dictated by the size of the relation since a full scan is needed in the worst case. The *UO* cost of in-place updates is also optimal because only the base data intended to be updated is ever updated.

Prop. 3 $\min(\text{MO}) = 1.0 \Rightarrow \text{RO} = N$ and $\text{UO} = 1.0$

3. THE RUM CONJECTURE

Achieving the optimal value for one overhead is not always as important as finding a good balance across all RUM overheads. In fact, in the previous section, we saw that striving for the optimal may create impractical access method designs. The next logical step is to provide a fixed bound only for one of the overheads, however, this raises the question of how to quantify the impact of such an optimization goal for the remaining two overheads. Given our analysis above, we conjecture that it is not possible to optimize across all three dimensions at the same time.

The RUM Conjecture. *An access method that can set an upper bound for two out of the read, update, and memory overheads, also sets a lower bound for the third overhead.*

In other words, we can choose which two overheads to prioritize and optimize for, and pay the price by having the third overhead

greater than a hard lower bound. In the following section we describe how the RUM Conjecture manifests in existing access methods by showing that current solutions are typically optimized for one of the three overheads, while in Section 5 we discuss a roadmap for RUM access methods.

4. RUM IN PRACTICE

The RUM Conjecture captures in a concise way the tension between different optimization goals that researchers face when building access methods. We present here the competing nature of the RUM tradeoffs, as it manifests in state-of-the-art access methods. Different access method designs can be visually represented based on their RUM balance. The RUM tradeoffs can be seen as a three dimensional design space or, if projected on a two-dimensional plane, as the triangle shown in Figure 1. Each access method is mapped to a point or – if it can be tuned to have varying RUM behavior – to an area. Table 1 shows the time and size complexity of representative data structures, illustrating the conflicting read, update, and memory overheads.

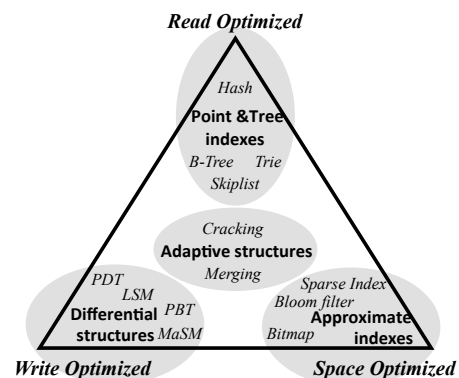

Figure 1: Popular data structures in the RUM space.

Read-optimized access methods (top corner in Figure 1) are optimized for low read overhead. Examples include indexes with constant time access such as hash-based indexes or logarithmic time structures such as *B-Trees* [22], *Tries* [19], *Prefix B-Trees* [9], and *Skiplists* [45]. Typically, such access methods offer fast read access but increase space overhead and suffer with frequent updates.

Write-optimized differential structures (left corner in Figure 1) reduce the write overhead of in-place updates by storing updates in secondary differential data structures. The fundamental idea is to consolidate updates and apply them in bulk to the base data. Examples include the *Log-structured Merge Tree* [44], the *Partitioned B-tree* (PBT) [21], the *Materialized Sort-Merge* (MaSM) algorithm [7, 8], the *Stepped Merge* algorithm [35], and the *Positional Differential Tree* [28]. *LA-Tree* [3] and *FD-Tree* [38] are two prime examples of write optimized trees aiming at exploiting flash while respecting at the same time its limitations, e.g., the asymmetry between read and write performance [6] and the bounded number of physical updates flash can sustain [7]. Typically, such data structures offer good performance under updates but increase read costs and space overhead.

Space-efficient access methods (right corner in Figure 1) are designed to reduce the storage overhead. Example categories include compression techniques and lossy index structures such as *Bloom filters* [12], lossy hash-based indexes like *count-min sketches* [16], *bitmaps with lossy encoding* [51], and *approximate tree indexing* [5, 40]. *Sparse indexes*, which are light-weight secondary indexes, like *ZoneMaps* [18], *Small Materialized Aggregates* [42] and *Col-*

Parameter	N	m	B	P	T	MEM
Explanation	dataset size (#tuples)	query result size (#tuples)	block size (#tuples)	partition size (#tuples)	LSM levels ratio	memory (#pages)

Access Method	Bulk Creation Cost	Index Size	Point Query	Range Query (size: m)	Insert/Update/Delete
B^+ -Tree	$O(N/B \cdot \log_{MEM/B}(N/B))$	$O(N/B)$	$O(\log_B(N))$	$O(\log_B(N) + m)$	$O(\log_B(N))$
Perfect Hash Index	$O(N)$	$O(N/B)$	$O(1)$	$O(N/B)$	$O(1)$
ZoneMaps	$O(N/B)$	$O(N/P/B)$	$O(N/P/B)$	$O(N/P/B)$	$O(N/P/B)$
Levelled LSM	N/A	$O(\frac{N \cdot T}{T-1})$	$O(\log_T(N/B) \cdot \log_B(N))$	$O(\log_T(N/B) \cdot \log_B(N) + \frac{m \cdot T}{T-1})$	$O(T/B \cdot \log_T(N/B))$
Sorted column	$O(N/B \cdot \log_{MEM/B}(N/B))$	$O(1)$	$O(\log_2(N))$	$O(\log_2(N) + m)$	$O(N/B/2)$
Unsorted column	$O(1)$	$O(1)$	$O(N/B/2)$	$O(N/B)$	$O(1)$

Table 1: The base data typically exist either as a *sorted column* or as an *unsorted column*. When using an additional index we (i) spend time building it, (ii) allocate space for it, and (iii) pay the cost to maintain it. The I/O cost [2] (time and space complexity) of four representative access methods (B^+ -Trees, Hash Indexes, ZoneMaps, and levelled LSM) illustrates that there is no single winner. ZoneMaps have the smaller size – being a sparse index, but Hash Indexes offer the fastest point queries, while B^+ -Trees offer the fastest range queries. Similarly, the update cost is best for Hash Indexes, while LSM can support efficient range queries having very low update cost as well.

umn Imprints [50] fall into the same category. Typically, such data structures and approaches reduce the space overhead significantly but increase the write costs (e.g., when using compression) and sometimes increase the read costs as well (e.g., a sparse index).

Adaptive access methods (middle region in Figure 1) are comprised of flexible data structures designed to gradually balance the RUM tradeoffs by using the workload access pattern as a guide. Most existing data structures provide tunable parameters that can be used to balance the RUM tradeoffs offline, however, adaptive access methods balance the tradeoffs online across a larger area of the design space. Notable proposals are *Database Cracking* [31, 32, 33, 48], *Adaptive Merging* [22, 25], and *Adaptive Indexing* [23, 24, 26, 34], which balance the read performance versus the overhead of creating an index. The incoming queries dictate which part of the index should be fully populated and tuned. The index creation overhead is amortized over a period of time, and it gradually reduces the read overhead, while increasing the update overhead, and slowly increasing the memory overhead. Although much more flexible than traditional data structures, existing adaptive data structures cannot cover the whole RUM spectrum as they are designed for a particular type of hardware and application.

The RUM tradeoffs of four representative access methods as well as two data organizations are presented in Table 1 in order to illustrate the need to balance them. The memory overhead is represented in the form of space complexity (index size), and the read and the update overheads in the form of the I/O complexity of the operations. We differentiate between point queries and range queries, to allow for a more detailed classification of access methods. We examine B^+ -Trees², Hash Indexing, ZoneMaps³, and levelled LSM [36], assuming that each LSM level is a B^+ -Tree with branch factor B . Typically, sparse indexing like ZoneMaps gives the lowest access method size, however, it delivers neither the best point query performance, nor the best range query performance. The lowest point query complexity is provided by Hash Indexing, and the lowest range query complexity by B^+ -Trees. In addition, even without any additional secondary index, maintaining a sorted column allows for searching with logarithmic cost, with the downside of having linear update cost. Hence, even without an auxiliary data structure, adding structure to the data affects read and write be-

Figure 2: RUM overheads in memory hierarchies.

havior. We envision RUM access methods to take this a step further, and morph between data structures and different data organizations in order to build access methods that have tunable performance and can change behavior both adaptively and on-demand.

The Memory Hierarchy. For ease of presentation, the previous discussion assumes that all data objects are stored on the same storage medium. Real systems, however, have a more complex memory/storage hierarchy making it harder to design and tune access methods. Data is stored persistently only at the lower levels of the hierarchy and is replicated, in various forms, across all levels of the hierarchy; each memory level experiences different access patterns, resulting in different read and write overheads, while the space overhead at each level depends on how much data is cached.

Several approaches leverage knowledge about the memory hierarchy to offer better read performance. *Fractal Prefetching B^+ -Trees* [15] use different node sizes for disk-based and in-memory processing in order to have the optimal for both cases. *Cache-sensitive B^+ -Trees* [47] physically cluster sibling nodes together to reduce the number of cache misses, and decrease the node size using offsets rather than pointers. *SB-Trees* [43] operate in an analogous way when the index is disk-based, while *BW-Tree* [37] and *MassTree* [41] presents a number of optimizations related to cache memory, main memory and flash-based secondary storage. *SILT* [39] combines write-optimized logging, read-optimized immutable hashing, and, a sorted store, carefully designed around the memory hierarchy to balance the tradeoffs of its various levels.

The RUM tradeoffs, however, still hold for each level individually as shown in Figure 2. The fundamental assumption that data has a minimum access granularity holds for all storage mediums today, including main memory, flash storage, and disks; the only difference is that both access time and access granularity vary. The RUM tradeoffs can also be viewed vertically rather than horizontally. For example, the RO_n read and the WO_n update overheads at memory level n can be reduced by storing more data, updates, or meta-data, at the previous level $n - 1$, which results, at least, in a

²Bulk loading requires sorting. The best sorting algorithm depends on type of storage. Here we assume external multi-way mergesort.

³We consider the best case for ZoneMaps; only a single partition needs to be read or updated.

higher MO_{n-1} . Overall, we expect this interaction of hardware and software to become increasingly more complex as hierarchies become deeper and as hardware trends shift the relative performance of one level compared to the others, resulting in the need for more fine tuning of access methods.

Viewing the hierarchy from the bottom towards the top, we first have cold storage which today may be shingled disks [29], or traditional rotational disks. They are followed typically by flash storage for buffering and read performance. The next levels are main memory and the different levels of cache memory. In the future an additional layer of non-volatile main memory will be added or it will replace main memory altogether [30]. Different layers of this new storage and memory hierarchy have different requirements. More specifically, shingled disks are similar to flash devices regarding the need to minimize update cost to respect their internal characteristics. On the other hand, when designing access methods for traditional rotational disks – sitting in-between shingled disks and flash in the hierarchy – we need to minimize the read overhead. As we move higher in the hierarchy, read performance and index size is typically more important than update cost.

Cache-Oblivious Access Methods. A different way to build access methods is to completely remove the memory hierarchy from the design space, using cache-oblivious algorithms [20]. Cache-oblivious access methods, however, achieve that by having a larger constant factor in read performance [11]. In addition, cache-oblivious access methods have a larger memory overhead because they require more pointers to guarantee that search performance will be orthogonal to the memory hierarchy [10]. Finally, cache-oblivious designs are less tunable. In order to tune a data structure and be able to balance between read performance, update performance, and memory consumption we need to be cache-aware [10]. As a result, in order to build RUM-tunable access methods we have to use a cache-aware design and take into account the exact shape of the memory hierarchy.

5. BUILDING RUM ACCESS METHODS

For several decades, the database research community has been redesigning access methods, trying to balance the RUM tradeoffs with every change in hardware, workload patterns, and applications. As a result, every few years new variations of data management techniques are proposed and adaptation to new challenges becomes increasingly harder. For example, most data management software is still unfit to natively exploit solid-state drives, multi-cores, and deep non-uniform memory hierarchies, even though the concepts used to adapt past techniques and structures rely on ideas that were proposed several decades ago (like partitioning, and avoiding random access). In other words, what changes is how one *tunes* the structures and techniques for the new environment.

Both hardware and applications change rapidly and continuously. As a result, we need to frequently adjust data management software to meet the evolving challenges. In the previous sections we laid the groundwork for RUM access methods, by providing an intuitive analysis of the RUM overheads and the RUM Conjecture. Moving further, here we propose the necessary research steps to design versatile access methods that have variable balance between the RUM overheads. In Figure 3 we visualize the ideal RUM access method, which will be able to seamlessly transition between the three extremes: read optimized, write optimized, and space optimized. In practice, it may not be feasible to aim for building a single access method able to cover the whole spectrum. Instead, an alternative approach is to build multiple access methods able to navigate partly in the RUM space, however, covering the whole space in aggregate.

Studying The RUM Tradeoffs. The first step towards building

Figure 3: Tunable behavior in the RUM space.

RUM access methods is to extend the discussion in Section 4. A detailed study of the nature of RUM tradeoffs in practice, will lead to a detailed classification of access methods based on their RUM balance. Most existing access methods can be depicted as a static point in the RUM space (Figure 3). The exact position of the point may differ based on some parameters (for example, the fan-out of B⁺-Trees, the number of partitions in PBT, the number of sorted runs in MaSM). Moreover, adaptive indexing techniques like cracking behave in a dynamic manner yet are not tuneable: as they touch more data they add structure to the data and gradually reduce the read overhead at the expense of update overhead.

A concrete outcome of this analysis is the gleaning of all the fundamental building blocks and strategies of access methods. For example, logarithmic access cost (trees, exponentially increasing logs), fixed access cost (tries, hash tables), trading-off computation for auxiliary data size (hashing for hash tables, compression for bitmaps), and lazy updates (log-structure approaches).

Tunable RUM Balance. Using the above classification and analysis we can make educated decisions about which access method should be used based on the application requirements and the hardware characteristics, effectively creating a powerful access method wizard. In addition to that, we investigate how to build access methods that have tunable behavior. Such access methods are not single points in the RUM space; instead they can move within an area in the design space.

We envision future data systems with a suite of access methods that can easily adapt to different optimization goals. For example:

- B⁺-Trees that have dynamically tuned parameters, including tree height, node size, and split condition, in order to adjust the tree size, the read cost, and the update cost at runtime.
- Approximate (tree) indexing that supports updates with low read performance overhead, by absorbing them in updatable probabilistic data structures (like quotient filters).
- Morphing access methods, combining multiple shapes at once. Adding structure to data gradually with incoming queries, and building supporting index structures when further data reorganization becomes infeasible.
- Update-friendly bitmap indexes, where updates are absorbed using additional, highly compressible, bitvectors which are gradually merged.
- Access methods with iterative logs enhanced by probabilistic data structures that allows for more efficient reads and updates by avoiding accessing unnecessary data at the expense of additional space.

Dynamic RUM Balance. We envision access methods that can automatically and dynamically adapt to new workload requirements

or hardware changes, like a sudden increase or decrease of availability of storage or memory. For example, in the case of access methods based on iterative merges, by changing the number of merge trees dynamically, the depth of the merge hierarchy and the frequency of merging, we can build access methods that dynamically adapt to workload and hardware changes.

Compression and Computation. Orthogonally to the tension between the three overheads, when accessing data today compression is often used to reduce the amount of data to be moved. This trade-off between computation (compressing/decompressing) and data size does not affect the fundamental nature of the RUM Conjecture. Compression is seldom used only for transferring data through the memory hierarchy. Rather, modern data systems operate mostly on compressed data and decompress as late as possible, usually when presenting the final answer of a query to the user.

6. SUMMARY

Changes in hardware, applications and workloads have been the main driving forces in redesigning access methods in order to get the read-update-memory tradeoffs right. In this paper, we show through the RUM Conjecture that creating the ultimate access method is infeasible as certain optimization and design choices are mutually exclusive. Instead, we propose a roadmap towards data structures that can be tuned given hardware and application parameters, leading to the new family of *RUM-aware* access methods.

Although building RUM access methods represents a grand new challenge, we see it as the natural next step inspired by our collective past efforts. Past research in areas such as data structures, tuning tools, adaptive processing and indexing, and hardware-conscious database architectures is the initial pool for concepts and principles to be generalized.

ABSTRACT

The success of relational databases is due in part to the simplicity of the tabular representation of data, the clear separation of the physical and logical view of data, and the simple representation of the logical view (meta-data) as a flat schema. But we are now witnessing a paradigm shift owing to the explosion of data volume, variety and veracity, and as a result, there is a real need to knit together data that is naturally heterogeneous, but deeply interconnected. To be useful in this world, we argue that today's tabular *data model* must evolve into a *holistic data model* that views meta-data as a new semantically rich source of data and unifies data and meta-data such that the data becomes *descriptive*. Furthermore, given the dynamicity of data, we argue that fundamental changes are needed in how data is consolidated continuously under uncertainty to make the data model naturally more *adaptive*. We further envision that the entire *query model* must evolve into a *context-aware model* in order to automatically discover, explore, and correlate data across many independent sources in real-time within the context of each query. We argue that enriching data with semantics and exploiting the context of the query are the two key prerequisites for building *self-curating databases* in order to achieve a *real-time exploration and fusion of enriched data at web scale*. These needs highlight a series of interesting challenges for database research and alter some of the tenets of Codd's rules for how we think about data.

1. INTRODUCTION

We believe that the relational database system will remain the de facto standard for well-structured data. The success of relational database theory is partly due to its simple tabular representation over a predefined relational schema. Tabular data is manipulated through a well-defined declarative relational algebra that is written over the data schema (a logical view). Expressing queries over the logical view has led to decades of query optimization in order to transform queries written over logical views into efficient access methods over the physical layout. As database engines advance, the logical view remains constant, and this has been a key success factor for relational database systems (i.e., data independence).

However, the tabular data represented by the relational schema is limited to a flat schema for describing each table column.¹ One may

¹ Although the database schema has remained a simple flat structure, there have been

argue that the relational schema, in addition to forming a logical view for querying the data, is nothing but a simple blueprint of how to parse the data at the physical level. This blueprint ends at the granularity of columns, which is why often it is referred to as a table schema because it is not at the record level. Homogeneity at the record level is also pre-assumed in the relational theory, in fact, the Boyce-Codd normal forms to some extent already penalize any column heterogeneity [6]. Similarly, NoSQL databases such as key-value stores are still fundamentally tabular, but the "value" column is now heterogeneous with a flexible schema [4].²

Although databases were designed for a system of records in order to maintain corporate transactional data, the tabular data model in databases can represent many types of non-transactional data. However, it has certain fundamental limitations. The chief limitation is that the tabular model does not natively capture instance-level relations, which is why a whole class of functional dependency (FD) and referential integrity (RI) constraints had to be developed to express schema-level relationships (e.g., RI) and to avoid record-level inconsistencies (e.g., FDs). In general, integrity constraints are used to ensure that data instances conform to a given schema while only limited knowledge (e.g., relation transitivity) can be expressed using constraints because the primary role of constraints is to restrict the data as opposed to enriching the data [12].

We observe that today's data is no longer limited to systems of records; we now have a variety of data coming from thousands of sources. Data is being generated at an astonishing rate of 2.5 billion gigabytes daily, and further, 80% of data is unstructured and comes in the form of images, video, and audio data to social media (e.g., Twitter, Facebook, Blogosphere) and from embedded sensors and distributed devices [1]. The explosion is partly due to the Internet of Things (IoT) that increasingly connects data sources (including objects and devices) to form a complex network, a network that is expected to exceed one trillion nodes [1].

These emerging data sources are heterogeneous by nature and are independently produced and maintained, yet the data are inherently related. For example, sales patterns correlate with the popularity of the product in social media, and the popularity of the product itself can be measured in terms of how often images or tweets are posted of the product. Even if one considers only the "structured" data after the extraction from the unstructured data, the task of integrating all these disparate data sources leaves islands of data with thousands (if not millions) of tables and schemata that are simply impossible to understand and query by any individual.

Arguably data is a new natural resource in the enterprise world with an unprecedented degree of proliferation and heterogeneity and countless possible ways of aggregating and consuming it to find

attempts to at least model the data conceptually as a hierarchy, e.g., the entity-relation (ER) or object-oriented models.

² In fact, several NoSQL initiatives even motivate the need for a *schema-less* paradigm [4] that is in a diametrically opposite position from our self-curating database vision.

actionable insights [1]. However, this inherently interconnected data is trapped in disconnected islands of information, which forces analytics-driven decision making to be carried out in isolation and on stale (and possibly irrelevant) data; thus, making today’s *first-ingest-then-process* model insufficient and unnecessary at a time when the cloud is disrupting the entire computing landscape.³ More importantly, existing database technologies fail to alleviate the data exploration challenges that continue to be a daunting process especially at a time when an army of data scientists are forced to manually and continuously refine their analyses as they sift through these islands of disconnected data sources, a labor-intensive task occupying 50-80% of time spent [11].

We argue that today’s database systems need to be fundamentally re-designed to capture data heterogeneity (within local and external data sources) and the semantic relationship among data instances (i.e., data interconnectedness) as first class-citizens. To address these requirements, we propose a *holistic data model* to capture all dimensions of the data, so that we can push the burden of semantic enrichment and integration of the data in a systematic and transparent way into the database engines. We view the data fusion as a *gradual curation* process that transforms the raw data into a new unified entity that has *knowledge-like characteristics*; thereby, we envision the evolution of database systems into *self-curating databases* to meet the continuous enrichment and integration challenges of the information explosion.

In moving from databases to self-curating systems, the schema is no longer a table schema as a separate entity that is limited to necessary information to only parse the data. Instead, the data schema becomes part of the data in order to make the data self-descriptive. Furthermore, it is expected that both the data and meta-data continuously evolve either by ingesting new data sources or through the process of *context-aware query* execution. By context-aware query execution, we emphasize redefining the existing *query model* to enable the discovery of new data linkage and semantic relationships in the specific context of a given query. Thus, while the query must automatically be refined to enable discovery, the data will also become sufficiently enriched in order to enable continuous integration and adjustment of the interconnectedness of instances/types.

In short, our broader vision is a systematic methodology to achieve a *real-time fusion and enrichment of data at web scale* hosted virtually. We argue for a unified view of semantically enriched data by introducing a novel *holistic data model* (i.e., *rethinking the data model*), so queries can be answered by an online consolidation of the most up-to-date data from a variety of sources at query time without the need for offline ingestion and curation. Furthermore, we envision that querying and analytics in general will become explorative in nature to provide deeper and quicker insights by proactively refining and raising new queries based on the context of the query submitted by the user, making the query model *context-aware* (i.e., *rethinking the query model*).

Thus far, we have provided the desired properties of self-curating databases. In the subsequent sections, we elaborate on the specific properties of self-curating databases and highlight the challenges and short- and long-term research opportunities they bring in a systematic fashion. We further broadly classify our proposed statements as either *functional statements* (for adding new capabilities) or *optimization statements* (for improving system performance); these open problems are summarized in Table 1.

2. RELATED WORK

Our vision is partly motivated by the recent shift towards semantically enriched information retrieval. We observe a trend among

³ We anticipate that in the near future all data sources and analytics computation will be hosted virtually on the cloud [1]; thus, there is no need to first ingest data from one computing infrastructure to another before querying the data.

Table 1: Open problems in self-curating databases

Web search engines such as Google and Bing in moving away from a pure information retrieval system towards knowledge-based retrieval by not only retrieving a set of documents relevant to the users’ queries, but also identifying *entities* and returning *facts* regarding the identified entities [13]. Another prominent initiative is IBM *Watson*, which is an open-domain question answering system for outperforming the best players in Jeopardy [7]. Such knowledge-based retrieval has become possible through the use of rich knowledge bases created by academic and community efforts such as Freebase, DBpedia, and YAGO [13].

What we observe in all these emerging projects [13, 7] is that moving forward, simple information retrieval will be insufficient, and that information will continuously be expanded and semantically enriched as a result of the continuous integration of heterogeneous sources (i.e., the evolution of information to knowledge). Consequently, we argue the need for the evolution of relational databases to handle the challenges in this new enriched data era. We envision that the database systems of the future will no longer be solely responsible for the storage and retrieval of structured data, but they will transform into self-curating databases that are capable of *real-time exploration and fusion of enriched data at web scale*.

We acknowledge that we are not the first to argue for the high-level concepts such as semantic enrichment or continuous integration; in fact, there are several existing efforts in Semantic Web technologies (e.g., [13]) and dataspace and pay-as-you-go integration models (e.g., [8]) that strive for similar high-level objectives. But to achieve these objectives, we argue for a fundamental rethinking of how we view the data and query. We envision the need for a new *holistic data model* to unify the data and meta-data, and to view the meta-data as a new semantically rich source of data. Furthermore, we envision a simpler and more effective way to query and compute answers by automatically refining the query and continuously discovering new data sources within the context of each query, giving rise to a novel *context-aware query model*. Further, what is unique to our vision, in addition to extending past attempts in light of new applications and possibilities (e.g., [7]), is systematically sketching the requisite properties of a self-curating database and providing an extensive list of the concrete research challenges and opportunities needed to make such a vision a reality.

3. DATA MODEL: UNIFIED & ENRICHED

In our view, a self-curating database must have a hierarchy of layers to transform raw data incrementally into a *holistic data model* (depicted in Figure 1). First is the *instance layer*, to store the raw data (or data instances) spanning both structured and unstructured. The second layer is the *relation layer*, a horizontal expansion of data to formulate and capture the interconnectedness of data instances within and across data sources (i.e., the fine-grained instance-level linkage). In cases where the raw data layer is unstructured, this layer may additionally capture the results of information extraction. The third layer is the *semantic layer*, a vertical expansion of data to conceptualize data instances and their rela-

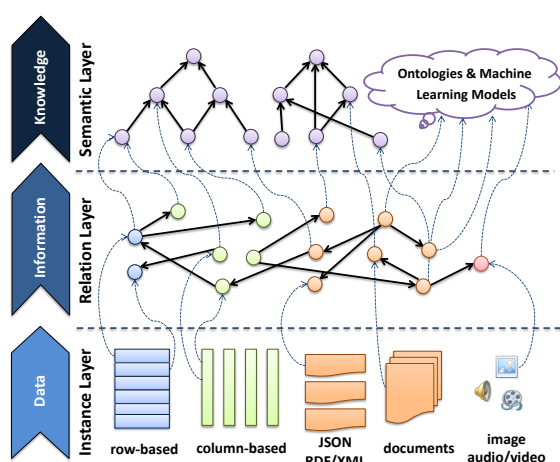

Figure 1: Holistic data model.

tions as semantic types and to formulate the interconnectedness of archetypes and data instantiated types (e.g., ontology). The semantic layer is a way of succinctly capturing conceptual relationships among data instances. This final layer will bring an unprecedented level of expressiveness power and discovery potentials. The last two layers of self-curating databases can be viewed as meta-data, but such a distinction no longer holds in a self-curating database as meta-data is also seen as a rich source of data.

We argue that such a holistic approach is essential to efficiently represent, enrich, manipulate, and query both data and meta-data. Our running example of an enriched data model is extracted from the life science domain, as illustrated in Figure 2. This example is motivated by the overwhelming challenge to unify and enrich data from a variety of heterogeneous sources to develop an assisted diagnosis and personalized treatment and medicine [7].

3.1 Instance Layer: Raw Data

The first layer is what today's relational database systems heavily rely on to represent structured data. But future databases must naively also support semi-structured data such as XML and JSON (already supported by most commercial databases) and unstructured data such as text documents, images, audio, and video. In the example shown in Figure 2, the data comes from different external sources such as DrugBank that offers data about known drugs and diseases, Comparative Toxicogenomics Database that provides information about gene interaction, and Uniprot that provides details about the functions and structure of genes.

One may argue that the proposed instance layer shares similar properties to those already found in the tabular representation of the relational model. However, a deeper question here is whether a tabular representation is an optimal choice for a *holistic data model*. Analytical workloads, for instance, benefit greatly from a columnar decomposition of tabular representation. In contrast, a self-curating database must manage data and meta-data in a unified way, but it is unclear what the optimal representation is for such systems. For example, could the relational model be further decomposed in non-linear and non-tabular form in order to cluster data based on the instance relations and semantic relationships of higher layers?

OPTIMIZATION STATEMENT 1. *Given the abundance of instance relations and semantic relationships, what are the data clustering opportunities to improve retrieval, access locality, and compression? Is it possible to develop dynamic instance-level, fine-grained clustering in the presence of the enriched data model?*⁴

⁴Imagine a representation that could adapt to the locality of access for a workload

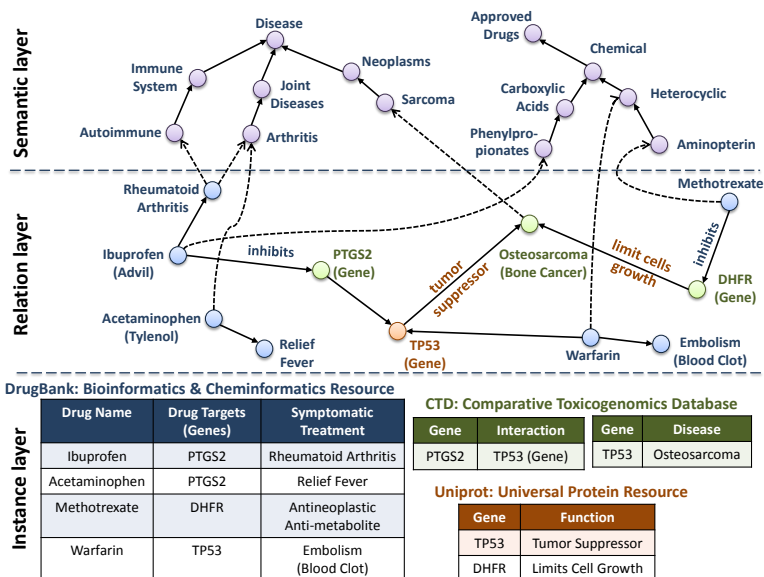

Figure 2: An example of an enriched data model in the life science domain.

3.2 Relation Layer: Horizontal Expansion

A relational model has no notion of which columns refer to real world entities (i.e., data instances). But a holistic data model must possess a clear notion of what the entities are, and what relations exist for each instance in order to capture the data interconnectedness. These may be relations to other entities, or the relations of the attributes of the entity to data values. As an example, a database might have a table for *Drug*, and have the columns *Name*, *Targets*, *Symptomatic Treatment*. A rich data model has an identifier for a real world drug *Methotrexate*, and captures its attributes such as *Molecular Structure*, as well as relations to other entities including *Genes* that *Methotrexate* targets (e.g., *DHFR*), and subsequently, *Conditions* that it treats such as *Osteosarcoma (bone cancer)* that are reachable through its target genes, as shown in Figure 2.

The key characteristics of the relation layer are to capture entity interconnectedness and to establish the identity of an entity within and across multiple data sources – a process we term *horizontal data expansion* to transform data into information. An important challenge of the relation layer is to uniquely identify similar entities even when external sources are dynamically changing. There is a long history of entity resolution in the database literature, but the real challenge in this layer is that there is no ability to rely on manual ETL jobs to perform offline schema alignment, and it is not wise to assume that as each source is added to the self-curating database, an all-to-all entity resolution is performed comprehensively across all data sources.

FUNCTIONALITY STATEMENT 1. *A self-curating database must adaptively manage instance relations in light of new information. How does one adapt existing entity resolution techniques so they work across different schemata without requiring prior knowledge about external data sources to enable efficient incremental schema evolution in local data sources?*

FUNCTIONALITY STATEMENT 2. *Furthermore, what is the right formalism to express and capture the interconnectedness in order to assess and measure the richness of each data source based on the connectivity and density? For example, information content and capacity are a common measure for assessing the richness, and graph-theocratic approaches are well suited for studying the connectivity, flow properties, partitioning, and topology, but there is a lack of general formalism to assess the interconnectedness of data.*

based on the interconnectness of data. The frequently accessed data could be packed together to be used efficiently in the limited, but fast-access memory of modern hardware including CPU cache or GPU and FPGA on-chip memory.

Another challenge is how to efficiently manage relation interconnectedness. One may argue that a graph is the right abstraction model, but it leaves open the question of how to provide fast traversal abilities. Alternatively, one may argue that traditional indexes (e.g., B-Tree) may improve lookup, but at the high-level, indexes only provide one-hop away direct accesses, which are already captured in the explicit interconnectedness of the data. Thus, direct access is no longer beneficial, but rather the open challenge is how to improve the locality of multi-hop traversal.

OPTIMIZATION STATEMENT 2. *Given that the instance interconnectedness already encompasses the benefit of one-hop away direct access, what is an optimal representation that provides efficient locality-aware traversal that is tightly coupled with the instance and semantic layers and is update-friendly?*

3.3 Semantic Layer: Vertical Expansion

The instance layer together with relations between the instances, as discussed thus far, constitute what is often conceptually referred to as the ABox in the description logic and semantic web literature [3]. That is, instances refer to individual entities in the real world, relations among them are expressed in terms of semantic properties, and each instance is a member of one or more concepts or types. The concepts and semantic properties that are used in the ABox constitute meta-data about the instance data. Concepts themselves may have relationships to each other and semantic properties.

As a somewhat simple example, a *Drug* can be defined as a chemical with an existential quantification over the relation *has Target*. This means that if the actual instance data only stated that *Acetaminophen (Tylenol)* is a *Drug*, a self-curating database could infer that *Acetaminophen* has a target, even if the specific relation has yet to be discovered and expressed as a relationship between *Acetaminophen* and any particular gene. In fact *Acetaminophen* targets *PTGS2* (even though it is not shown in Figure 2).

These richer semantic reasonings are formulated and expressed in taxonomies or web ontology language (OWL), a subset of first-order logic (FOL). Relationships among the concepts and properties are typically referred to in the semantic web as the TBox [3]. To formalize our discussion, we focus on a widely employed OWL-DL language, which is based on the semantics of SHIN. The SHIN semantics is defined as $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$, where \mathcal{I} refers to an interpretation, $\Delta^{\mathcal{I}}$ is a non-empty set (the domain of the interpretation), and $\cdot^{\mathcal{I}}$ is the interpretation function that maps every atomic concept C to a set $C^{\mathcal{I}} \subseteq \Delta^{\mathcal{I}}$ (*Approved Drugs* is an example of the concept), every atomic role R to a binary relation $R^{\mathcal{I}} \subseteq \Delta^{\mathcal{I}} \times \Delta^{\mathcal{I}}$ (e.g., *has Therapeutic Efficacy* as a role), and every individual a to $a^{\mathcal{I}} \in \Delta^{\mathcal{I}}$.

An RBox \mathcal{R} is a finite set of transitivity axioms and role inclusion axioms of the form $R \sqsubseteq P$ where R and P are roles. A Tbox \mathcal{T} is a set of concept inclusion axioms of the form $C \sqsubseteq D$, where C and D are concept expressions (e.g., *Neoplasms* \sqsubseteq *Disease*). An Abox \mathcal{A} is a set of axioms of the form $a : C$ (a is a member of the concept C), $R(a, b)$ (there is an R relationship between a and b), e.g., *has Target*(*Acetaminophen*, *PTGS2*). Finally, an interpretation \mathcal{I} is a model of an Abox \mathcal{A} with respect to a Tbox \mathcal{T} and a Rbox \mathcal{R} iff it satisfies all the axioms in \mathcal{A} , \mathcal{R} , and \mathcal{T} .

A key strength of knowledge representation (KR) formalisms (such as OWL) derived from FOL stems from their capability to represent complex information in a knowledge rich domain, e.g., the biomedical domain. Unfortunately, FOL is incapable of dealing with inconsistency and uncertainty, which naturally arise when information from independent data sources is combined. The KR formalism should capture and aggregate information from both hard and soft sources. Hard sources may have a clear mathematical model of uncertainty, e.g., sensor data. Soft sources, on the other hand, provide vague statements of truth (often fuzzy), such as “a

sudden stomach bleed was attributed to the *recent intake* of *Ibuprofen*”. In contrast, there have been only isolated efforts to extend the KR languages to handle only a particular form of uncertainty, e.g., probabilistic or fuzziness [3]; thus, we raise the following question.

FUNCTIONALITY STATEMENT 3. *Is it possible to define a new unifying approach, but perhaps less expressive, to aggregate these isolated forms of uncertainty in a single tractable formalism?*

In general, we view the enrichment of data with semantics as *vertical data expansion* because this layer allows the database to infer new facts about the lower layers. We note that there is an increasing need for the vertical data expansion layer to be more general than the current notion of TBox \mathcal{T} . Increasingly, conceptual statistical models are being derived from the data to derive new connections between instance data. We therefore propose that the vertical data expansion be enriched by adding statistical models, such as those offered by machine learning, specifically to improve the linkage coverage and accuracy as well, considering that the purpose of this layer is to add semantic inference and reasoning capabilities about the instance types and the relationships among types.

FUNCTIONALITY STATEMENT 4. *In the semantic web literature, the assumption is that a user can specify the ontology as a logical view that can be applied over data with respect to a given query. Is it reasonable to have users be aware of the meta-models needed to understand the structure of the data, especially as one allows statistical models? And how does one describe a specific statistical model that should be applied over the data declaratively?*

To further benefit from the enriched data, there is a need for new formalism to combine the expressiveness power of database querying languages (e.g., SQL) with the semantic formalism of description logic (e.g., OWL) to capture the knowledge about the data.

FUNCTIONALITY STATEMENT 5. *Is it possible to develop a new semantically enriched query language that combines the expressiveness and declarativeness power of SQL (subset of FOL) and the leading semantic formalisms such as OWL (also subset of FOL) while retaining decades long advancement of query optimization and scalable query execution? Furthermore, is it possible to extend this new combined language with machine learning models that are based on non-declarative statistical, mathematical, or numerical formalism rather than the logical FOL formalism?*

Through semantically enriched data, there is an enormous opportunity to improve query optimization by inferring statistics given that today’s optimizers fail completely in the absence of statistics on the data.

OPTIMIZATION STATEMENT 3. *How to extend the predominant rule- and cost-based query optimization to leverage the explicit semantics within our data model, so the optimizers are no longer limited to only statistics on data (e.g., selectivity estimates) to guide the query optimization (often missing or unavailable for external sources)? Is it possible to exploit the available semantics (e.g., exploiting class and subclass relationships) by inferring the selectivity and rewriting the query to a more efficient query (e.g., by inferring that certain predicates can be collapsed together semantically or can be dropped because they are redundant or unsatisfiable)?*

4. QUERY MODEL: EMBRACE CONTEXT

There is a compelling case to make queries less complicated through automatic exploration and refinement given the query context while the results must become evidence-based and justified (not limited to just a confidence score). Considering our proposed *holistic data model*, there are new opportunities to formalize and leverage the context of queries throughout the entire query pipeline, giving rise to a new way of thinking about how to query islands of data. We declare a pressing need to *rethink the entire query model* in a self-curating database; in particular, we focus on refining queries and computing answers through the continuous discovery and integration of data made possible by the rich data model.

4.1 Continuous Discovery and Refinement

In the database literature, we have the notion of adaptive query processing for collecting more accurate statistics during query execution to proactively optimize the query plan [2]. But conceptually our proposed *context-aware query model* opens up new avenues of research, in which not only more accurate statistics are gathered, but the query is also refined. In addition to refining the query, the data is also being adapted. Specifically, new instance relations or semantics relationships are discovered within the context of a given query (and its refined queries) as part of an online incremental integration, a step towards achieving the continuous integration.

Consider the task of determining an effective dosage of a drug by querying multiple clinical data sources. It is well-known that ethnicity and race have a major role in determining drug responses [9]. Now if these isolated data sources correspond to populations that are biased to genetic, ethnicity, and environmental conditions, then there is a tremendous value in automatically and judiciously navigating through these data sources without forcing the user to be fully aware of the semantics and interpretation of data that would be embedded in the enriched data model.

Suppose the initial query is “What is an effective dosage of Warfarin for preventing a blood clot?” (captured in Figure 2). Now to offer an accurate and justified answer in the presence of many disconnected data sources, there is a crucial need to develop an explorative querying framework that exploits the context of the query. To discover the necessary information and to fill the gap, the following refined queries may be posed automatically: “Is Warfarin sensitive to ethnic background?” (necessary to be aware of any medical facts); “What are the disjoint classes of population with respect to Warfarin?” (necessary for drilling down further); or “Does Warfarin have a narrow therapeutic range?” (necessary to quantify the dosage sensitivity and its range). We argue that such exploration is only possible by enriching data with sufficient semantics in order to interpret the context of queries and raise additional questions.

FUNCTIONALITY STATEMENT 6. *A new formalism is needed to express and execute the context-aware query model such that the discovery of new data connections and the refinement of query are feasible. Is it possible to formulate the discovery and refinement process as a random walk problem, where the initial seeds or the probability of each step taken is driven by query predicates and/or query partial results?*

FUNCTIONALITY STATEMENT 7. *Alternatively, is it possible to extend the query-by-example formalism [14] for filling missing data to introduce an incremental process so the query answer is partially computed, and the partial answer becomes an example with incompleteness (missing values) for raising/refining additional queries?*

To judge and choose the right formalism for context-aware query answering, we also need to revisit the existing evaluation criteria both in terms of completeness and feasibility.

FUNCTIONALITY STATEMENT 8. *To improve the discovery, is it possible to extend the crowdsourcing formalism to identify and assess the necessity to fetch incomplete data given certain qualitative (to improve the accuracy and coverage of answers) or quantitative (to find information faster) cost functions?*

4.2 Continuous Online Integration

The importance of online incremental integration for the *context-aware query model* is twofold. First, in a setting consisting of independently managed (but linked) data sources, individual data sources may change over time and one cannot be assured that all updates are propagated in a timely fashion. In fact, one of the main shortcomings of today’s linked data initiative, in which large data sources are linked statically once, is the inability to deal with stale linked data [13]. Second, large scale one-time integration requires

a priori knowledge to perform the integration, and this is not always feasible [8]. Moreover, it discards the knowledge of the users of the systems. Every time a user submits a query, the query may contain knowledge about the data, e.g., how two pieces of data are connected. One can think of a submitted query as a small scale but more focused and accurate integration that is at the instance-level and not necessarily at the schema-level.

FUNCTIONALITY STATEMENT 9. *There is a need for a new formalism to assess the correctness of query answering within the context of a single query while we discover and consult overlapping or even conflicting sources of information. More importantly, how do we formulate the feedback mechanism to materialize the discovered information guided by the context of query? If the discovered information is conflicting, then how could we automatically assess the richness or validity of discovered entities based on the degree of richness of each source (e.g., information content)?*

Today’s formalisms for computing query answers focus on the inconsistencies, incompleteness, and uncertainty that arise within each data source or a set of integrated sources (i.e., a single consolidated view of data). The traditional probabilistic query answering relies on possible world semantics to assess the likelihood of answers by enumerating all possible worlds [5]. A well-known expressive representational model is a conditional table (c-table), in which each tuple t_i is associated with a Boolean formula (the condition c_i) [10]. The existence of a tuple in a possible world is subject to the satisfaction of its condition [10], c-tables are formally expressed as the valuation function of conditions $v(c)$.

Given an instance of data with uncertainty, we have a discrete probability space of $\mathcal{P} = (W, \mathbf{P})$, where W is a set of all the possible worlds given by $W = \{I_1, \dots, I_n\}$ and \mathbf{P} is a probability model that assigns probability $\mathbf{P}(I_i)$ to each possible world I_i such that $0 \leq \mathbf{P}(I) \leq 1$ and $\sum_{i=1}^n \mathbf{P}(I_i) = 1$. The probability of any tuple t is the total probability of all worlds in which t exists and can simply be computed by $\sum_{i=1, t \in I_i}^n \mathbf{P}(I_i)$.

Similarly, the incompleteness semantics $\llbracket \cdot \rrbracket$ is defined for an incomplete database D as a set of complete databases $\llbracket D \rrbracket$ that are constructed given an interpretation of null values $\mathcal{I}^{\text{null}}$ under either as open- or closed-world assumption, $\llbracket \cdot \rrbracket_{\text{OWA}}$ or $\llbracket \cdot \rrbracket_{\text{CWA}}$, respectively [10]. The domain of the database consists of a set of constants (denoted by Const) and a set of nulls (denoted by Null), where the null represents the missing/unknown values. An example of a different interpretation of null values $\mathcal{I}^{\text{null}}$ is Codd’s three-valued logic.

Subsequently, the problem of query answering is reformulated as finding certain answers for the query Q . Given an interpretation of nulls $\mathcal{I}^{\text{null}}$: the certain answer is defined as $\text{certain}(Q, D) = \bigcap_i \{Q(D_i) \mid D_i \in \llbracket D \rrbracket\}$, which amounts to finding an intersection among a set of possible worlds. Notably, an incomplete database can be represented by a c-table [5], an important step towards unifying the representation model for both uncertainty and incompleteness [5, 10]. For instance, to capture both incompleteness and uncertainty, the c-tables semantics can be extended to included the valuation of nulls $v(t_i)$ and the valuation of conditions $v(c_i)$ so that a possible complete database instance I can be computed.

The existing techniques based on possible world semantics focus on deriving possible data instances from a single consolidated representation of data with uncertainty/incompleteness. However, there is no formalism to deal with multiple databases, where each source is complete and certain, but when viewed together without sufficient semantics, then uncertainty, incompleteness, and inconsistencies could arise. Let us revisit querying a set of independent sources, where each source captures clinical trials carried out in a different country and data is demographically biased; thus, naively combining the data from these sources may result in conflicting outcomes, even if data in each source is consistent/certain [9].

Consider a simple Boolean query “Is 5.0 mg an effective dosage

of Warfarin for preventing blood clot?”. If the data was collected in white-dominant population, the effective daily dosage is expected to be around 5.1 mg, while in Asian and black population, daily doses of 3.4 mg and 6.1 mg are recommended, respectively [9]. Now, a naive evaluation may return false as the certain answer to our question (because not all sources report a 5.0 mg dosage rate) while semantically enriched data can infer that these reported dosage rates belong to three disjoint ethnic classes, and to compute the certain answer it is sufficient to have at least one dataset with a daily dose of “close” to 5.0 mg. Now the notion of closeness can further be formulated based on fuzzy logic in light of the fact that “Warfarin has a very narrow therapeutic range” [9]. Therefore, we argue that sufficient semantics are needed to capture the knowledge about the data premises (beyond today’s lineage and provenance information) when integrating multiple data sources, and a new query answering formalism is needed to leverage the added knowledge.

In general, *derived possible worlds* are all constructed from a single integrated and consolidated actual world with incompleteness and/or uncertainty. But data at the web scale consisting of a large set of actual worlds (independent data sources) not just postulated probable worlds. These independent actual worlds, which we refer to as “*parallel worlds*” to distinguish them from the existing *possible worlds* semantics, may have conflicting facts, an alternative view of worlds, or relative facts that are only locally consistent given the premise of the particular world (i.e., semantics of the data). In short, information is relative with respect to the perspective of each independent source, and even in the absence of local inconsistency or uncertainty, the data may become contradictory when combined in the absence of sufficient semantics.

FUNCTIONALITY STATEMENT 10. *Firstly, is the exiting c-table formalism sufficiently expressive and concise to model our notion of parallel worlds with our proposed enriched and unified data model? For example, is the c-table representation required to be extended with relation and semantic layers (analogous to our holistic model) to faithfully capture the answers? Now, assuming a representational model, how do we formulate the notion of parallel world semantics for computing justified answers that may not always be globally justified in the presence of overlapping, complementary, and/or opposite relative views of worlds, where “justify” is taken as a fuzzy definition of “certain” to capture, possibly in a relaxed form, correctness and consistency for query semantics?*

In addition to the need for formalism and the semantics of query answering, there are other research challenges related to the execution semantics. As we continuously seek to discover and integrate new data sources and our holistic data model becomes more expressive, a whole set of challenges arise for transaction processing. For example, how do we ensure repeatability and guard against non-deterministic phantoms in transaction processing?

FUNCTIONALITY STATEMENT 11. *If the relation and semantic layers can be changed continuously, even when the instance layer does not change, and these layers are further enhanced with non-deterministic predictive inference power, could the classical isolation semantics (e.g., repeatability or snapshot) ever be satisfied? In what ways must concurrency control be extended to account for the non-determinism that is not the result of explicit update queries? Is it possible to introduce relaxed isolation semantics (e.g., eventual consistencies) to account not only for a delay in receiving changes (i.e., pushed and eventually received), but also to account for situations where changes may never be sent explicitly and once received may be non-deterministic (i.e., pulled and eventually received with uncertainty)? These fundamental changes to the concurrency model will inevitably have implication for other components such as logging and recovery protocols.*

A system-level dimension of continuous integration and avoidance of today’s pre-dominant *first-ingest-then-process* arises when

considering the landmark shift of pushing both query execution and hosting of data sources on the cloud [1]. This synergy will introduce a whole new class of workload orchestration and optimization to reduce the cost of online integration and query answering.

OPTIMIZATION STATEMENT 4. *How can existing placement strategies be adapted to transition from disk data placement to placing data in distributed main memory at cloud scale? How can the data be judiciously placed in distributed shared memory with close affinity when online integration of data sources is likely in order to eliminate the storage access cost and to reduce the main memory footprint by avoiding data cache duplication?*

5. REVISITING DATABASE PRINCIPLES

In conclusion, to characterize our vision of self-curating databases, we revisit Codd’s classical rules for relational systems and elaborate on how these rules must be extended to account for self-curating databases. In the process, we develop a comprehensive list of criteria that may serve as a test for self-curating databases.

- Deviation from *the foundation rule*: A self-curating database cannot assume that all data is managed locally and all data is in a relational model as was prescribed by Codd.
- Deviation from *the information rule*: Information is not limited to only the tabular form. A richer representation is essential to store information about the data. Meta-data and data representations must be unified and their distinction eliminated. Furthermore, every piece of information needs to be represented in the hierarchical multi-layered data model, where each layer semantically enriches the data, unlike Codd’s vision that information is represented in only one way, namely, as a value in a table.
- Extending *the systematic treatment of null values rule*: The data model must allow each data item to be noisy, fuzzy, uncertain, or incomplete so that it can be manipulated systematically, in addition to the need for the nulls to represent missing values as advocated by Codd.
- Extending *the comprehensive data sublanguage rule*: The employed language must also support (1) data discovery and refinement operators and (2) multi-source transactions with limited access and concurrency enforcement on external sources, in addition to the language requirements stated by Codd.
- Deviation from *the view updating rule*: External views may not be updatable or forced to be updated incrementally and lazily, whereas Codd assumes all views must be strictly updatable.
- Deviation from *the integrity independence rule*: Constraints on data and meta-data are not limited to an independent set of rules maintained in the catalog (as required by Codd) because constraints are now modeled at the relation and semantic layers and data instances are physically linked.

ABSTRACT

Data wrangling is the process by which the data required by an application is identified, extracted, cleaned and integrated, to yield a data set that is suitable for exploration and analysis. Although there are widely used Extract, Transform and Load (ETL) techniques and platforms, they often require manual work from technical and domain experts at different stages of the process. When confronted with the 4 V's of big data (volume, velocity, variety and veracity), manual intervention may make ETL prohibitively expensive. This paper argues that providing cost-effective, highly-automated approaches to data wrangling involves significant research challenges, requiring fundamental changes to established areas such as data extraction, integration and cleaning, and to the ways in which these areas are brought together. Specifically, the paper discusses the importance of comprehensive support for context awareness within data wrangling, and the need for adaptive, pay-as-you-go solutions that automatically tune the wrangling process to the requirements and resources of the specific application.

1. INTRODUCTION

Data wrangling has been recognised as a recurring feature of big data life cycles. Data wrangling has been defined as:

a process of iterative data exploration and transformation that enables analysis. ([21])

In some cases, definitions capture the assumption that there is significant manual effort in the process:

the process of manually converting or mapping data from one "raw" form into another format that allows for more convenient consumption of the data with the help of semi-automated tools. ([35])

The general requirement to reorganise data for analysis is nothing new, with both database vendors and data integration companies providing Extract, Transform and Load (ETL) products [34]. ETL platforms typically provide components for wrapping data sources, transforming and combining data from different sources, and for loading the resulting data into data warehouses, along with some means of orchestrating the components, such as a workflow language. Such platforms are clearly useful, but in being developed principally for enterprise settings, they tend to limit their scope to supporting the specification of wrangling workflows by expert developers.

Does big data make a difference to what is needed for ETL? Although there are many different flavors of big data applications, the 4 V's of big data¹ refer to some recurring characteristics: *Volume* represents scale either in terms of the size or number of data sources; *Velocity* represents either data arrival rates or the rate at which sources or their contents may change; *Variety* captures the diversity of sources of data, including sensors, databases, files and the deep web; and *Veracity* represents the uncertainty that is inevitable in such a complex environment. When all 4 V's are present, the use of ETL processes involving manual intervention at some stage may lead to the sacrifice of one or more of the V's to comply with resource and budget constraints. Currently,

data scientists spend from 50 percent to 80 percent of their time collecting and preparing unruly digital data. ([24])

and only a fraction of an expert's time may be dedicated to value-added exploration and analysis.

In addition to the technical case for research in data wrangling, there is also a significant business case; for example, vendor revenue from big data hardware, software and services was valued at \$13B in 2013, with an annual growth rate of 60%. However, just as significant is the nature of the associated activities. The UK Government's Information Economy Strategy states:

the overwhelming majority of information economy businesses – 95% of the 120,000 enterprises in the sector – employ fewer than 10 people. ([14])

As such, many of the organisations that stand to benefit from big data will not be able to devote substantial resources to value-added

¹<http://www.ibmbigdatahub.com/infographic/four-vs-big-data>.

data analyses unless massive automation of wrangling processes is achieved, e.g., by limiting manual intervention to high-level feedback and to the specification of exceptions.

Example 1 (e-Commerce Price Intelligence). When running an e-Commerce site, it is necessary to understand pricing trends among competitors. This may involve getting to grips with: Volume – thousands of sites; Velocity – sites, site descriptions and contents that are continually changing; Variety – in format, content, targeted community, etc; and Veracity – unavailability, inconsistent descriptions, unavailable offers, etc. Manual data wrangling is likely to be expensive, partial, unreliable and poorly targeted.

As a result, there is a need for research into how to make data wrangling more cost effective. The contribution of this vision paper is to characterise research challenges emerging from data wrangling for the 4Vs (Section 2), to identify what existing work seems to be relevant and where it needs to be further developed (Section 3), and to provide a vision for a new research direction that is a prerequisite for widespread cost-effective exploitation of big data (Section 4).

2. DATA WRANGLING – RESEARCH CHALLENGES

As discussed in the introduction, there is a need for cost-effective data wrangling; the 4 V's of big data are likely to lead to the manual production of a comprehensive data wrangling process being prohibitively expensive for many users. In practice this means that data wrangling for big data involves: (i) *making compromises* – as the perfect solution is not likely to be achievable, it is necessary to understand and capture the priorities of the users and to use these to target resources in a cost-effective manner; (ii) *extending boundaries* – as relevant data may be spread across many organisations and of many types; (iii) *making use of all the available information* – applications differ not only in the nature of the relevant data sources, but also in existing resources that could inform the wrangling process, and full use needs to be made of existing evidence; and (iv) *adopting an incremental, pay-as-you-go approach* – users need to be able to contribute effort to the wrangling process in whatever form they choose and at whatever moment they choose.

The remainder of this section expands on these features, pointing out the challenges that they present to researchers.

2.1 Making Compromises

Faced with an application exhibiting the 4 V's of big data, data scientists may feel overwhelmed by the scale and difficulty of the wrangling task. It will often be impossible to produce a comprehensive solution, so one challenge is to make well informed compromises.

The *user context* of an application specifies functional and non-functional requirements of the users, and the trade-offs between them.

Example 2 (e-Commerce User Contexts). In price intelligence, following on from Example 1, there may be different user contexts. For example, routine *price comparison* may be able to work with a subset of high quality sources, and thus the user may prefer features such as *accuracy* and *timeliness* to *completeness*. In contrast, where sales of a popular item have been falling, the associated *issue investigation* may require a more complete picture for the product in question, at the risk of presenting the user with more incorrect or out-of-date data.

Thus a single application may have different *user contexts*, and any approach to data wrangling that hard-wires a process for se-

lecting and integrating data risks the production of data sets that are not always fit for purpose. Making well informed compromises involves: (i) capturing and making explicit the requirements and priorities of users; and (ii) enabling these requirements to permeate the wrangling process. There has been significant work on decision-support, for example in relation to multi-criteria decision making [37], that provides both languages for capturing requirements and algorithms for exploring the space of possible solutions in ways that take the requirements into account. For example, in the widely used Analytic Hierarchy Process [31], users compare criteria (such as timeliness or completeness) in terms of their relative importance, which can be taken into account when making decisions (such as which mappings to use in data integration).

Although data management researchers have investigated techniques that apply specific user criteria to inform decisions (e.g. for selecting sources based on their anticipated financial value [16]) and have sometimes traded off alternative objectives (e.g. precision and recall for mapping selection and refinement [5]), such results have tended to address specific steps within wrangling in isolation, often leading to bespoke solutions. Together with high automation, adaptivity and multi-criteria optimisation are of paramount importance for cost-effective wrangling processes.

2.2 Extending the Boundaries

ETL processes traditionally operate on data lying within the boundaries of an organisation or across a network of partners. As soon as companies started to leverage big data and data science, it became clear that data outside the boundaries of the organisation represent both new business opportunities as well as a means to optimize existing business processes.

Data wrangling solutions recently started to offer connectors to external data sources but, for now, mostly limited to open government data and established social networks (e.g., Twitter) via formalised APIs. This makes wrangling processes dependent on the availability of APIs from third parties, thus limiting the availability of data and the scope of the wrangling processes.

Recent advances in web data extraction [19, 30] have shown that fully-automated, large scale collection of long-tail, business-related data, e.g., products, jobs or locations, is possible. The challenge for data wrangling processes is now to make proper use of this wealth of “wild” data by coordinating extraction, integration and cleaning processes.

Example 3 (Business Locations). Many social networks offer the ability for users to check-in to places, e.g., restaurants, offices, cinemas, via their mobile apps. This gives to social networks the ability to maintain a database of businesses, their locations, and profiles of users interacting with them that is immensely valuable for advertising purposes. On the other hand, this way of acquiring data is prone to data quality problems, e.g., wrong geo-locations, misspelled or fantasy places. A popular way to address these problems is to acquire a curated database of geo-located business locations. This is usually expensive and does not always guarantee that the data is really clean, as its quality depends on the quality of the (usually unknown) data acquisition and curation process. Another way is to define a wrangling process that collects this information right on the website of the business of interest, e.g., by wrapping the target data source directly. The extraction process can in this case be “informed” by existing integrated data, e.g., the business url and a database of already known addresses, to identify previously unknown locations and correct erroneous ones.

2.3 Using All the Available Information

Cost-effective data wrangling will need to make extensive use of

automation for the different steps in the wrangling process. Automated processes must take advantage of all available information both when generating proposals and for comparing alternative proposals in the light of the user context.

The *data context* of an application consists of the sources that may provide data for wrangling, and other information that may inform the wrangling process.

Example 4 (e-Commerce Data Context). In price intelligence, following on from Example 1, the data context includes the catalogs of the many online retailers that sell overlapping sets of products to overlapping markets. However, there are additional data resources that can inform the process. For example, the e-Commerce company has a product catalog that can be considered as master data by the wrangling process; the company is interested in price comparison only for the products it sells. In addition, for this domain there are standard formats, for example in `schema.org`, for describing products and offers, and there are ontologies that describe products, such as The Product Types Ontology².

Thus applications have different *data contexts*, which include not only the data that the application seeks to use, but also local and third party sources that provide additional information about the domain or the data therein. To be cost-effective, automated techniques must be able to bring together all the available information. For example, a product types ontology could be used to inform the selection of sources based on their relevance, as an input to the matching of sources that supplements syntactic matching, and as a guide to the fusion of property values from records that have been obtained from different sources. To do this, automated processes must make well founded decisions, integrating evidence of different types. In data management, there are results of relevance to data wrangling that assimilate evidence to reach decisions (e.g. [36]), but work to date tends to be focused on small numbers of types of evidence, and individual data management tasks. Cost effective data wrangling requires more pervasive approaches.

2.4 Adopting a Pay-as-you-go Approach

As discussed in Section 1, potential users of big data will not always have access to substantial budgets or teams of skilled data scientists to support manual data wrangling. As such, rather than depending upon a continuous labor-intensive wrangling effort, to enable resources to be deployed on data wrangling in a targeted and flexible way, we propose an incremental, pay-as-you-go approach, in which the “payment” can take different forms.

Providing a pay-as-you-go approach, with flexible kinds of payment, means automating all steps in the wrangling process, and allowing feedback in whatever form the user chooses. This requires a flexible architecture in which feedback is combined with other sources of evidence (see Section 2.3) to enable the best possible decisions to be made. Feedback of one type should be able to inform many different steps in the wrangling process – for example, the identification of several correct (or incorrect) results may inform both source selection and mapping generation. Although there has been significant work on incremental, pay-as-you-go approaches to data management, building on the dataspace vision [18], typically this has used one or a few types of feedback to inform a single activity. As such, there is significant work to be done to provide a more integrated approach in which feedback can inform all steps of the wrangling process.

Example 5 (e-Commerce Pay-as-you-go). In Example 1, automated approaches to data wrangling can be used to select sources of

²<http://www.productontology.org/>

product data, and to fuse the values from such sources to provide reports on the pricing of different products. These reports are studied by the data scientists of the e-Commerce company who are reviewing the pricing of competitors, who can annotate the data values in the report, for example, to identify which are correct or incorrect, along with their relevance to decision-making. Such feedback can trigger the data wrangling system to revise the way in which such reports are produced, for example by prioritising results from different data sources. The provision of domain-expert feedback from the data scientists is a form of payment, as staff effort is required to provide it. However, it should also be possible to use crowdsourcing, with direct financial payment of crowd workers, for example to identify duplicates, and thereby to refine the automatically generated rules that determine when two records represent the same real-world object [20]. It is of paramount importance that these feedback-induced “reactions” do not trigger a re-processing of all datasets involved in the computation but rather limit the processing to the strictly necessary data.

3. DATA WRANGLING – RELATED WORK

As discussed in Section 2, cost-effective data wrangling is expected to involve best-effort approaches, in which multiple sources of evidence are combined by automated techniques, the results of which can be refined following a pay-as-you-go approach. Space precludes a comprehensive review of potentially relevant results, so in this section we focus on three areas with overlapping requirements and approaches, pointing out existing results on which data wrangling can build, but also areas in which these results need to be extended.

3.1 Knowledge Base Construction

In *knowledge base construction* (KBC) the objective is to automatically create structured representations of data, typically using the web as a source of facts for inclusion in the knowledge base. Prominent examples include YAGO [33], Elementary [28] and Google’s Knowledge Vault [15], all of which combine candidate facts from web data sources to create or extend descriptions of entities. Such proposals are relevant to data wrangling, in providing large scale, automatically generated representations of structured data extracted from diverse sources, taking account of the associated uncertainties.

These techniques have produced impressive results but they tend to have a single, implicit *user context*, with a focus on consolidating slowly-changing, common sense knowledge that leans heavily on the assumption that correct facts occur frequently (instance-based redundancy). For data wrangling, the need to support diverse user contexts and highly transient information (e.g., pricing) means that user requirements need to be made explicit and to inform decision-making throughout automated processes. In addition, the focus on fully automated KBC at web-scale, without systematic support for incremental improvement in a pay-as-you-go manner, tends to require expert input, for example through the writing of rules (e.g., [28]). As such, KBC proposals share requirements with data wrangling, but have different emphases.

3.2 Pay-as-you-go Data Management

Pay-as-you-go data management, as represented by the dataspace vision [18], involves the combination of an automated *bootstrapping* phase, followed by incremental *improvement*. There have been numerous results on different aspects of pay-as-you-go data management, across several activities of relevance to data wran-

gling, such as data extraction (e.g., [12]), matching [26], mapping [5] and entity resolution [20]. We note that in these proposals a single type of feedback is used to support a single data management task. The opportunities presented by crowdsourcing have provided a recent boost to this area, in which, typically, paid micro-tasks are submitted to public crowds as a source of feedback for pay-as-you-go activities. This has included work that refines different steps within an activity (e.g. both blocking and fine-grained matching within entity resolution [20]), and the investigation of systematic approaches for relating uncertain feedback to other sources of evidence (e.g., [13]). However, the state-of-the-art is that techniques have been developed in which individual types of feedback are used to influence specific data management tasks, and there seems to be significant scope for feedback to be integrated into all activities that compose a data wrangling pipeline, with reuse of feedback to inform multiple activities [6]. Highly automated wrangling processes require formalised feedback (e.g., in terms of rules or facts to be added/removed from the process) so that they can be used by suitable reasoning processes to automatically adapt the wrangling workflows.

Data Tamer [32] provides a substantially automated pipeline involving schema integration and entity resolution, where components obtain feedback to refine the results of automated analyses. Although Data Tamer moves a significant way from classical, largely manually specified ETL techniques, user feedback is obtained for and applied to specific steps (and not shared across components), and there is no user context to inform where compromises should be made and efforts focused.

3.3 Context Awareness

There has been significant prior work on context in computing systems [3], with a particular emphasis on mobile devices and users, in which the objective is to provide data [9] or services [25] that meet the evolving, situational needs of users. In information management, the emphasis has been on identifying the portion of the available information that is relevant in specific ambient conditions [8]. For data wrangling, classical notions of context such as location and time will sometimes be relevant, but we anticipate that for data wrangling: (i) there may be many additional features that characterise the *user and data contexts*, for individual users, groups of users and tasks; and (ii) that the information about context will need to inform a wide range of data management tasks in addition to the selection of the most relevant results.

4. DATA WRANGLING – VISION

In the light of the scene-setting from the previous sections, Figure 1 outlines potential components and relationships in a data wrangling architecture. To the left of the figure, several (potentially many) *Data Sources* provide the data that is required for the application. A *Data Extraction* component provides wrappers for the potentially heterogeneous sources (files, databases, documents, web pages), providing syntactically consistent representations that can then be brought together by the *Data Integration* component, to yield *Wrangled Data* that is then available for exploration and analysis.

However, in our vision, these extraction and integration components both *use all the available data* and *adopt a pay-as-you-go approach*. In Figure 1, this is represented by a collection of *Working Data*, which contains not only results and metadata from the *Data Extraction* and *Data Integration* components, but also:

1. all relevant *Auxiliary Data*, which would include the *user context*, and whatever additional information can represent the *data context*, such as *reference data*, *master data* and *do-*

Figure 1: Abstract Wrangling Architecture.

main ontologies;

2. the results of all *Quality* analyses that have been carried out, which may apply to individual data sources, the results of different extractions and components of relevance to integration such as matches or mappings; and
3. the feedback that has been obtained from users or crowds, on any aspect of the wrangling process, including the extractions (e.g. users could indicate if a wrapper has extracted what they would have expected), or the results of integrations (e.g. crowds could identify duplicates).

To support this, data wrangling needs substantial advances in data extraction, integration and cleaning, as well as the co-design of the components in Figure 1 to support a much closer interaction in a context-aware, pay-as-you-go setting.

4.1 Research Challenges for Components

This section makes the case that meeting the vision will require changes of substance to existing data management functionalities, such as *Data Extraction* and *Data Integration*.

To respond fully to the proposed architecture, *Data Extraction* must make effective use of all the available data. Consider web data extraction, in which wrappers are generated that enable deep web resources to be treated as structured data sets (e.g., [12, 19]). The lack of context and incrementality in data extraction has long been identified as a weakness [11], and research is required to make extraction components responsive to quality analyses, insights from integration and user feedback. As an example, existing knowledge bases and intermediate products of data cleaning and integration processes can be used to improve the quality of wrapper induction (e.g. [29]).

Along the same lines, *Data Integration* must make effective use of all the available data in ways that take account of the *user context*. As data integration acts on a variety of constructs (sources, matches, mappings, instances), each of which may be associated with its own uncertainties, automated functionalities such as those for identifying matches and generating mappings need to be revised to support multi-criteria decision making in the context of uncertainty. For example, the selection of which mappings to use must take into account information from the user context, such as the number of results required, the budget for accessing sources, and quality requirements. To support the complete data wrangling

process involves generalising from a range of point solutions into an approach in which all components can take account of a range of different sources of evolving evidence.

4.2 Research Challenges for Architectures

This section makes the case that meeting the vision will require changes of substance to existing data management architectures, and in particular a paradigm-shift for ETL.

Traditional ETL operates on manually-specified data manipulation workflows that extract data from structured data sources, integrating, cleaning, and eventually storing them in aggregated form into data warehouses. In Figure 1 there is no explicit control flow specified, but we note that the requirements of automation, refined on a pay-as-you-go basis taking into account the user context, is at odds with a hard-wired, user-specified data manipulation workflow. In the abstract architecture, the pay-as-you-go approach is achieved by storing intermediate results of the ETL process for on-demand recombination, depending on the user context and the potentially continually evolving data context. As such, the *user context* must provide a declarative specification of the user's requirements and priorities, both functional (data) and non-functional (such as quality and cost trade-offs), so that the components in Figure 1 can be automatically and flexibly composed. Such an approach requires an autonomic approach to data wrangling, in which self-configuration is more central to the architecture than in self-managing databases [10].

The resulting architecture must not only be autonomic, it must also take account of the inherent uncertainty associated with much of the *Working Data* in Figure 1. Uncertainty comes from: (i) *Data Sources* in the form of unreliable and inconsistent data; (ii) the wrangling components, for example in the form of tentative extraction rules or mappings; (iii) the auxiliary data, for example in the form of ontologies that do not quite represent the user's conceptualisation of the domain; and (iv) the feedback which may be unreliable or out of line with the user's requirements or preferences. With this complex environment, it is important that uncertainty is represented explicitly and reasoned with systematically, so that well informed decisions can build on a sound understanding of the available evidence.

This raises an additional research question, on how best to represent and reason in a principled and scalable way with the *working data* and associated *workflows*; there is a need for a uniform representation for the results of the different components in Figure 1, which are as diverse as domain ontologies, matches, data extraction and transformation rules, schema mappings, user feedback and provenance information, along with their associated quality annotations and uncertainties.

In addition, the ways in which different types of user engage with the wrangling process is also worthy of further research. In Wrangler [22], now commercialised by Trifacta, data scientists clean and transform data sets using an interactive interface in which, among other things, the system can suggest generic transformations from user edits. In this approach, users provide feedback on the changes to the selected data they would like to have made, and select from proposed transformations. Additional research could investigate where such interactions could be used to inform upstream aspects of the wrangling process, such as source selection or mapping generation, and to understand how other kinds of feedback, or the results of other analyses, could inform what is offered to the user in tools such as Wrangler.

4.3 Research Challenges in Scalability

In this paper we have proposed responding to the *Volume* as-

pect of big data principally in the form of the number of sources that may be available, where we propose that automation and incrementality are key approaches. In this section we discuss some additional challenges in data wrangling that result from scale.

The most direct impact of scale in big data results from the sheer volume of data that may be present in the sources. ETL vendors have responded to this challenge by compiling ETL workflows into big data platforms, such as map/reduce. In the architecture of Figure 1, it will be necessary for extraction, integration and data querying tasks to be able to be executed using such platforms. However, there are also fundamental problems to be addressed. For example, many quality analyses are intractable (e.g. [7]), and evaluating even standard queries of the sort used in mappings may require substantial changes to classical assumptions when faced with huge data sets. Among these challenges are understanding the requirement for query scalability [2] that can be provided in terms of access and indexing information [17], and developing static techniques for query approximation (i.e., without looking at the data) as was initiated in [4] for conjunctive queries. For the architecture of Figure 1 there is the additional requirement to reason with uncertainty over potentially numerous sources of evidence; this is a serious issue since even in the classical settings data uncertainty often leads to intractability of the most basic data processing tasks [1, 23]. We also observe that knowledge base construction has itself given rise to novel reasoning techniques [27], and additional research may be required to inform decision-making for data wrangling at scale.

5. CONCLUSIONS

Data wrangling is a problem and an opportunity:

- A problem because the 4 V's of big data may all be present together, undermining manual approaches to ETL.
- An opportunity because if we can make data wrangling much more cost effective, all sorts of hitherto impractical tasks come into reach.

This vision paper aims to raise the profile of data wrangling as a research area within the data management community, where there is a lot of work on relevant functionalities, but where these have not been refined or integrated as is required to support data wrangling. The paper has identified research challenges that emerge from data wrangling, around the need to make compromises that reflect the user's requirements, the ability to make use of all the available evidence, and the development of pay-as-you-go techniques that enable diverse forms of payment at convenient times. We have also presented an abstract architecture for data wrangling, and outlined how that architecture departs from traditional approaches to ETL, through increased use of automation, which flexibly accounts for diverse user and data contexts. It has been suggested that this architecture will require changes of substance to established data management components, as well as the way in which they work together. For example, the proposed architecture will require support for representing and reasoning with the diverse and uncertain working data that is of relevance to the data wrangling process. Thus we encourage the data management research community to direct its attention at novel approaches to data wrangling, as a prerequisite for the cost-effective exploitation of big data.

Acknowledgments

ABSTRACT

The world is fast moving towards a data-driven society where data is the most valuable asset. Organizations need to perform very diverse analytic tasks using various data processing platforms. In doing so, they face many challenges; chiefly, platform dependence, poor interoperability, and poor performance when using multiple platforms. We present RHEEM, our vision for big data analytics over diverse data processing platforms. RHEEM provides a three-layer *data processing* and *storage* abstraction to achieve both platform independence and interoperability across multiple platforms. In this paper, we discuss our vision as well as present multiple research challenges that we need to address to achieve it. As a case in point, we present a data cleaning application built using some of the ideas of RHEEM. We show how it achieves *platform independence* and the performance benefits of following such an approach.

1. WHY TIED TO ONE SINGLE SYSTEM?

Data analytic tasks may range from very simple to extremely complex pipelines, such as data extraction, transformation, and loading (ETL), online analytical processing (OLAP), graph processing, and machine learning (ML). Following the dictum “one size does not fit all” [23], academia and industry have embarked on an endless race to develop data processing platforms for supporting these different tasks, *e.g.*, DBMSs and MapReduce-like systems. Semantic completeness, high performance, and scalability are key objectives of such platforms. While there have been major achievements in these objectives, users still face two main roadblocks.

The **first roadblock** is that applications are tied to a single processing platform, making the migration of an application to new and more efficient platforms a difficult and costly task. Furthermore, complex analytic tasks usually require the combined use of different processing platforms. As a result, the common practice is to develop several specialized analytic applications on top of different platforms. This requires users to manually combine the results to draw a conclusion. In addition, users may need to re-implement existing applications on top of faster processing platforms when

these become available. For example, Spark SQL [3] and MLlib [2] are the Spark counterparts of Hive [24] and Mahout [1].

The **second roadblock** is that datasets are often produced by different sources and hence they natively reside on different storage platforms. As a result, users often perform tedious, time-intensive, and costly data migration and integration tasks for further analysis.

Let us illustrate these roadblocks with an Oil & Gas industry example [13]. A single oil company can produce more than 1.5TB of diverse data per day [6]. Such data may be structured or unstructured and come from heterogeneous sources, such as sensors, GPS devices, and other measuring instruments. For instance, during the exploration phase, data has to be acquired, integrated, and analyzed in order to predict if a reservoir would be profitable. Thousands of downhole sensors in exploratory wells produce real-time seismic data for monitoring resources and environmental conditions. Users integrate these data with the physical properties of the rocks to visualize volume and surface renderings. From these visualizations, geologists and geophysicists formulate hypotheses and verify them with ML methods, such as regression and classification. Training of the models is performed with historical drilling and production data, but oftentimes users have to go over unstructured data, such as notes exchanged by emails or text from drilling reports filed in a cabinet. Thus, an application supporting such a complex analytic pipeline has to access several sources for historical data (relational, but also text and semi-structured), remove the noise from the streaming data coming from the sensors, and run both traditional (such as SQL) and statistical analytics (such as ML algorithms) over different processing platforms.

Similar examples can be drawn from many other domains such as healthcare: *e.g.*, IBM reported that North York hospital needs to process 50 diverse datasets, which are on a dozen different internal systems [15]. These emerging applications clearly show the need for complex analytics coupled with a diversity of processing platforms, which raises two major research challenges.

Data Processing Challenge. Users are faced with various choices on where to *process* their data, each choice with possibly orders of magnitude differences in terms of performance. However, users have to be intimate with the intricacies of the processing platform to achieve high efficiency and scalability. Moreover, once a decision is taken, users may end up being tied up to a particular platform. As a result, migrating the data analytics stack to a more efficient processing platform often becomes a nightmare. Thus, there is a need to build a system that offers *data processing platform independence*. Furthermore, complex analytic applications require executing tasks over different processing platforms to achieve high performance. For example, one may aggregate large datasets with traditional queries on top of a relational database such as PostgreSQL, but ML tasks might be much faster if executed on Spark [28]. How-

*Work done while at QCRI.

ever, this requires a considerable amount of manual work in selecting the best processing platforms, optimizing tasks for the chosen platforms, and coordinating task execution. Thus, this also calls for *multi-platform task execution*.

Data Storage Challenge. Data processing platforms are typically tightly coupled with a specific *storage* solution. Moving data from a certain storage (e.g., a relational DB) to a more suitable processing platform for the actual task (e.g., Spark on HDFS) requires shuffling data between different systems. Such shuffling may end up dominating the execution time. Moreover, different departments in the same organization may go for different storage engines due to legacy as well as performance reasons. Dealing with such heterogeneity calls for *data storage independence*.

To tackle these two challenges, we envision a system, called RHEEM¹, that provides both platform independence and interoperability (Section 2). In the following, we first discuss our vision for the data processing abstraction (Section 3), which is fully based on user-defined functions (UDFs) to provide adaptability as well as extensibility. This processing abstraction allows both users to focus only on the logic of their data analytic tasks and applications to be independent from the data processing platforms. We then discuss how to divide a complex analytic task into smaller subtasks to exploit the availability of different processing platforms (Section 4). As a result, RHEEM can run simultaneously a single data analytic task over multiple processing platforms to boost performance. Next, we present our first attempt to build an instance application based on some of the ideas of RHEEM and the resulting benefits (Section 5). We then show how we push down the processing abstraction idea to the storage layer (Section 6). This storage abstraction allows both users to focus on their storage needs and the processing platforms to be independent from the storage engines.

Some initial efforts are also going into the direction of providing data processing platform independence [11, 12, 21] (Section 7). However, our vision goes beyond the data processing. We not only envision a data processing abstraction but also a data storage abstraction, allowing us to consider data movement costs during task optimization. We give a research agenda highlighting the challenges that need to be tackled to build RHEEM in Section 8.

2. OUR VISION

We envision a system that frees applications and users from being tied to a single data processing platform (platform independence) and provides interoperability across different platforms (multi-platform task execution). We discuss these two aspects in the following. We discuss data storage independence in Section 6.

Processing Platform Independence. Whenever a new platform that achieves better performance than existing ones becomes available, one is enticed to move to the new platform. However, such move does not usually come without pain. There is a clear need for a system that frees us from the burden and cost of re-implementing applications from one platform to another. Mahout [1] and MLlib [2] clearly illustrate this need, as all ML algorithms initially implemented in Hadoop had to be re-implemented in Spark. In addition, there are cases where, for the same task but with a different input, one platform is better than another. Thus, the system we envision should not only provide platform independence, but also should be able to select the best available platform to execute a given task in order to deliver better performance.

Multi-Platform Task Execution. We are witnessing the emergence of complex data analytic pipelines in many different do-

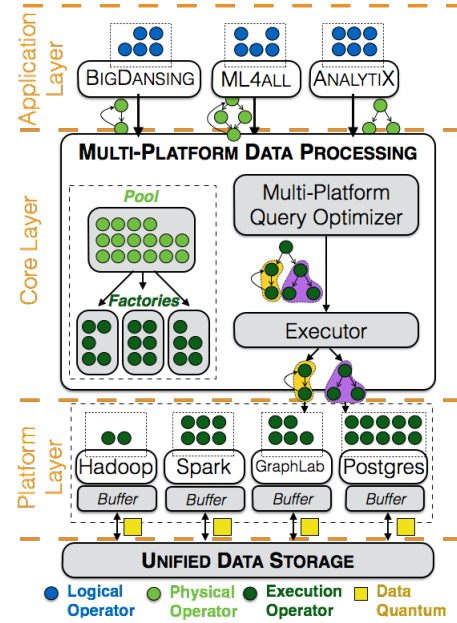

Figure 1: RHEEM data processing abstraction.

ains [4, 6, 13, 15]. These pipelines require first combining multiple processing platforms to perform each task of the process and then integrating the results. For instance, many companies are already adopting a lambda architecture, which combines both batch and stream processing. Our vision goes beyond batch or stream processing to any kind of data analytics paradigm. We envision a system that eases the integration among different processing platforms by automatically dividing a task into subtasks and determining the underlying platform for each subtask.

RHEEM. The foundation of our vision is a three-layer data processing abstraction that sits between user applications and data processing platforms (e.g., Hadoop or Spark). Figure 1 depicts these three layers: the *application* layer models all application-specific logic; the *core* layer provides the intermediate representation between applications and processing platforms; and the *platform* layer embraces the underlying processing platforms. In contrast to DBMSs, RHEEM decouples physical and execution levels. This separation allows applications to express physical plans in terms of algorithmic needs only, without being tied to a particular processing platform. The communication among these levels is enabled by operators defined as UDFs. These three layers allow RHEEM to provide applications with platform independence. Providing platform independence is the first step towards realizing multi-platform task execution, which is crucial to achieve the best performance at all times. For example, Figure 2 shows the benefits of running the SVM algorithm on different datasets from LIBSVM² with only one hundred iterations, as a Spark job and as a plain Java program. We observe that, for small datasets, executing SVM as a plain Java program is up to one order of magnitude faster than executing it on Spark. Indeed, this performance gap gets bigger with the number of iterations. Using Spark pays off for big datasets only. Such results show a great potential for platform independence and ultimately multi-platform execution. RHEEM will be able to receive a complex analytic task, seamlessly divide it into subtasks, schedule each task on the best processing platform, monitor task execution, and aggregate results for users or applications. Achieving our vision requires tackling several challenges that we will discuss throughout

¹Rheem is a native gazelle species in Qatar.

²<http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/>

Figure 2: SVM on Spark and Java.

the paper and then summarize in Section 8.

To show the benefits of our RHEEM vision, we have fully developed one data cleaning application based on it [19]. While this initial instance provides only platform independence, its performances are encouraging and already demonstrate the advantages of our vision (see Section 5).

Similar to the data processing abstraction, we envision a three-level data storage abstraction to uphold data processing tasks. The data storage abstraction is also composed of an *application*, a *core*, and an *execution* level. The RHEEM data storage abstraction functions symmetrically as the data processing abstraction. We shall further discuss this storage abstraction in Section 6.

3. DATA PROCESSING ABSTRACTION

In this section, we detail the abstraction layers of RHEEM and show how users can interact with the system at each layer.

3.1 Abstraction Layers

RHEEM provides a set of operators at each layer, namely, logical operators, physical operators, and execution operators. The input of the application layer is the logical operators provided by users (or generated by a declarative query parser) and the output is a physical plan. The physical plan is then passed to the core layer where multi-platform optimizations take place to produce an execution plan. In contrast to a DBMS, RHEEM decouples the physical level from the execution one. This separation allows applications to express a physical plan in terms of algorithmic needs only, without being tied to a particular processing platform.

Application Layer. A logical operator is an abstract UDF that acts as an *application-specific* unit of data processing. One can see a logical operator as a template where users provide the logic of their tasks. Such abstraction enables both ease-of-use, by hiding implementation details from users, and high performance, by allowing several optimizations, *e.g.*, seamless distributed execution.

A logical operator works on *data quanta*, which are the smallest units of data elements from the input datasets. For instance, a data quantum represents a tuple in the input dataset or a row in a matrix. This fine-grained data model allows RHEEM to apply operators in a highly parallel fashion and thus achieve better performance.

Example 1: Consider a developer who wants to offer end users logical operators to implement various ML algorithms. The developer can define three basic operators: (i) Initialize, for initializing algorithm-specific parameters, *e.g.*, initializing cluster centroids, (ii) Process, for the computations required by the ML algorithm, *e.g.*, finding the nearest centroid of a point, (iii) Loop, for specifying the stopping condition. Users implement algorithms such as SVM, K-means, and linear/logistic regression with them. □

The application optimizer translates logical operators into physical operators that will form the *physical plan* at the core layer.

Core Layer. This layer is the heart of RHEEM. It exposes a pool of *physical* operators, each representing an algorithmic decision for executing an analytic task. A physical operator is a *platform-independent* implementation of a logical operator. These operators

are available to the developer to deploy a new application on top of RHEEM. Developers can still define new operators as needed.

Example 2: In the above ML example, the application optimizer maps Initialize to a Map physical operator and Process to a GroupBy physical operator. RHEEM provides two different implementations for GroupBy: the SortGroupBy (sort-based) and HashGroupBy (hash-based) operators from which the optimizer of the core level will have to choose. □

Once an application has produced a physical plan for a given input task, RHEEM divides this physical plan into *task atoms*, *i.e.*, sub-tasks, which are the units of execution. A task atom (a part of the execution plan) is a sub-task to be executed on a single data processing platform. It will then translate the task atoms into an *execution plan* by optimizing each task atom according to a target platform. Finally, it schedules each task atom to be executed on its corresponding platform. Therefore, in contrast to DBMSs, RHEEM produces execution plans that can run on multiple platforms.

Platform Layer. At this layer, *execution* operators (in an execution plan) define how a task is executed on the underlying processing platform. In other words, an execution operator is the *platform-dependent* implementation of a physical operator. RHEEM relies on existing data processing platforms to actually run input tasks.

Example 3: Again in the above ML example, the MapPartitions and ReduceByKey execution operators for Spark are one way to perform Initialize and Process. □

In contrast to a logical operator, an execution operator works on multiple data quanta rather than a single one, which enables the processing of multiple data quanta with a single function call.

Flexible operator mappings. Defining mappings between execution and physical operators is the developers' responsibility whenever a new platform is plugged to the core. Our goal is to rely on a mapping structure to model the correspondences between operators together with context information. Such context is needed for the effective and efficient execution of each operator. For instance, the Process logical operator maps to two different physical operators (SortGroupBy and HashGroupBy). In this case, a developer could use the context to provide hints to the optimizer for choosing the right physical operator at run time. Developers will provide only a declarative specification of such mappings; the system will use them to translate physical operators to execution operators.

3.2 User Interaction

We distinguish between two types of users: *end-users*, who interact with the applications, and *developers*, who interact with the system at all the three layers. We discuss below how developers define operators (UDFs) at every layer of the abstraction.

Application layer. At this layer, developers model a data processing application by specifying a set of abstract logical operators. End-users implement these operators to express their analytic tasks. RHEEM provides an abstract LogicalOperator that defines the method applyOp. Logical operators of any application extend LogicalOperator and provide an implementation of applyOp. RHEEM invokes this method at runtime to apply a logical operator. In addition to logical operators, an application developer could also expose a declarative language for users to define their tasks (*e.g.*, queries). The application is then responsible for translating a declarative query into a logical plan. Then, the application optimizer translates the logical plan into a physical plan.

Core layer. RHEEM provides a pool of physical operators for applications to produce physical plans. To enable extensibility, the

system also provides an abstract `PhysicalOperator`, with the abstract method `applyOp`, for developers to define their own physical operators. Developers define a new physical operator to fill two different needs. First, developers define a *wrapper* operator to execute the logical operator together with some physical details, such as algorithmic decisions and schema details. The wrapper operator follows the signature of the logical operator. Second, since the output of a specific operator might not fit as input of a subsequent operator, developers define *enhancer* operators to fill possible gaps between wrapper operators. For example, an application for *K*-means clustering might only expose the `GetCentroid` (for getting the closest centroid of a data point) and `SetCentroids` (for computing the new centroids) logical operators. `GetCentroid` outputs a data point and its closest centroid, while `SetCentroids` requires a centroid and all its closest data points. Here, the developer provides a `GroupBy` enhancer operator between `GetCentroid` and `SetCentroid`.

Platform layer. To model a data processing platform, developers extend the abstract `ExecutionOperator` and implement its `applyOp` method. There are two main scenarios. If a new physical operator has been defined, *e.g.*, because the developer is adding a new application, then it must be supported with a corresponding execution operator in the actual execution platform. In a different scenario, the developer is adding a new platform to the execution layer. In this case, every physical operator must be supported with a corresponding execution operator in the new execution platform. RHEEM uses these execution operators to produce an execution plan and pushes “down” execution details to the underlying platform, such as data distribution, parallel execution, and data storage. At the end, the target processing platform simply performs an execution plan in its own data and processing model.

4. MULTI-LAYER OPTIMIZATIONS

In contrast to traditional data management systems, which are tied to a specific data processing platform, RHEEM’s goal is not only platform independence but also multi-platform execution. To efficiently deal with both aspects, we envision optimizations at each layer: (i) at the application layer, we validate an input task, translate it into a logical plan, and then produce an optimized physical plan, (ii) at the core layer, we translate a physical plan into an execution plan by dividing the query into *task atoms*, and (iii) at the platform layer, we further refine a task atom based on the actual platform.

4.1 Application-Layer Optimizations

In our envisioned system, users will be able to express their tasks either procedurally (via logical operators) or declaratively (using a query language). Given an input task, the application optimizer builds a logical plan and performs some pre-defined optimizations, such as operator push-down. Once the logical plan is built, the application optimizer produces an optimized physical plan by translating each logical operator into a wrapper physical operator. Recall that a wrapper receives a logical operator as input. Additionally, the application optimizer might use enhancer physical operators to boost performance; for example, it may plug-in a `GroupBy` physical operator followed by a `CrossProduct` operator to perform a cross product inside a group only. This avoids a costly cross product over the entire input dataset. As an example of this kind of optimization we refer to [19]. Then, the application sends the optimized physical plan to the core layer.

4.2 Core-Layer Optimizations

The optimizations at the core layer are the responsibility of the multi-platform task optimizer (see Figure 1). RHEEM receives

a physical plan from an application and passes it to the multi-platform task optimizer to generate a plan for execution on the underlying processing platforms. We envision the multi-platform task optimizer to deal with five aspects. First, the optimizer should consider operators as first-class citizens. That is, its optimization process should be fully based on UDFs optimization techniques. We will base our solutions on different existing optimization techniques, such as Manimal [16], PACTs [25], and SOFA [22], but we also need to devise new optimization techniques to support different processing platforms. Second, the optimizer should consider rules and cost models for its optimizations as plugins and not hard-coded as in traditional database optimizers. In other words, these two aspects should be decoupled from the optimizer in order to allow for extensibility when new processing platforms are added by developers. Third, it has to consider inter-platform cost models to effectively take into account the cost of moving data and computation across underlying processing platforms. The main difficulty here comes from the fact that underlying frameworks are typically highly heterogeneous in terms of both data representations and processing paradigms. Fourth, it should divide a physical plan into task atoms according to the supported underlying data processing platforms. Recall that it is the underlying processing platform that ensures the execution of task atoms. The main challenge in this aspect is to find a way to divide a task into atoms seamlessly from users. Last, but not least, it should also apply traditional physical optimizations, whenever possible. Examples are shared scans and optimized data access paths, such as index access. Achieving this is difficult as such optimizations should be general in order to be efficient on any processing platform.

Once an execution plan is built, the multi-platform task optimizer passes it to the `Executor` (see Figure 1) for: (i) scheduling the resulting execution plan on the selected data processing frameworks, (ii) monitoring the progress of plan execution, (iii) coping with failures, and (iv) aggregating and returning results to users.

4.3 Platform-Layer optimizations

Once at a target processing platform, we envision a third optimization phase that uses plugged-in platform-specific optimization tools. For instance, if the selected platform for a task atom is Hadoop, we could further optimize an execution plan by using Starfish [14]. Notice that the data processing platform itself can also perform some additional optimizations, *e.g.*, if an execution plan is given as input to Spark in the form of a Shark query [26].

5. APPLICATIONS

Clearly, a large number of applications benefit from our vision. As a proof of concept, we present here a data cleaning application we developed using part of RHEEM’s vision, mainly platform independence. We are currently developing two other applications: a machine learning application and a graph processing application.

5.1 Data Cleaning in RHEEM

Demand. Ensuring high quality data is challenging because of the variety of data dirtiness, such as typos, duplicates, and missing values. However, detecting errors is a combinatorial problem that quickly becomes expensive with the size of the data, thus limiting the applicability of cleaning systems.

Our solution. We built BIGDANSING, a Big Data Cleansing on top of RHEEM [19]. The two distinct features of BIGDANSING are its *ease-of-use* and *high scalability*; both natural consequences of the RHEEM abstraction vision. BIGDANSING models data quality rules with five operators, namely `Scope`, `Block`, `Iterate`, `Detect`, and `GenFix`. These operators allow users to capture the semantics

Figure 3: RHEEM execution times for violations detection.

of error detection and possible repairs generation at the application layer (see [19] for details).

Ease-of-use. The developer of the application has to come up with the physical plan of the cleaning process (preferably via an automatic optimization process). The detection part of BIGDANSING is composed of a sequence of five physical operators, which are fed with the logics coming from the corresponding logical operators. Similarly, the logical operators require only a few lines of code [19], allowing for ease-of-use.

High scalability. Figure 3 shows a comparison of the performance for a single Detect UDF versus our operators for the same task. The left-side subfigure clearly shows the benefits of the abstraction with operators that enables finer granularity for the distributed execution. The right-side subfigure shows a comparison of BIGDANSING against state-of-the-art approaches on Spark. We observe that RHEEM enables orders of magnitude better performance than base-lines, which we had to stop after 22 hours. Here, as an example of extensibility, we extended the set of physical RHEEM operators with a new join operator (called IEJoin [20]) to boost performance.

5.2 When to Use RHEEM?

It should be clear at this point how the proposed three layers enable better performance and more freedom in developing applications with respect to existing solutions. However, there is a trade-off. A developer who decides to use RHEEM instead of one of the alternative systems may need to implement new operators as required by the target application. This is because our pool of default physical operators is not as exhaustive as the operators provided by the specific underlying platforms. For example, we had to implement the IEJoin operator in RHEEM to boost the performance of our data cleaning application. While this may require extra effort from a developer, we believe that this a reasonable price to pay for platform independence when performance is crucial.

6. DATA STORAGE ABSTRACTION

So far we have focused our attention on the data processing side of our vision. Symmetrically to the data processing, we envision a data storage abstraction to provide interoperability among different data storage platforms.

Figure 4 illustrates the RHEEM data storage abstraction. Each layer of abstraction has a set of operators (*i.e.*, UDFs): logical operators (*l-store*) at the application layer, physical operators (*p-store*) at the core layer, and execution operators (*x-store*) at the platform layer. At the application layer different storage applications, *e.g.*, Dropbox, or data processing platforms, *e.g.*, Hadoop or PostgreSQL, output a physical storage plan in a homogeneous format defined by RHEEM. Then, at the core layer, RHEEM takes the physical storage plan as input and produces an optimized execution storage plan. Finally, at the platform layer, a data storage platform stores or accesses a dataset according to the execution storage plan. Note that an execution storage plan is composed of *storage atoms*, *i.e.*, the counterpart of task atoms, which are processed by a different data storage platform. It is worth noting that while a data quantum is the data unit itself (*e.g.*, a tuple), a storage atom is the

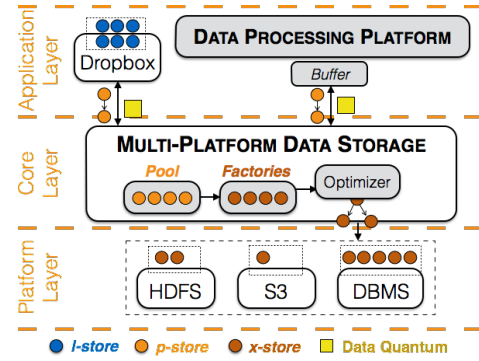

Figure 4: RHEEM data storage abstraction.

minimum unit of data quanta transformation (*e.g.*, projection).

The benefit of such a data storage abstraction is twofold. First, it provides interoperability across storage platforms to simplify users specification about how to store or transform their datasets from one platform to another. Second, it offers opportunities to fully optimize a data flow in order to further improve the performance of data processing tasks. Still, two main challenges make this problem hard: (i) how to unify the abstraction for data storage and access over multiple platforms, and (ii) how to seamlessly decide where and how to store data. Our current efforts into this direction include Cartilage [18], which is a unified data storage representation. In summary, Cartilage introduces the notion of data transformation plans, analogous to logical query plans, that specify a sequence of data transformations that should be applied to raw data as it is uploaded into a storage system. This allows for intermediate storage optimizations based on users and applications needs. For example, WWHow! [17] is a first effort for a unified data storage optimizer.

Embracing hot data. Accessing data through a unified data storage might degrade the performance of processing platforms because the data might not be in the required format. Thus, we envision processing platforms or storage applications with specialized buffers for embracing frequently accessed data in their native format.

7. RELATED WORK

The closest work to us is Musketeer [12], which provides an intermediate representation between applications and data processing platforms. While Musketeer has the merit of proposing an optimizer for the supported applications and platforms, it considers neither the costs of data movement across processing platforms nor the fact that multiple platforms may be able to perform the same job. Furthermore, it lacks the extensibility that we advocate with our proposal. In fact, only Musketeer developers can integrate new processing platforms or applications. This is in fact similar to integrating a new storage system on an existing processing platform, such as Spark or Hadoop MapReduce. In contrast, in RHEEM, users can achieve these tasks with mappings and new physical operators.

DBMS⁺ [21] is another work that aims at embracing several processing and storage platforms for declarative processing. However, DBMS⁺ is not adaptive and extensible as it is limited by the expressiveness of its declarative language. Furthermore, it is unclear how it abstracts underlying platforms seamlessly. BigDAWG [11] has recently been proposed as a federated system that enables users to run their queries over multiple vertically-integrated systems such as column stores, NewSQL engines, and array stores. As a result, users can leverage the advantages of each of them. However, users explicitly specify the underlying platforms (called islands) on which their queries must run on. This implies that users need to know how to divide their queries into subqueries and which underlying platform is best suited for each of them.

Other groups have been working on a general platform for big data analytics [5, 7–9, 27, 29]. For example, AsterixDB [5] offers an open data model, native data storage and indexing, declarative querying over multiple datasets, and a rule-based optimizer. SimSQL [10] compiles SQL queries into Java code that can run on top of Hadoop. Moreover, users can use UDFs to materialize views with simulated data, which enables a range of applications requiring stochastic analytics. PACTs [7] extends the MapReduce programming model with second-order functions on top of Nephele, a processing platform that RHEEM can also use as underlying platform. However, none of the above systems provides the multi-platform data processing and storage we propose with RHEEM.

8. ROAD TO FREEDOM

“I have walked that long road to freedom. I have tried not to falter; I have made missteps along the way. But I have discovered the secret that after climbing a great hill, one only finds that there are many more hills to climb... and I dare not linger, for my long walk is not yet ended.”

– Nelson Mandela –

Oftentimes, users are confronted with the hard decision to choose the right processing platform given the requirements of their analytic application. In addition, their data, born out of various processes, ends up in different storage platforms. To make things worse, the same application may have tasks requiring different platforms to be performed efficiently. Thus, there is a real urgency to free both users and data from (i) being tied to a specific platform, either for processing or storage, and (ii) going through the pain of moving from one platform to another, depending on the requirements of their applications and the characteristics of their data. While the *road to freedom* is full of challenges, RHEEM data processing and storage abstractions hold promise to achieve this freedom. As a case in point, a data cleaning application [19] is our first success towards this goal. IEJoin [20] also showcases the extensibility of RHEEM. While we have laid down the basic ideas on how to build RHEEM, many challenges remain to be addressed.

(1) Extensibility. *How to adapt to extensions and improvements in a data processing platform without requiring the developers to go into the source code? What is the right language to provide hints to the optimizer?* We envision an optimization process based on a flexible data model, such as RDF. Developers will specify mappings between operators as well as encode rule- and cost-based models in RDF triples. The optimizer will use this RDF representation as a first-class citizen in its optimization process.

(2) Multi-platform optimization. *How to divide a task into atoms, assign the best platform to each atom, and combine results?* We envision a solution based on data processing profiles and inter-platform cost models. A data processing profile denotes the type of data processing a platform can support, e.g., batch-processing profile for Hadoop. An inter-platform cost model will capture different multi-platform aspects, such as the cost of transferring and transforming data from one processing platform to another.

(3) Unified storage abstraction. *How to provide a unified abstraction for data storage and access for multiple storage platforms? How to decide where and how to store data?* We envision a three-layer abstraction as discussed in Section 6. This abstraction will enable storage platforms with specialized data buffers to embrace frequently accessed data in their native format.

In summary, the above challenges can be categorized into five main research themes: (i) processing and storage abstractions, (ii) platform-independent task specification, (iii) multi-platform optimization, (iv) multi-platform execution, and (v) data storage and data movement optimizations.

ABSTRACT

Next-generation sequencing (NGS) has dramatically reduced the cost and time of reading the DNA. Huge investments are targeted to sequencing the DNA of large populations, and repositories of well-curated sequence data are being collected. Answers to fundamental biomedical problems are hidden in these data, e.g. how cancer arises, how driving mutations occur, how much cancer is dependent on environment. So far, the bio-informatics research community has been mostly challenged by *primary analysis* (production of sequences in the form of short DNA segments, or "reads") and *secondary analysis* (alignment of reads to a reference genome and search for specific features on the reads); yet, the most important emerging problem is the so-called *tertiary analysis*, concerned with multi-sample processing of heterogeneous information. Tertiary analysis is responsible of *sense making*, e.g., discovering how heterogeneous regions interact with each other.

This new scenario creates an opportunity for rethinking genomic computing through the lens of fundamental data management. We propose an essential data model, using few general abstractions that guarantee interoperability between existing data formats, and a new-generation query language inspired by classic relational algebra and extended with orthogonal, domain-specific abstractions for genomics. They open doors to the seamless integration of descriptive statistics and high-level data analysis (e.g., DNA region clustering and extraction of regulatory networks). In this vision, computational efficiency is achieved by using parallel computing on both clusters and public clouds; the technology is applicable to federated repositories, and can be exploited for providing integrated access to curated data, made available by large consortia, through user-friendly search services. Our most far-fetching vision is to move towards an *Internet of Genomes* exploiting data indexing and crawling.

Genomic data management

1. INTRODUCTION

Modern genomics promises to answer fundamental questions for biological and clinical research, e.g., how protein-DNA interactions and DNA three-dimensional conformation affect gene activity, how cancer develops, how driving mutations occur, how much complex diseases such as cancer are dependent on personal

genomic traits or environmental factors. Unprecedented efforts in genomics are made possible by **Next Generation Sequencing (NGS)**, a family of technologies that is progressively reducing the cost and time of reading the DNA. Huge amounts of sequencing data are continuously collected by a growing number of research laboratories, often organized through world-wide consortia (such as ENCODE [1], TCGA [2], the 1000 Genomes Project [3], and Epigenomic Roadmap [4]); personalized medicine based on genomic information is becoming a reality.

Several organizations are considering genomics at a global level. Global Alliance for genomics and Health¹ is a large consortium of over 200 research institutions with the goal of supporting voluntary and secure sharing of genomic and clinical data; their work on data interoperability is producing a data conversion technology² recently provided as an API to store, process, explore, and share DNA sequence reads, alignments, and variant calls, using Google's cloud infrastructure³. Parallel frameworks are used to support genomic computing, including Vertica⁴ (used by Broad Institute and NY Genome Center) and SciDB⁵ (used by NCBI for storing the data of the 1000 Genomes project [3]). A survey of current challenges in computational analysis of genomic big data can be found in [5]. According to many biologists, answers to crucial genomic questions are hidden within genomic data already available in these repositories, but such research questions go simply unanswered (or even unasked) due to the lack of suitable tools for genomic data management and processing.

So far, the bio-informatics research community has been mostly challenged by **primary analysis** (production of sequences in the form of short DNA segments, or "reads") and **secondary analysis** (alignment of reads to a reference genome and search for specific features on the reads, such as variants/mutations and peaks of expression); but the most important emerging problem is the so-called **tertiary analysis**, concerned with multi-sample processing, annotation and filtering of variants, and genome browser-driven exploratory analysis [6]. While secondary analysis targets *raw data* in output from NGS processors by using specialized methods, tertiary analysis targets processed data in output from secondary analysis and is responsible of *sense making*, e.g., discovering how heterogeneous regions interact with each other (see Figure 1).

<http://blog.goldenhelix.com/grudv/a-hitchhiker%E2%80%99s-guide-to-next-generation-sequencing-part-2/>

Tertiary processing consists of integrating DNA features; these can be specific DNA variations (e.g., a variant or mutation in a DNA position), or signals and peaks of expression (e.g., regions with higher DNA read density). Processing can also give structural properties of the DNA, e.g., break points (where the DNA is damaged) or junctions (where DNA creates loops, and then locations which are distant on the 1D string become close in the 3D space).

While gigantic investments are targeted to sequencing the DNA of larger and larger populations, comparably much smaller investments are directed towards a computational science for mastering tertiary analysis. Bio-informatics resources are dispersed in provisioning a huge number of tools for ad-hoc processing of genomic data, targeted to specific tasks and adapted to technology-driven formats, with little emphasis on powerful abstractions, format-independent representations, and out-of-the-box thinking and scaling. Programming data manipulation operations directly in Python or R is customary.

Another source of difficulty comes from “metadata”, which describe DNA region-invariant properties of the biological sample processed by NGS, i.e., the sample cell line, tissue, preparation (antibody used), experimental conditions, and in case of human samples the race, gender, and other phenotype-related traits. This information should be stored in principled data schemes of a “LIMS” (laboratory information management system) and be compliant with standards, but biologists are very liberal in omitting most of it, even in well-cured repositories.

2. OUR CONTRIBUTION

Bio-informatics suffers its interdisciplinary nature and is considered by biologists and clinicians as a commodity that should immediately respond to their pressing needs, while it stays too far from foundational science to attract the interest of many core computer scientists. We understood that it is “mission impossible” for basic computer science to have an impact on primary and secondary analysis: algorithms are biologically driven and very specialized and efficient. Hence, we decided not

to interfere with current biologists’ practices, but rather to empower them with radically new data processing capabilities.

We propose a paradigm shift based on introducing a very simple data model which mediates all existing data formats, and a high-level, declarative query language which supports data extraction as well as the most standard data-driven computations required by tertiary data analysis. The **Genomic Data Model (GDM)** is based on just two entities: genomic region and metadata. Regions (upper part of Figure 2) have a normalized schema (i.e., a table of typed attributes) where the first five attributes are fixed and the next attributes are variable and reflect the “calling process” that produced them. The fixed attributes include the sample identifier and the region coordinates (the chromosome whom the region belongs to, its left and right ends, and the strand - i.e., the “+” or “-” of the two DNA strands on which the region is read, and “*” if the region is not stranded). The model can be adapted to the rare cases of regions across chromosomes. Metadata (lower part of Figure 2) are even simpler. They are arbitrary, semi-structured attribute-value pairs, extended into triples to include the sample identifier. We consider this model a paradigm shift, because a single model describes, though simple concepts, all types of processed data (peaks, signals, mutations, DNA sequences, loops, break points).

ID	(CHR, LEFT, RIGHT, STRAND)	P_VALUE
1	(1, 3245, 4535, +)	0.000024
1	(1, 6340, 7400, -)	0.000053
1	(1, 7540, 8563, -)	0.000013
1	(2, 1440, 2506, -)	0.000034
1	(2, 3540, 4541, +)	0.00006
2	(1, 4020, 5073, *)	0.000017
2	(1, 7020, 8061, *)	0.000035
2	(2, 1020, 3064, *)	0.000016
2	(2, 4020, 4101, *)	0.000022

ID	ATTRIBUTE	VALUE
1	cell	CLL
1	karyotype	cancer
1	tissue	blood
1	sex	M
2	cell	H9ES
2	sex	F
2	tissue	embryonic

Figure 2. GDM schema and instances for NGS ChIP-Seq data.

The data model is completed by a constraint: data samples can be included into a named dataset when their genomic regions have the same schema. Thus, the above figure shows the PEAKS dataset for “ChIP-Seq” data with two samples (1 and 2) whose regions fall within two chromosomes (1 and 2) and whose variable part of the schema consists of the attribute P_VALUE (each peak’s statistical significance). Note that the sample ID provides a many-to-many connection between regions and metadata of the same sample; e.g., sample 1 has 5 regions and 4 metadata attributes, sample 2 has 4 regions and 3 metadata attributes; regions of the first sample are stranded (positively or negatively oriented along the DNA), while regions of the second sample are not stranded. Metadata tell us that sample 1 has karyotype “cancer” and sample 2 was taken from a “female”. This example is simple, but we can associate a schema with arbitrarily complex processed data, where typed and named attributes serve the purpose of any numerical or statistical operation across compatible values. An important operation is the **schema merging**, which allows merging datasets with different schemas (the operation builds a new schema such that fixed attributes are

in common and variable attributes are concatenated; in this way, we provide interoperability across heterogeneous processed data.

We also defined a query language, called **GenoMetric Query Language (GMQL)** - the name derives from its ability of computing distance-related queries along the genome, seen as a sequence of positions. GMQL is a **closed algebra over datasets**: results are expressed as new datasets derived from their operands. Thus, GMQL operations compute both regions and metadata, connected by IDs; they perform schema merging when needed. GMQL operations include classic algebraic transformations (SELECT, PROJECT, UNION, DIFFERENCE, JOIN, SORT, AGGREGATE) and domain-specific transformations (e.g., COVER deals with replicas of a same experiment; MAP refers genomic signals of experiments to user selected reference regions; GENOMETRIC JOIN selects region pairs based upon distance properties). The language brings to genomic computing the classic algebraic abstractions, rooted in Ted Codd's seminal work, and adds suitable domain-specific abstractions. Tracing provenance both of initial samples and of their processing through operations is a unique aspect of our approach; knowing why resulting regions were produced is quite relevant. In [7], we show GMQL at work in many heterogeneous biological contexts.

We give an intuition of GMQL through a simple example, consisting of three operations. We start from two datasets called ANNOTATIONS and ENCODE, the former includes samples with the reference regions from the UCSC database⁶, the latter includes thousands of samples from ENCODE (in BED format); both are available at our server, with both regions and metadata. Two selections are used to produce two intermediate datasets: PROMS extracts from ANNOTATIONS a single sample with all the promoter regions of known genes; PEAKS extracts the samples of type 'ChIPSeq' from ENCODE. Then, a map operation applies to the intermediate datasets PROMS and PEAKS and produces the RESULT dataset. The MAP operation, as well as all GMQL operations, implicitly iterates over all the samples of its operand datasets; it counts, for each input peak sample, all the peaks of expression over each region of PROMS, representing gene promoters. Thus, RESULT contains one output sample for each PEAK input sample, each with all the regions of PROMS; for each of such regions, it has the counter of peaks of the sample which fall within such region. This simple example shows the power of the language: with three algebraic operations, we select reference regions and experiments and then compute aggregate properties of each experiment over each reference region, with implicit iteration over all the experiment samples.

```
PROMS = SELECT(annType == 'promoter') ANNOTATIONS;
PEAKS = SELECT(dataType == 'ChIPSeq') ENCODE;
RESULT = MAP(peak_count AS COUNT) PROMS PEAKS;
```

This query above was executed over 2,423 ENCODE samples including a total of 83,899,526 peaks, which were mapped to 131,780 promoters, producing as result 29 GB of data.

3. DATA-DRIVEN GENOMIC PROBLEMS

An open problem that we are nowadays studying concerns the search for a correlation of cancer-inducing mutations and DNA string breaks with abnormal gene activity during cell replication

[8], as one of the possible basic mechanisms of cancer. The assumption under consideration is that the abnormal production of DNA string breaks correlates with the presence of mutations (simply explained: mutations occur where the genome is most fragile, fragility is revealed by DNA break points); this in turn may be caused by gene dis-regulation during the process of cell replication (certain genes omit to perform a regulatory function that should prevent mutations during replication, or should fix them afterwards). In this problem, we are therefore confronted with correlating the cell replication with gene regulations; we do it in experimental conditions (exposure of cells to oncogenes), and we study how the induction of the oncogene changes both replication time and expression of other genes. The study requires genome-wide comparison of heterogeneous datasets (breakpoints, mutations, gene replication times and gene expressions under different experimental conditions), challenging both GDM and GMQL, and then calling for specific data analysis; specifically, GMQL can extract differentially dis-regulated genes, intersect them with regions where string breaks occur, and then count the mutations in various conditions.

Another open problem is concerned with the tri-dimensional layout of DNA, which is induced by the chromatin structure revealed by peaks of the CTCF transcription factor, and **understanding how CTCF loops influence gene regulation** [9]; a loop is simply a binding of the DNA, so that two DNA regions which are far away from a 1D perspective become very close from a 3D perspective. In Figure 3, within yellow (thin) rectangles we see three signals which identify three non-coding regions of the genome, called enhancers, and within a black (thick) rectangle we see signals which identify the promoter of the gene *Fbln2*. They are enclosed within regions which represent short CTCF loops, and the assumption to be tested is whether there is a direct relationship between active enhancers and active genes (where activity is revealed by experiments) when enhancers and promoters are enclosed within CTCF loops (as this spatial condition may favor the enhancer-to-gene relationship); *determining the relationships of genes with enhancers is a fundamental aspect of epigenetics*. Such question corresponds to searching a pattern within the whole genome; GMQL can be used to extract candidate gene-enhancer pairs by suitable intersections of the signals in Figure 3 - i.e., CTCF regions, the regions of the three methylation experiments (H3K27Ac, H3K4me1, H3K4me3), and gene promoter regions (from RefSeq).

Figure 3. Interaction between CTCF loops and gene regulation by enhancers.

4. VISION

GDM and GMQL open new scenarios in approaching tertiary analysis of genomic data. We next discuss them.

4.1 Data Analysis

Data analysis methods which are most useful for genomic computing can be bridged to the high-level language, with a bottom-up, problem driven approach. In particular, query results can be expressed in the form of interaction networks between genomic regions. In biology, many genes are involved in complex regulatory processes; for us, genes are just DNA regions of a specific sample (they are “known annotations of the genome”) and thus we can MAP (using the domain-specific operation shown in the example of Section 2) arbitrary experiments to genes. MAP is the first transformation in Figure 4, which computes aggregates over those regions of regions of experiments that intersect with genes (represented by regions R1, R2, R3). In general, every map operation produces what we call a **genome space**, i.e., a tabular space of regions vs. experiments (in the middle of Figure 4), which is the starting point for data analysis (including advanced data mining and computational intelligence). Such table can be also interpreted as an adjacency matrix representing a network, where regions are nodes and arcs have a weight obtained by further aggregating properties across experiments; thus, the second transformation in Figure 4 yields to a **gene network**, producing as well the strength of gene-to-gene interactions. The interpretation of genome spaces in the form of networks is particularly important in genomics, as regulatory gene activities typically depend on multiple interacting genes.

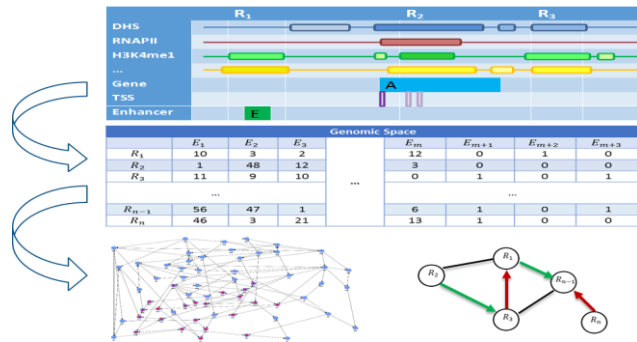

Figure 4. Interpretation of GMQL “map” query as a genome space, and further transformation of the genome space into a gene network.

Several data mining and computational intelligence approaches, including advanced *latent semantic analysis* and *topic modelling*, can be applied to evaluate relationships among genomic data, and between them and biological or clinical features of experimental samples expressed in their metadata, i.e., for *genotype-phenotype* correlation analysis.

4.2 Distributed Processing and Cloud Computing

With the growth of NGS experiments (whose cost is expected to drop to about 100 Euro in less than a decade, <https://www.genome.gov/sequencingcosts/>), we will see a deluge of NGS data. Although processed data are “smaller” than raw data (0.3 TB per full genome sample), we are still talking of samples with tens of thousands or even millions of regions. Genomic

repositories store thousands of full genome samples (i.e., 4,660 samples in [1], 5,400 samples in [2], and 2,500 samples in [3]). Our simple query in Section 3 produced 83 million regions, and simple queries over genes may produce genome spaces of 10K genes and 100M relationships between them, whose analysis requires using large-scale network management packages. Moreover, NGS is increasingly used for massive testing on restricted, pathology-specific mutation panels, so as to accelerate the use for diagnostics and for clinics. We are clearly facing one of the **most important “big data” problems for mankind**.

We are currently working towards a new GMQL release, that will be available in 2016, and will support two parallel implementations, respectively using Flink⁷ and Spark⁸, two emerging data frameworks. In our architecture, the two implementations differ only in the encoding of about twenty GMQL language components, while the compiler, logical optimizer, and APIs/UIs are independent from the adoption of either framework. In a recent paper [10] we present an early comparison of Flink and Spark at work on three genomic queries inspired by GMQL. Several tools were developed within the Hadoop framework for primary and secondary analysis, including BioPig [11], SeqPig [12] and SparkSeq [13]. Our preliminary work shows open source frameworks are effective computing systems also for tertiary data analysis; we foresee a growth of systems for genomic based upon parallel computing frameworks.

So far, our focus on tertiary data analysis is shared just by Paradigm4, a startup company founded by the Turing award Mike Stonebraker, whose products include genomic add-ons to SciDB, a vector-based data management system for scientific applications. They provide access to data from TCGA and 1000 Genomes Project, and they advocate the use of specialized databases for scientific computing rather than cloud computing – indeed, we find in [6] several arguments against the use of Spark. We expect that the alternative between open frameworks and specialized systems will shape the evolution of genomic data management in the forthcoming years.

4.3 Integrated Access to Repositories

Very large-scale sequencing projects are emerging; as of today, the most relevant ones include:

- The **Encyclopedia of DNA elements (ENCODE)** [1], the most general and relevant world-wide repository for basic biology research. It provides public access to more than 4,000 experimental datasets, including the just released data from its Phase 3, which comprise hundreds of epigenetic experiments of processed data in human and mouse;
- The **Cancer Genome Atlas (TCGA)** [2], a full-scale effort to explore the entire spectrum of genomic changes involved in human cancer;
- The **1000 Genomes Project** [3], aiming at establishing an extensive catalogue of human genomic variations from 26 different populations around the globe;
- The **Epigenomic Roadmap Project** [4], a repository of “normal” (not involved in diseases) human epigenomic data from NGS processing of stem cells and primary ex vivo tissues.

⁷ <https://flink.apache.org/>

⁸ <https://spark.apache.org/>

Data collected in these projects are open and public; all the Consortia release both raw and processed data, but biologists in nearly all cases trust the processing, which is of high-quality and well controlled and explained. All consortia provide portals for data access; some systems already provide integrated access to some of them (e.g., [14]; see also <http://www.paradigm4.com/>). The use of a high-level model and language, such as GDM and GMQL, is the ideal setting for provisioning next generation services over data collected and integrated from these and other repositories, improving over the current state-of-the-art in four directions:

- All the processed datasets available in the above data sources will be provided of compatible metadata;
- It will be possible to choose among a set of custom queries, representing the typical/most needed requests;
- It will be possible to provide user input samples to the services, whose privacy will be protected;
- Deferred result retrieval will be possible, through limited amount of staging at the sites hosting the services.

A simple protocol will facilitate input and output file transmissions and it will also be possible to visualize results on genome browsers or to selectively retrieve regions or metadata. Users will be enabled to write personalized queries, whose privacy will be protected. The main challenges in this vision include two new research objectives: the mediation of ontological knowledge and the statistical description of custom queries.

- Ontological reasoning will be required in order to establish the appropriate **conceptual relationships between the metadata** which are present at the various sources. The best option is to use the global ontology provided by the Unified Medical Language System (UMLS) [15], which collects and integrates well-established biomedical ontologies. Our initial solution, presented in [16], consists in semantically annotating the metadata of each repository's datasets by means of UMLS, and completing the information by performing the semantic closure [17] of such annotations. Then, a suitable UI would allow users to search for relevant experiments through keyword-based or free text queries.
- **Custom queries** will need to be augmented with suitable mechanisms for reasoning about data; such services could imitate the *Great* service developed by Gill Bejerano's group at Stanford [18], which includes powerful statistics to indicate the significance of query results.

4.4 Federated Query Processing and Protocols

The availability of a core data model as a data interoperability solution and of a high-level data processing language is a strong prerequisite for defining data exchange protocols. We expect that each data repository will be the owner of the data that are locally produced, and that nodes of cooperating organizations will be connected to form a federated database. In such systems, queries move from a requesting node to a remote node, are locally executed, and results are communicated back to the requesting node; this paradigm allows for distributing the processing to data, transferring only query results which are usually small in size.

Supporting a high-level query interface to a server is already making one big step forward, which is similar to the gigantic step made by SQL in the context of client-server architectures (which

dates a couple of decades). Indeed, once a system supports an API for submitting GMQL queries, these have the following properties: they are short texts and produce short answers. This comes from the nature of problems: the more they are biologically inspired, the more they produce results which are both short and ranked, and these will eventually be transmitted along any GMQL API; in contrast, most of today's implementations requires first a full data transmission and then to evaluate server-side imperative programs. This scenario opens up to the design of simple interaction protocols, typically for:

- **Requesting information about remote datasets**, facilitated by the availability of metadata (for locating data of interest) and of their region schemas (for formalizing queries).
- **Transmitting a query in high-level format and obtain data about its compilation**, not only limited to correctness, but including also estimates of the data sizes of results.
- **Launching query execution and then controlling the transmission of results**, so as to be in control of staging resources and of communication load.

4.5 Search Methods and Internet of Genomes

After having provided access to integrated sources of sequence data, we come to the question of how such knowledge can be searched. The problem can be approached progressively, starting first with opening search services over the integrated repositories. There are two intertwined problems:

- **Metadata search.** Search methods should locate relevant samples within very large bodies, using classical measures of precision and recall; keyword-based search or free text querying should be supported.
- **Feature-based region search.** Best-matching regions with user-specified features should be provided. For some regions (e.g., known genes) it is possible to define a priori the typical features, store them as attributes, and then use indexing; but in general features should be computed. We envision general search mechanisms where the user selects interesting regions, then provides information about the features of interest, then those features are computed, and finally regions are ordered based on their computed features and presented to the user. So, search and feature evaluation have to intertwine in a clever way.

The most ambitious and challenging vision is **building a search system upon an Internet of genomes**. The prerequisite to this vision is of course not in today's reach, and requires all research centers to agree on a deployment technology playing the role of HTML and HTTP for the Web. However, biologists are forced to publish the data which go together with their experiments: it is already in their practice to provide a link to a download site where experimental data should be available for downloading by reviewers. In such context, it is possible to envision the definition of a simple protocol for data publishing, prescribing how to publish a link to genomic data in their native format with suitable metadata; the protocol should offer the possibility of making such link public, i.e., visible within a host open to the visits of crawlers. With such infrastructure, a third party hosting a search service could periodically launch the crawlers, and these would download the metadata and links from the host; the search service could also download datasets from the hosts by using those links, with an agreed, non-intrusive protocol. The search service would then have all the required information for indexing all the

metadata and for storing some of the samples within a large repository, possibly pre-computing some features of their regions. Such search system could accept search queries and produce result snippets, with an indication of the presence of each dataset in the repository. In any case, users of the search system would be able to locate genomic data available at another host (a research or clinical center) and could download them asynchronously.

5. CONCLUSIONS

The progress in DNA and RNA sequencing technology has been so far coupled with huge computational efforts in primary and secondary genomic data management, consisting of producing “raw” data, aligning them to the reference genomes, and calling for specific features such as expression peaks and mutations. However, a new pressing need is emerging: making sense of data produced by these methods, in the so-called tertiary analysis. This need requires a substantial change of the dominating approach to bio-informatics. While primary and secondary analyses produce data formats which are typically intricate and incompatible, tertiary analysis must worry about their interoperability and ease of use. Tertiary analysis calls for raising the level of abstractions of models, languages and tools for genomics, going towards a broader vision where biologists and clinicians can observe the huge and complex body of genomic knowledge at a much higher level, using simple interfaces similar to search queries which have become widely available in the Internet.

In this paper, we have shown that a change of paradigm is possible, by means of a new data model and query language; we have then shown the biological applications that have become feasible thanks to this approach, and examined the relevant advantages that this approach may bring in the contexts of data analysis, distributed processing, integrated repository access, federated data management, and search of genomic data over the Internet. The corresponding scenario traces a five-to-ten year research trajectory.

ABSTRACT

Industrial enterprise data present classification problems which are different from those problems typically discussed in the scientific community – with larger amounts of classes and with domain-specific, often unstructured data. We address one such problem through an analytics environment which makes use of domain-specific knowledge. Companies are beginning to use analytics on large amounts of text data which they have access to, but in day-to-day business, manual effort is still the dominant method for processing unstructured data. In the face of ever larger amounts of data, faster innovation cycles and higher product customization, human experts need to be supported in their work through data analytics. In cooperation with a large automotive manufacturer, we have developed a use case in the area of quality management for supporting human labor through text analytics: When processing damaged car parts for quality improvement and warranty handling, quality experts have to read text reports and assign error codes to damaged parts. We design and implement a system to recommend likely error codes based on the automatic recognition of error mentions in textual quality reports. In our prototypical implementation, we test several methods for filtering out accurate recommendations for error codes and develop further directions for applying this method to a competitive business intelligence use case.

1. INTRODUCTION

Analytics and automatized processing of unstructured data to support business processes and decisions have become a topic of interest for the research community and the enterprise world in recent years only [15]. Companies are realizing that valuable knowledge can be gained especially from the large amounts of unstructured text data which they are storing internally and able to access publicly on the social web. In past decades, this knowledge was only accessible to the human mind. The means for storing and processing large amounts of data and scalable text analytics or cognitive computing tools [5] are both relatively new developments.

In cooperation with a large automotive original equipment manufacturer (OEM), we have developed an overarching use case in the area of quality management, with a concrete example for supporting human labor through text analytics. This use case presents a particularly challenging classification problem with several hundred possible classes and mainly unstructured text data as input. We develop a modular environment for classifying these data with the help of natural language processing. In this paper, our main points are (1) a first proof of concept for a “messy” industrial data source and (2) the investigation of the usefulness of a legacy domain-specific resource in the context of a new analytics task. To this end, we evaluate various adaptations of an established classification algorithm in order to customize it to the given situation.

1.1 Motivation

Industrial enterprises are generating and collecting large amounts of unstructured text data. These data are often highly domain-specific. Most current approaches to automatically analyzing these unstructured data with traditional

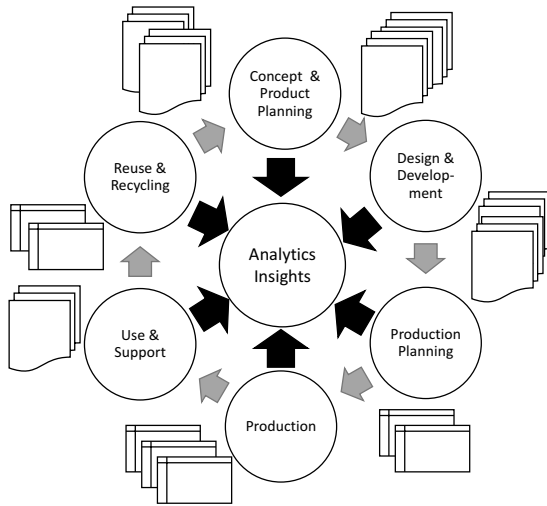

Figure 1: Data Analytics around the Product Life Cycle

analytics for structured data are either very specific and case-based or too generic [11]. What is needed is a flexible framework for analytics with re-usable and modular resources and analytics toolboxes.

Enterprises are beginning to transition to more widespread and streamlined use of text analytics. But in day-to-day business, a lot of manual effort is still used to process unstructured data, for example in quality management or customer relationship management. This effort is important because these data contain value-adding knowledge, and human expertise cannot and should not be fully replaced in these tasks. But in the face of ever larger amounts of data, faster innovation cycles and higher product customization especially in the manufacturing industry, human experts need to be better supported through data analytics. Beyond the support of current manual analytics tasks, data analytics can also provide important novel business insights (cf. Figure 1).

Domain-specific resources, for example taxonomies of domain-specific languages, are often developed for a single case-based analytics scenario and rarely re-used for others. This leads to inefficiencies and loss of valuable knowledge. Related research on this topic [11, 12] has proposed requirements and an architectural paradigm for flexible, re-usable and value-adding analytics software. Within this framework we develop a proof of concept for a toolbox using legacy code and semantic resources, unstructured data from several sources, and modular, tailored text analytics.

1.2 Contribution and Outline

When processing damaged car parts for quality improvement and warranty handling, quality experts have to read large numbers of text reports from various sources and assign error codes to damaged parts from a large pool of options. We investigate methods to handle these unstructured text data analytically and to support this labor through automatic recommendation of likely error codes, which is a specialized application of automatic classification.

This use case is different from typical classification problems in several respects: The amount of potential classes is

larger (several hundred), and the data to be classified are short text reports which we term “messy data”: Text which consists of non-standard, domain-specific language, riddled with spelling errors, idiosyncratic and non-idiomatic expressions and OEM-internal abbreviations.

We design and implement the Quality Engineering Support Tool QUEST with an included Quality Analytics Toolkit (QATK), a system to recommend likely error codes based on the automatic recognition of error mentions in textual quality reports. It also includes the functionality for comparing error distributions across different data sources, which we have implemented for a public data source, the database of automotive malfunctioning complaints maintained by the Office of Defects (ODI) of the National Highway Traffic Safety Administration (NHTSA) [13].

We test a domain-specific and a domain-ignorant version of a custom classification algorithm derived from k-Nearest-Neighbors (kNN), and evaluate both against a baseline which ignores the text content as well as with respect to their industrial feasibility.

We also investigate in more detail the influence of the report source and its place in the error classification process – early or late and contributed by mechanics or part suppliers.

In sum, we address three different industry-focused goals: (1) to make classification work easier for the workers who do it by sorting error codes in a meaningful way, (2) to do this as early as possible in the life cycle of a damaged car part, and (3) to make data comparable to other data sources through text analytics.

The remainder of this paper is structured as follows: In the following chapter 2, we present the research background. In chapter 3, we describe in detail the industrial context of our application (3.1) and discuss the challenges presented by the data (3.2). The methods and implementation are explained in chapter 4. We then present and evaluate two experiments and an extension of the original use case in chapter 5. We look at the feasibility of text-based error classification (5.2) and the role of the report source for classification accuracy (5.3) as well as the potential use of automated error code assignment to compare the performance of a product with competitors (5.4). Chapter 6 concludes our paper with a summary of the results and outlook on future research.

2. BACKGROUND

In prior research, we have motivated the need for Product Life Cycle Analytics integrating structured and unstructured data within a holistic framework [11]. In this chapter, we present two background foci which are relevant for the present research topic, namely text analytics in the automotive industry (2.1) and the general field of automatic text categorization (2.2), which deals with applying classification algorithms to text data.

2.1 Text Analytics in the Automotive Industry

In the automotive domain, there have been a number of efforts to use unstructured text data for business analytics. Most recently, several interconnected research projects [3, 16, 8] have developed software for extracting information about frequent problems from internal error reports and customer sentiment related to problems from social media. This research has also led to the creation of a valuable semantic resource, a taxonomy of parts and errors [17, 18], which we

use as a central component in our analytics framework (cf. 4.5.3) as well as in the domain-specific classification algorithm.

2.2 Automatic Text Categorization

Automatic text categorization has been a widely researched field since the late 1990s / early 2000s [19]. Typically, the task is to label texts as belonging to one of a small number of classes, e.g. one of five different topics for news texts or one of three known potential authors for literary works. Our task differs from this in that we have a very large number of classes.

Features for classification are usually derived by their information content across a large number of texts. Using pre-defined features such as author, user mentions and signal words in tweets [20] has also been shown to achieve high accuracies. We investigate the suitability of features drawn from a domain-specific knowledge resource.

An important part of this investigation is the mapping of words in the text to concepts from a semantic resource. We agree with the argument of [10] that words and stems do not represent the semantic content of a text very well. They try to map words to concepts using WordNet [4]. This is important for disambiguation, but also for highlighting and exposing shared concepts as latent features across texts with no shared word material. Because our semantic resource is rich in synonyms, we can map text to concepts via surface entity recognition.

[7] point out a weakness of the kNN algorithm which we also encounter – it is instance-based and thus potentially memory-intensive. They develop a modified kNN which creates generalized instances and representatives of instances based on local neighborhoods. We modify kNN to use representatives of instances based on abstractions of texts to contained concepts in our domain-specific variant, and also store these instances in a relational database with on-the-fly access to further address memory concerns.

3. PROBLEM DESCRIPTION

In this chapter, we present the industrial context of our use case (3.1) and discuss the challenges of the data we are working with (3.2).

3.1 Industrial Context

An automotive OEM is evaluating car parts which were removed during repairs in customer-owned vehicles for the warranty process and in order to gain insight into quality issues. The evaluation is a complex and multi-step process which involves unstructured text data from many sources and large amounts of human work:

The removed and potentially damaged car part is first evaluated in a short textual report by the mechanic who removed it. It is then shipped to the OEM, where an optional initial report can be written. Next, the car part is sent on to the supplier who manufactured it. The supplier evaluates the part’s damage, writes a textual report and assigns a damage responsibility code (indicating whom they hold responsible for the problem). Eventually, a quality expert at the OEM assigns the car part a final error code and writes a short final report. This process of data accumulation is depicted in Fig. 2.

In order to assign the correct error code, the quality expert needs to read all reports written about the part at hand and

Figure 2: Process of data accumulation

then pick the error code from a list of potentially over 100 error codes available for this type of car part.

Due to the largely textual nature of the data and the large number of potential error codes, a substantial amount of the quality experts’ time is taken up by assigning error codes to known errors. We want to support the quality workers by offering them automatically derived error code recommendations to speed up the decision process. If the set of error codes for a given part is smaller and sorted, the final error code assignment will take less time. The quality experts can then spend more time investigating novel or more complex errors, thus improving the overall quality of the evaluation.

3.2 Challenges of the Data

We developed our prototype around a randomized and anonymized subset of the original data input from the evaluation documentation tool. We extracted a fraction of the data concerning three larger component classes which have already been assigned error codes, such that a portion of the data can be used for evaluation. Other component classes are subject to future research to further validate the approach. Any information about individual persons (quality workers assigned to tasks, supplier contacts, etc.) was removed, as well as select mentions of supplier names and the OEM name, and the fields listing vehicle identification numbers and information about vehicle make and model. In total, we are working with data for 7500 individual car parts. These data, including the text reports, are stored across several tables in a relational database.

We define all data pertaining to an individual component as a data bundle. The data bundles for each component are structured in the following way:

- A component is identified by a unique reference number and also assigned an article code and a part ID. These have vastly different levels of granularity: In our data set, there are 831 distinct article codes and 31 distinct part IDs.
- A further challenge is the extremely high number of distinct error codes: There are 1271 distinct error codes in our data set of 7500 data bundles. 718 of these error codes only appear a single time, so we remove them for our experiments since nothing can be learned from them for the classification task at hand (for information extraction tasks we would of course consider them). This leaves us with 553 potential classes and 6782 data bundles with an error code that appears more than once. The largest number of distinct error codes for one part id in our data set is 146, and 25 of the 31 part IDs have instances of over 10 error codes.

Ref.No	Art.Code	Part ID	Error Code
Part Description		Error Description	
Mechanic Report			
Cleint says taht radio turns on and off by itself. Electiral smell, crackling sound.			
Supplier Report			
Unit non-functional. Lüfter funktioniert nicht. Kontakt defekt, durchgeschmort.			
Initial OEM Report			
Did test A470, no clear results, sending on to supplier. Removed some dirt.			

Figure 3: Structure of the data bundles before final classification, with missing structured data fields highlighted in red

- Each component is further associated with three or four textual reports: (1) the mechanic report, (2) the initial OEM report (optional), (3) the supplier report and (4) the final OEM report.

Other textual resources are the standardized descriptions of part id and error code in German and English. Fig. 3 shows a schematic overview of one data bundle and contains a fictional but representative text example.

These text resources can be used to derive textual indicators of error codes during the training phase of classification. In the testing phase, we use only the mechanic report, the optional initial report, the supplier report and the part id description. This reflects the circumstance that the final OEM report and the error code description are unavailable as sources for textual indicators in data which have not yet been assigned an error code. In 5.3, we investigate the performance of classification when using only the mechanic report or only the supplier report as input to the classifier.

The reports in our data sample are mostly a mix of German and English, but the entire data set contains several other languages. Robustly recognizing meaning in multilingual input is therefore a requirement for our system. In our prototype, we achieve this by using a multilingual semantic resource for the domain-specific approach and primarily relying on natural language processing steps which are language-independent. The domain-ignorant approach does not address multilinguality. Future investigations will also deal with how to incorporate language-specific tools.

4. METHODS AND IMPLEMENTATION

In this chapter, we present the general architecture of our analytics toolkit (4.1), develop a basic algorithm derived from kNN (4.2), discuss our adaptation of this algorithm in the domain-specific and the domain-ignorant variant (4.3), and describe the processing pipeline (4.4) as well as the prototypical implementation (4.5).

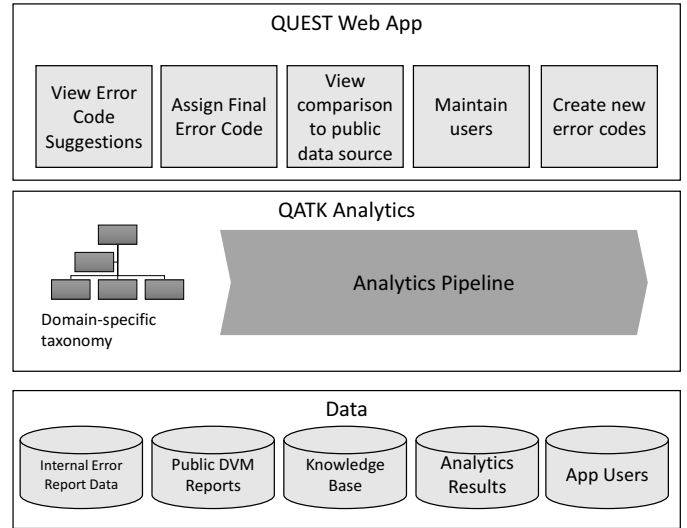

Figure 4: General architecture of the recommendation system

4.1 Architecture

The architecture of our general analytics framework comprises data sources and two main components (cf. Fig. 4), the Quality Analytics Toolkit (QATK) and the Quality Engineering Support Tool (QUEST) web application.

The QATK provides a highly modular analytics pipeline to process the text data, build a knowledge base representing structure extracted from the unstructured data, and assign scored and sorted potential error codes to new data bundles using the classification approach outlined in 4.3. This pipeline can be seen in detail in Fig. 8 and is further discussed in 4.4.

The functionality of the QATK can easily be adapted to classify data from a different source according to the same classification schema of part IDs and error codes as the internal source. This allows for comparisons of error distributions across different data sources. In 5.4, we show how such comparisons can be implemented for a public data source, the complaints database of the NHTSA ODI available via [safercar.gov](https://www.safercar.gov) [13].

4.2 Basic Classification

The reports and the error key and part ID labels contain unstructured text descriptions of the problems encoded by the error keys. If we can abstract from these descriptions to structured features, we can use them as input for a classification algorithm.

In our approach and in the prototypical implementation, we employ a classification algorithm derived from the k-Nearest-Neighbor algorithm. The standard kNN algorithm (Fig. 6) determines class membership of a data point by majority vote from the classes of the k nearest neighbors of this data point, where nearness is equivalent to similarity with respect to the chosen classification features. This majority vote can also be weighted by the individual nearness of neighbors, which is determined by a similarity measure of choice between the data points.

kNN is a „lazy” machine learning algorithm – it does not build a statistical model, it just holds instances of already

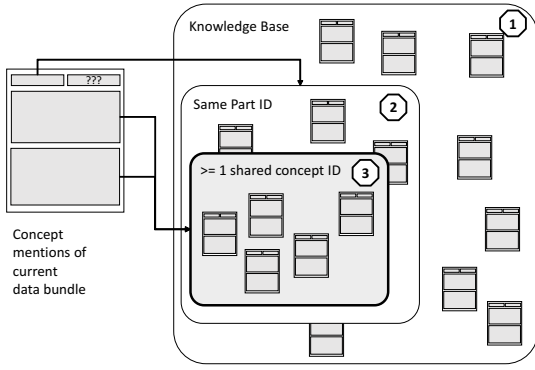

Figure 5: Selecting candidate nodes

classified data in memory (or on disk, as is the case in our implementation) for comparison with the data instances to be classified.

We have decided to focus on variants of kNN in our proof of concept for several reasons: We are dealing with an extreme multi-class classification problem, and in contrast to many other algorithms, kNN handles multi-class classification in a straightforward manner. It is also instance-based and therefore allows for predictions about class membership even with a small data set and a large number of classes, which makes it especially suitable for our example data. Further, since our focus is on establishing whether this particular multi-class classification problem can be solved semi-automatically and on investigating the role of domain-specific vs. domain-ignorant features, we decided in favor of an algorithm which allows for very straightforward control over the features, is easy to implement and easy to understand, and can easily be used with different similarity or distance measures, such that we are not fixed on representing our data in one particular way. Other algorithms are to be investigated in future research after we have established that the challenges of the data can be met at all.

Thus, we can derive a bare-bones classification algorithm with maximum parametrizability:

Given set of objects S with assigned classes, object o without assigned class

for o_i **in** S : calculate $\text{similarity}(o, o_i)$

sort S by descending similarity

assign class to o based on sorting of S

The similarity measure, the choice of features on which to base the similarity measure and the method for deriving the class assignment from the similarity ranking can be adjusted to the needs of the use case.

4.3 Adaptation and Parametrization

Starting from the basic algorithm described in 4.2, we make the following modifications: It is unlikely that a clear majority of the nearest neighbors of a data bundle will all share the same error key because of the sparsity introduced by the large number of classes and the small size of the data set. Therefore, instead of majority vote to determine one definitive class, we output a list of all potential error keys ranked by the distance of the knowledge base instances to the data bundle, then cut off the list at k for initial presentation to the expert (see the schematic depiction in Fig. 7). A similar type of ranking categorization is already mentioned

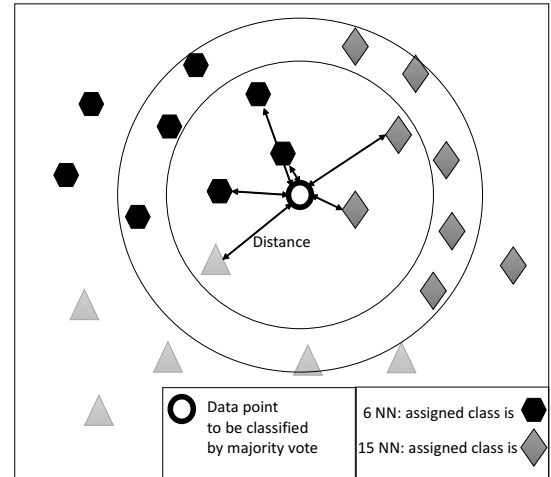

Figure 6: Standard unweighted instance-based kNN classification for $k = 6$ and $k = 15$ with class assignment by majority vote

Figure 7: Adapted ranked-list kNN classification for abstracted data bundle representations

in [19]. Thus, we also address a weakness of standard kNN which becomes evident in Fig. 6 – the sensitivity to local data structures. For $k = 6$, the class assigned by majority vote is different from that for $k = 15$. Since our goal is to support the human expert, not fully automatic classification, we can avoid this inconsistency. Items lower on the list can be accessed by the quality expert in the user interface (cf. Fig. 4).

We determine the closeness of the data bundles by comparing them with respect to features derived from the text. For the domain-ignorant approach, we use all words in the text (*bag-of-words*), for the domain-specific approach, we choose mentions of parts and errors as features (*bag-of-concepts*). On average, a text has about 70 words, resulting in as many bag-of-word features. With the domain-specific approach, we detect on average 26 part/error mentions per text. We use the concept mentions as attributes without distinguishing between types of concepts (part or error). Annotating the text with the help of a domain-specific, synonym-

rich part-and-error taxonomy from prior research with the OEM [16] allows us to collapse mentions of the same part in different wordings into identical features. For example, „mud guard“, „splashboard“ and „fender“ all belong to the same concept within the taxonomy and are all represented by the same concept ID. The taxonomy has about 1.800 / 1.900 distinct concepts in German and English, respectively. Thus, we can represent each unique combination of part ID, error key and concept mentions as a node in a knowledge base, which is derived in a first training step.

This also allows us to abstract from data instances to configuration instances, reducing the size of the knowledge base and allowing for faster data comparisons when calculating similarity measures. We thus address one of the weaknesses of the standard kNN approach in a way which is similar to the kNN Model algorithm in [7]. For the bag-of-words approach we accordingly store combinations of part ID, error key and individual words (excluding punctuation) in a knowledge base of the same structure.

We retrieve error code suggestions for data bundles from the knowledge structure by computing the similarity of potential nearest neighbors. In order to do this efficiently, we filter the knowledge nodes to first retrieve a neighbor *candidate set* fitting to the data bundle under consideration (Fig. 5). From the entire set of knowledge nodes (1), we first select the subset of nodes with the same part ID as the data bundle to be classified (2). From this subset, we select those knowledge nodes which share at least one concept mention with the data bundle under investigation (3) – or one word for the bag-of-words approach. This selection is made via the indexes of the knowledge structure. If the part ID is not found in the knowledge structure, we select all nodes into our neighbor candidate set.

Next, we compute a pairwise similarity score for each candidate node with reference to the current data bundle. We retrieve the error codes of the 25 best-scored candidate nodes. For each of these error codes, we assign an error code with associated score to the data bundle under investigation. These scored error codes are stored in a relational database and presented to the quality worker via the web app interface for final error code assignment.

To evaluate performance of the classification algorithm, we have experimented with two established similarity measures – the Jaccard similarity, computed as the number of shared attributes divided by the total number of attributes, and the overlap similarity, computed as the number of shared attributes divided by the size of the smaller attribute set.

Jaccard Similarity Coefficient: The similarity of two items (knowledge nodes) with feature sets A and B is represented by:

$$\frac{|A \cap B|}{|A \cup B|}$$

Overlap Similarity Coefficient: The similarity of two items (knowledge nodes) with feature sets A and B is represented by:

$$\frac{|A \cap B|}{\min(|A|, |B|)}$$

4.4 Processing Pipeline

The classification step is embedded in a pipeline which includes linguistic preprocessing and the creation of a knowl-

edge base. This processing pipeline is detailed in the following.

Figure 8 shows the entire analytics pipeline for the domain-specific approach. It can conceptually be split in two parts: one to extract structure from unstructured data, which includes data preparation, linguistic preprocessing and annotation with domain-specific knowledge, and one for processing the extracted structured data, which includes the building of a knowledge base and the classification step.

We assume the classical phase-oriented data mining process which differentiates a training phase from the subsequent test phase and the application phase.

In the *training phase*, we extract domain-specific classification features from within the unstructured data portion, following several steps:

1. Creating Data Bundles: read data from the database and combine related reports into one document.
2. Unstructured Data Analytics
 - (a) Text Preprocessing: Tokenization and Language Recognition
 - (b) Concept Annotation: mark up domain-specific concepts in the text (words describing parts and errors)
3. Structured Data Analytics
 - (a) Knowledge Base Extraction: for each data bundle, extract into a "knowledge node" (cf. Fig. 9)...
 - the error code
 - the part number
 - the occurring concepts (numeric IDs)
 - (b) Knowledge Base Persistence: store knowledge nodes in a relational database

After the knowledge base has been created, we exploit this knowledge for the classification step (cf. 4.3) in the *test and application phases*. Steps 1 - 2 of the process are identical to the training phase:

1. Creating Data Bundles: read data from the database and combine related reports into one text document.
2. Unstructured Data Analytics
 - (a) Text Preprocessing: Tokenization and Language Recognition
 - (b) Concept Annotation: mark up domain-specific concepts in the text (words describing parts and errors)
3. Structured Data Analytics
 - (a) Candidate Set Generation: select knowledge nodes which share a minimum of 1 feature with the data bundle to be classified (cf. Fig. 5)
 - (b) Classification of the data bundle (cf. 4.3)
 - (c) Result Persistence: store scored error code suggestions in a relational database

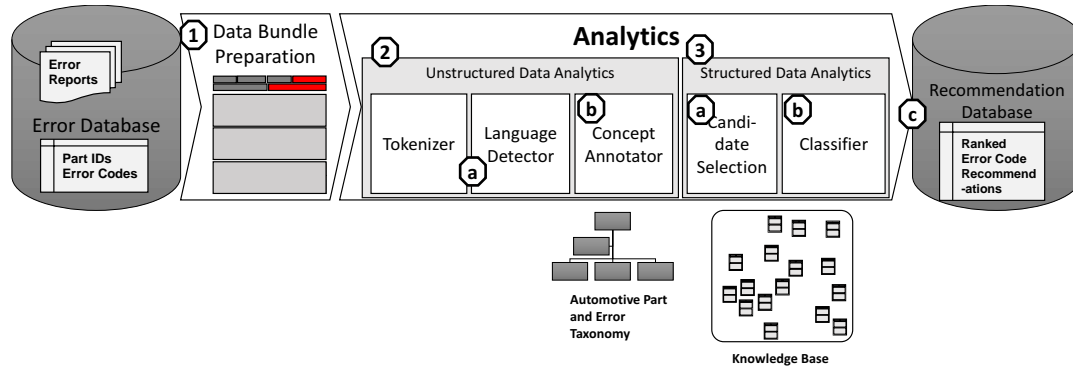

Figure 8: Detailed view of the domain-specific classification pipeline

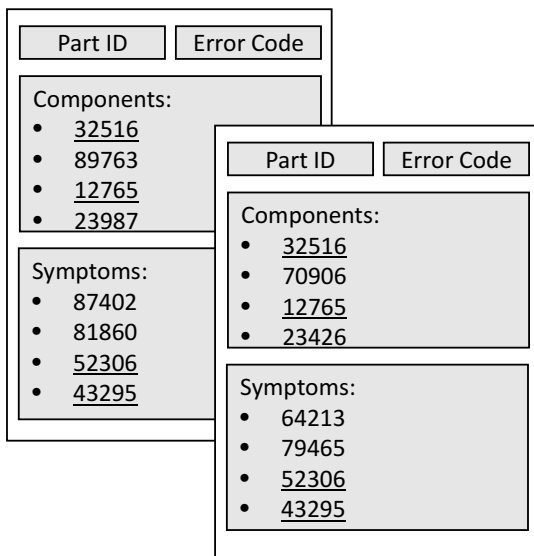

Figure 9: Two Knowledge Nodes with shared concepts underlined

The domain-ignorant approach proceeds accordingly but eliminates the concept annotation step and instead extracts all words of the document as features to be stored in the knowledge nodes.

It is obvious that this approach to a processing pipeline reflects a high degree of flexibility and extensibility for both preprocessing and classification steps. In our current setting we use the kNN-derived algorithm described in 4.3 for the classification step. This step is realized as an extension point where different classification algorithms can be plugged in easily.

4.5 Prototypical Implementation

In the following, we give a short overview of the technologies used in the prototypical implementation of the QATK framework and QUEST app.

4.5.1 Data Storage

For data storage, we use relational databases. We store raw data from the industrial source as well as from the NHTSA ODI source and the knowledge bases and classi-

fication results.

4.5.2 Text Analytics and Classification

In our implementation of the Quality Analytics Toolkit, we build on the Java version of the open-source Apache standard UIMA (Unstructured Information Management Architecture) [6], which enables us to easily build modular linguistic processing pipelines. These pipelines are composed of Analysis Engines containing annotators with single text analytics functionalities. Annotations on the text are recorded as typed feature structures with a start and end index relative to the document text in the Common Analysis Structure (CAS) which is handed over from one Analysis Engine to the next, such that annotators can build on findings from previous steps of analysis. In our case, one CAS contains one data bundle, including all available reports and text descriptions plus the part ID and error code.

We chose this framework for several reasons: It is open-source, extremely modular and well supported by the research community. High-quality implementations exist for a large number of standard natural language processing components, e.g. in the DKPro repository [21]. Functionality for quick and flexible pipeline building and testing is provided by the uimaFIT library [14].

The core of the QATK toolkit is a UIMA pipeline corresponding to the processing steps explained in 4.4 and depicted in Fig. 8. It reads the report and identifier data bundles from a database, segments the text into words using a simple custom whitespace-/punctuation-tokenizer, identifies occurrences of car part and problem synonyms in the text, builds a knowledge base from these identified concepts and uses the knowledge base to assign error code suggestions to previously unseen data bundles.

4.5.3 Domain-specificity: The Automotive Part and Error Taxonomy

A domain-specific resource used in our analytics module is a taxonomy of car parts and error symptoms, developed in prior research and originally used for an information extraction task on social media data [18, 9]. The taxonomy is stored in a custom XML format and has a shallow structure which is nevertheless well suited to the differentiations we want to make: It distinguishes components, symptoms, location and solutions. The error codes we want to recommend correspond to symptoms and also depend on components, which is why we choose to annotate the texts with occur-

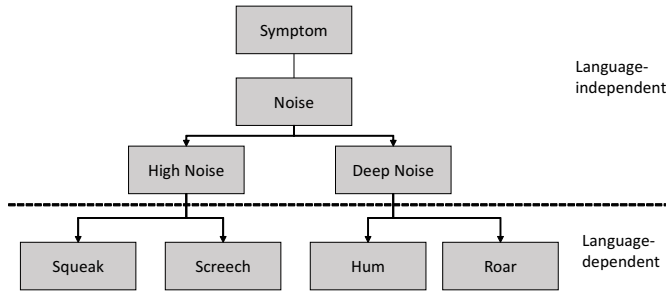

Figure 10: Automotive Taxonomy (graphic adapted from [18])

rences of components and symptoms from the taxonomy as features for our classification task. The taxonomy is multilingual – its upper category levels are language-independent with multilingual labels, its leaf categories are language-specific and contain synonyms of terms for the same concept (cf. Fig. 10).

QATK builds upon some closed-source legacy libraries for maintaining and using the taxonomy resource: An editor GUI for adding, changing and removing taxonomy concepts and concept features, as well as compiled Java archives which contain the classes needed for modifying and using the taxonomy. Among them are UIMA components for annotating occurrences of taxonomy concept words in text documents. These libraries do not entirely meet the requirements of the present use case. Therefore, some efforts had to be made in order to be able to use the taxonomy for text annotation.

We made a number of changes to the representation of the taxonomy and to the taxonomy annotator component which improve performance (cf. [12]): Annotation becomes faster, less memory-intensive, achieves higher coverage and is more accurate for multiwords. We represent the taxonomy as a trie data structure, a tree structure which allows for fast search and retrieval. Like the original approach, we expand the concepts of the taxonomy with synonyms of concept label substrings as found in the taxonomy itself.

Our optimized implementation has a left-bounded greedy longest-match approach for mapping text sequences to taxonomy concepts, eliminating concept matches which are completely enclosed by other concept matches. By applying multilingual annotation and correctly capturing multiwords, we achieve an overall higher recall of concepts than the annotator from the legacy code. For instance, the original taxonomy annotator does not recognize any taxonomy concepts in 2530 out of the 7500 data bundles, but the new annotator finds concepts in all of these.

4.5.4 User Interface

The QUEST web application partly reconstructs the user interface and functionality of the original quality engineering software which is used by the automotive OEM to record, maintain, and classify the data. In QUEST as in the original software, users can view the data and assign error codes. The core difference is that in the QUEST error code assignment interface, the user is first presented with a selection of the 10 most likely error codes in descending order of likelihood. If the user decides that the correct error code is not among these 10 codes, they can access the list of all error

codes available for the part ID of the current data bundle, as is the default in the original software.

Also, users with extended rights can define new error codes right in the QUEST interface. Furthermore, all users can view the comparison of error code distributions between the OEM data set and the public US complaints database (cf. 5.4). The QUEST web app is compatible with most browsers and implements responsive design to be viewable on mobile devices. It is written in Java, uses PrimeFaces graphical components [1] and is deployed on a WSO2 web server [2].

5. EXPERIMENTS

In this section we present and discuss the results of two experiments into the feasibility of text-based classification with our data set. In 5.1 we establish the conditions for our experiments, in 5.2 we compare the performances of the domain-specific and the domain-ignorant modified classification algorithms with respect to a baseline, and in 5.3 we test the performance of classification on different report types (mechanic and supplier report). In 5.4, we describe the setup of an extended use case in the web app which is currently under development and evaluation.

5.1 Experiment Setup

We test the classification algorithm (cf. chapter 4.3) with different similarity measures and with different data abstraction models.

As a performance measure, we report accuracy defined as the percentage of test data which include the correct error code in the error code list at $k \leq 1, 5, 10, 15, 20$ and 25, respectively.

Accuracy@k:

For D_k the set of data bundles where the correct error code is found within the first k suggestions, corresponding to the k nearest neighbors, and T the test set,

$$A@k = \frac{|D_k|}{|T|}$$

We run all experiments with stratified 5-fold cross-validation on the 6782 data bundles whose error code appears more than once in the data. This means that for each error code, we use 4/5 of the data bundles with this error code as input to the knowledge base and assign error codes to the remaining 1/5 using the knowledge base built from the rest of the data. We do this five times with distinct splits of the data and average the accuracies obtained in each iteration. The test data sets consist of 1250 data bundles on average.

We use two similarity measures, the Jaccard coefficient and the overlap measure (cf. 4.3). We work on whitespace- and punctuation-tokenized text without further preprocessing or normalization.

We compare the results of the classification to two baselines obtained without or with very little consideration of the text:

1. the *code frequency* baseline, where all error codes which are available in the database for the part ID of the data bundle under consideration are sorted by their frequency in this database, and the first k returned
2. the unsorted *candidate set* baseline (cf. 4.3), containing all nodes in the knowledge base which share the

part ID and at least one concept / word with the data bundle under consideration

The baselines themselves merit a look at their performance: The *candidate set* baseline depends on the applied variant of the algorithm, but all candidate set baselines have similar accuracy profiles. Accuracies are rather low throughout, with $<1\%$ accuracy for $k = 1$ and approximately linear development towards around 83 % accuracy for $k = 25$ (cf Fig. 11). This baseline could obviously not be used for automated recommendations of error codes.

The *code frequency* baseline performs better than the candidate set baseline, with an accuracy@1 of 35 %, accuracy@5 of 76 % and accuracy@10 of 88 %. At $k = 25$, it even has perfect accuracy of 100 %. Since we know that there are potentially over hundred error codes for one part ID, we assume that this is an artifact of our randomly selected data set. In any case, sorting available codes by their frequency can be a first step towards supporting quality workers in finding the correct error code more quickly.

5.2 Experiment 1 – Text-Based Error Code Prediction

In this experiment we establish whether error codes can be predicted at all on the basis of the text reports alone. We compare two variants of the classifier, a domain-ignorant bag-of-words model on the tokenized text, and a domain-specific bag-of-concept model created with the help of domain-specific text annotations from the automotive part and error taxonomy.

5.2.1 Results

The results of experiment 1 can be seen in Figure 11. We find that both the bag-of-words and the bag-of-concepts classifier outperform the baselines for $k < 25$ when using Jaccard similarity. The four variants we tested – bag-of-words and bag-of-concepts with each similarity measure respectively – differ considerably in their performance.

In general, overlap similarity performs worse than Jaccard, and the bag-of-concepts classifier does not perform significantly better than the code frequency baseline (in fact, slightly worse for $k = 1$) when combined with the overlap measure.

Combined with the Jaccard measure, the bag-of-concepts approach out-performs both baselines with accuracy@1 of 56 %, accuracy@5 of 85 %, and accuracy@10 of 92 %. For k of 15, 20 and 25, all approaches as well as the baseline deliver accuracies between 90 and 100 %.

For smaller k (1 and 5), the accuracy of the bag-of-words classifier is markedly better than that of the bag-of-concepts classifier regardless of similarity measure used, with accuracy@1 of 76 % (overlap) and 81 % (Jaccard), accuracy@5 of 93 % (overlap) and 94 % (Jaccard), respectively.

5.2.2 Discussion

Three out of the four text-based classification algorithm variants provide accuracies which out-perform the code frequency baseline, and all four could be used for recommending error codes on the basis of text reports. The bag-of-words model is currently providing better accuracies than the bag-of-concept model, especially for small k . This means that its ranking of the potential error codes more closely resembles the actual probabilities of error codes based on the content of the problem reports.

Figure 11: Results of experiment 1, with k on the x-axis and accuracy@ k on the y-axis.

This tells us that the concepts which are currently being recognized using the automotive parts and error taxonomy do not represent ultimately accurate features for classification and are not the best option for recommending error codes to the quality worker. This is not altogether surprising, since the taxonomy was originally developed for a different task (information extraction, cf. [17]) and has not yet been adapted to the current data source. Adapting the taxonomy thus suggests itself as a next step.

However, the bag-of-words variant is not a feasible industrial solution because of time and memory needs due to the larger number of features per data bundle and the larger number of pairwise similarity computations to be made. On our small data set which includes only 3 out of hundreds of components, running the bag-of-words classifier takes about 11 minutes for one iteration of the five-fold cross-validation, classifying ca. 1250 data bundles, which means computation time per data bundle is at ca. 0.5 seconds. In contrast, running the bag-of-concepts classifier takes about three minutes for one iteration, which means computation time per data bundle is at ca. 0.14 seconds. When applying our processing pipeline to the entire data set with a larger number of data bundle to data bundle comparisons, it is important to keep the number of pairwise feature comparisons low. Removing German and English stopwords (articles and personal pronouns) as an additional step during the bag-of-words approach has no impact on the accuracy of classification, but shortens the runtime to ca. 7 minutes for one iteration and ca. 0.3 seconds per data bundle. This is still slower than the bag-of-concepts approach.

Figure 12: Classification results for features derived from the mechanic reports only, with k on the x-axis and accuracy@ k on the y-axis.

In contrast to the bag-of-concepts approach, the bag-of-words approach is also not suited for further domain-specific analysis steps. Improving the coverage of the taxonomy used for the bag-of-concepts approach is therefore a worthwhile avenue to pursue. An overview of the issue of taxonomy extension and an argument for re-using semantic resources across tasks is given in [12]. Investigations into methods to automate the extension of a domain-specific semantic resource are on-going.

There are thus two conclusions to be drawn from experiment 1: (1) the text reports can indeed be used to support quality workers by automatic recommendation of error codes, (2) to create a feasible industrial solution, an improved domain-specific resource is needed.

5.3 Experiment 2 – Point of Entry for Error Code Prediction

In the second experiment, we test how early it is possible to make a prediction about the error code of a report bundle. Recall that data about the nature of the problem from different sources – mechanic, OEM and supplier – accumulate over time during the quality evaluation process (cf. Fig. 2). The earliest report which reaches the OEM is the mechanic report, whereas the supplier report is added later. It would be beneficial if the error code could already be predicted on the basis of the mechanic report only.

Retaining the knowledge base models learned on all reports, we have therefore attempted classification with all variants of our adapted classification algorithm on test data bundles which included only one type of report, namely, the mechanic report or the supplier report.

Figure 13: Classification results for features derived from the supplier reports only, with k on the x-axis and accuracy@ k on the y-axis.

5.3.1 Results

The results of experiment 2 can be seen in Figures 12 and 13. We find that the classifier performs very badly on test data which only include the mechanic report (cf. Fig. 12): All four variants of the algorithm have lower accuracies across the board than those provided by the code frequency baseline, with accuracy@1 between 16 and 29 % vs. the baseline's 35 %. Still, the bag-of-word models perform slightly better than the bag-of-concept models.

On test data which only include the supplier report, we observe accuracies which are nearly as good as those for the test data including mechanic report and supplier report (and in some cases an early OEM report): 78 % accuracy@1 for the bag-of-words model with Jaccard similarity, accuracies of > 90 % starting at $k = 5$ for the bag-of-words model and at $k = 10$ for the bag-of-concepts model, and a very close resemblance of accuracies between the bag-of-concepts with overlap similarity and the code frequency baseline (cf. Fig. 13).

5.3.2 Discussion

It is evident that the mechanic reports alone do not contain good features for predicting error codes with the adapted classifier, either as bag-of-words or as bag-of-concepts representations. In contrast, the supplier reports are a more reliable source of features. This is in accordance with observations about the information content and the data quality of the respective data sources: Mechanic reports tend to be poor in detail, focused on superficial problem description and often error-riddled, such that even human experts cannot draw conclusions about the detailed nature of the problem, whereas supplier reports tend to contain more

Figure 14: Data Comparison Screen in the QUEST web app, showing a side-by-side comparison of the top 3 error codes in two different databases.

detail and include descriptions of potential causes.

While we have to conclude that (1) an earlier entry point into automatic error code suggestion is not feasible, we also find that (2) even a comparatively simple text-based classification approach accurately reflects the amount of information which human experts can draw from the text sources.

5.4 Extending the Use Case – Error Distribution in Different Data Sources

As mentioned earlier, it is easy to exploit additional data sources using the knowledge bases created with the internal OEM error report data. This allows for an interesting extension of our use case. If we assign error codes from the schema we use to classify our own quality data to texts from a different data source, for instance one which covers complaints from a different market and includes reports about other manufacturers' vehicles, we can gain insights about where we stand in terms of product quality in contrast to the competitors. This is crucial business intelligence for staying competitive, e.g. by identifying brand-specific weaknesses or issues with shared suppliers.

Obviously, there will be substantial inaccuracies in the fully automatic classification of the public data source. In particular, the bag-of-words approach suffers in accuracy as soon as test and training data are different text types or in different languages, whereas the bag-of-concepts approach is in principle independent of the document language or other text features. However, an approximate impression of the distribution of similar errors can still be gained from the data. The usability and desirability of this functionality have been confirmed in conversation with the OEM.

In the QATK/QUEST implementation, we provide a mockup of this use case extension: We use our knowledge base to classify problem reports from the US-American complaints database maintained by the Office of Defects (ODI/NHTSA) [13]. In the web app, we have implemented the function for viewing side-by-side pie charts showing the distribution of the n most frequent error codes in both data sources (cf. Fig 14).

6. CONCLUSIONS AND FUTURE DIRECTIONS

In this paper, we have presented a specific multi-class classification problem from a real-life industry context, namely,

the filtering and recommendation of error codes for bundles of textual reports concerning damaged car parts. This problem is challenging because of the nature of the data, which are mostly unstructured text using domain-specific vocabulary, and because of the high number of classes.

We have tested alternative variants, domain-specific and domain-ignorant, of a custom classification algorithm derived from k-Nearest-Neighbors (kNN), and evaluated both against a baseline which ignores the text content as well as with respect to their industrial feasibility. We have shown the QATK/QUEST toolkit as a viable approach and presented a prototypical implementation.

In order to identify domain-specific terms in the text, we have used a legacy semantic resource originally designed for a different task. We have tested the validity of these domain-specific features with a custom classification algorithm adapted from k-Nearest-Neighbors. We have shown that the use of domain-specific knowledge leads to good accuracies of recommended classes, with up to 92% of correct classes recovered within the first 10 ranked recommendations. We have compared this domain-specific approach to a domain-ignorant bag-of-words approach and found that the domain-ignorant approach currently performs better, although it is not a viable solution in the industrial context due to performance and scalability properties.

Therefore, we plan the following extensions of our work:

- introducing more linguistic preprocessing – here we will profit from the modularity of the UIMA framework and of the QATK/QUEST toolkit
- enhancing the domain-specific taxonomy
- evaluating the extended use case and discovering more use case extensions
- evaluating the web UI in a field study with quality experts

Work on improving the coverage and maintainability of the domain-specific taxonomy is already in progress.

7. ACKNOWLEDGMENTS

Many thanks to our colleagues in the quality management and quality engineering departments for providing inspiration for the use case and ongoing discussions, as well as to our colleague C. Kiefer for important feedback and to the students of project „Mobile User-Driven Infrastructure for Factory IT Integration“ for crucial implementation work. We also thank the Graduate School advanced Manufacturing Engineering (GSaME) for supporting the broader research context of this paper.

Discovering Correlations in Annotated Databases

Xuebin He Stephen Donohue Mohamed Y. Eltabakh
Worcester Polytechnic Institute, Computer Science Department, MA, USA
{xhe2, donohues, meltabakh}@cs.wpi.edu

ABSTRACT

Most emerging applications, especially in science domains, maintain databases that are rich in metadata and annotation information, e.g., auxiliary exchanged comments, related articles and images, provenance information, corrections and versioning information, and even scientists' thoughts and observations. To manage these *annotated databases*, numerous techniques have been proposed to extend the DBMSs and efficiently integrate the annotations into the data processing cycle, e.g., storage, indexing, extended query languages and semantics, and query optimization. In this paper, we address a new facet of annotation management, which is the discovery and exploitation of the hidden corrections that may exist in annotated databases. Such correlations can be either between the data and the annotations (data-to-annotation), or between the annotations themselves (annotation-to-annotation). We make the case that the discovery of these annotation-related correlations can be exploited in various ways to enhance the quality of the annotated database, e.g., discovering missing attachments, and recommending annotations to newly inserted data. We leverage the state-of-art in association rule mining in innovative ways to discover the annotation-related correlations. We propose several extensions to the state-of-art in association rule mining to address new challenges and cases specific to annotated databases, i.e., incremental addition of annotations, and hierarchy-based annotations. The proposed algorithms are evaluated using real-world applications from the biological domain, and an end-to-end system including an Excel-based GUI is developed for seamless manipulation of the annotations and their correlations.

1. INTRODUCTION

Most modern applications annotate and curate their data with various types of metadata information—usually called *annotations*, e.g., provenance information, versioning timestamps, execution statistics, related comments or articles, corrections and conflict-related information, and auxiliary exchanged knowledge from different users. Interestingly, the number and size of these annotations is growing very fast, e.g., the number of annotations is around 30x, 120x, and 250x larger than the number of data records in Data-

Bank biological database [3], Hydrologic Earth database [4, 47], and AKN ornithological database [5], respectively. Existing techniques in annotation management, e.g., [9, 15, 17, 21, 24], have made it feasible to systematically capture such metadata annotations and efficiently integrate them into the data processing cycle. This includes propagating the related annotations along with queries' answers [9, 15, 17, 24, 46], querying the data based on their attached annotations [21, 24], and supporting semantic annotations such as provenance tracking [11, 14, 20, 43], and belief annotations [23]. Such integration is very beneficial to higher-level applications as it complements the base data with the auxiliary and semantic-rich source of annotations.

In this paper, we address a new facet of annotation management that did not receive much attention before and has not been addressed by existing techniques. This facet concerns the discovery and exploitation of the hidden correlations that may exist in annotated databases. Given the growing scale of annotated databases—both the base data and the annotation sets—important correlations may exist either between the data values and the annotations, i.e., *data-to-annotations correlations*, or among the annotations themselves, i.e., *annotations-to-annotations correlations*. By systematically discovering such correlations, applications can leverage them in various ways as motivated by the following scenarios.

Motivation Scenario 1—Discovery of Missing Attachments: Assume the example biological database illustrated in Figure 1. Typically, many biologists may annotate subsets of the data over time—each scientist focuses only on few genes of interest at a time. For example, some of the data records in Figure 1 are annotated with a “Black Flag” annotation. This annotation may represent a scientific article or a comment that is attached to these tuples. By analyzing the data, we observe that most genes having value F1 in the Family column have an attached “Black Flag” annotation. Such correlation suggests that gene JW0012 is probably missing this annotation, e.g., none of the biologists was working on that gene and thus the article did not get attached to it. However, by discovering the aforementioned correlation, the system can proactively learn and recommend this missing attachment to domain experts for verification. Correlations may also exist among the annotations themselves, e.g., between the “Black Flag” and the “Red Flag” annotations. Without discovering such correlations the database may become “under annotated” due to these missing attachments.

Motivation Scenario 2—Annotation Maintenance under Evolving Data: Data is always evolving and new records are always added to the database. Hence, a key question is: “For the newly added data records, do any of the existing annotations apply to them?”. Learning the correlations between the data and the annotations can certainly help in answering such question. For ex-

GID	Name	Seq	Family	Exp-Id
JW0013	grpC	TGCT...	F1	101
JW0014	groP	GGTT...	F6	105
JW0015	insL	GGCT...	F1	105
...
JW0018	nhaA	CGTT...	F1	101
JW0019	yaaB	TGTG...	F3	101
JW0012	Yaal	TTCG...	F1	103
...				
JW0027	namE	GTTT...	F4	101

Sequence needs to be shifted by 2 bases

Newly inserted record

Figure 1: Examples of Annotation-Related Correlations.

ample, the cloud-shaped comment in Figure 1 is attached to all data records having value 101 in the Exp-Id column. Based on this correlation, the system can automatically predict—at insertion time—that this annotation also applies to the newly inserted JW0027 tuple. Otherwise, such attachment can be easily missed and important information is lost. Clearly, delegating such task to end-users without providing system-level support—which is the state of existing annotation management engines—is not a practical assumption.

Motivation Scenario 3—Annotation-Driven Exploration: The discovered correlations may reveal information about the underlying data that trigger further investigation or exploration by domain experts. For example, as highlighted in Figure 1, the “Red Flag” annotation semantically means invalid or incorrect data. Since these annotations can be added by different biologists and at different times, none of them may observe a pattern in the data. In contrast, by discovering (and reporting) that the “Red Flag” annotation has strong correlation with experiment id 105, the domain experts may re-visit the experimental setup of this wet-lab experiment and may revise and re-validate all data generated from it.

These scenarios demonstrate the potential gain from capturing the annotation-related correlations. Unfortunately, relying on domain experts or DB admins to manually define or capture these correlation patterns is evidently an infeasible approach. This is because the correlations may not be known in advance, hard to capture or express, dynamically changing over time, or even not 100% conformed. Moreover, the manual exploration process is error-prone, will not scale to the size of modern annotated databases, and it is a very time- and resource-consuming process. For example, the UniProt biological database has over 150 people working as full-time to maintain and annotate the database [6, 12]. Certainly, such scale of investments may not be viable to many other domains and scientific groups, e.g., it is reported in a recent science survey [49] that 80.3% of the participant research groups do not have sufficient fund for proper data curation. For these reasons, we argue in this paper that the analysis and discovery of the annotation-related associations and correlations should be an integral functionality of the annotation management engine. As a result, the correlations can be timely discovered and maintained up-to-date, and also systematic actions can be taken based on them as highlighted by the motivation scenarios.

In this paper, we investigate applying the well-known techniques of association rule mining, e.g., [8, 31, 52], to the domain of annotated databases. This is a new and promising domain for association

rule mining due to the following reasons:

- Many emerging applications—especially scientific applications—maintain and rely on large-scale annotated databases [3, 5, 6]. It is reported in [1] that the *ebird* ornithological database receives more than 1.6 million annotations per month from scientists and bird watchers worldwide. These applications will benefit from the proposed techniques.
- Many annotated databases go under the very expensive and time-consuming process of manual curation, e.g., [2, 6]. The goal from this process is to ensure that correct annotations and curation information are attached to the data, and to enrich the annotations whenever possible. Nevertheless as illustrated in the motivation scenarios, the discovery of the annotation-related correlations can help in enhancing the quality of the annotated database in an automated way. And hence, reducing the effort needed in the manual curation process and freeing the domain scientists for their main task, which is scientific experimentation.

- Interestingly, annotated databases stretch the traditional techniques of association rule mining, and present new challenges as discussed in Section 3. For example, the state-of-art techniques in association rule mining fall short in efficiently handling several new cases specific to annotated databases, i.e., they cannot perform incremental maintenance of the discovered rules and they have to re-process the entire database. These cases include:

(1) *Generalization of Annotations:* Annotations can be free-text comments, which may differ in their values but have the same semantics. And hence, discovering the correlations based on the values of the raw annotations may miss important patterns. For example, referring to Figure 1, the correlation pattern involving the *Black Flag* annotation, i.e., “Family:F1 \Rightarrow Black Flag” can be detected based on the raw annotation value. This is because all instances of the *Black Flag* annotation refer to the same scientific article. In contrast, for the *Red Flag* annotation, the actual annotations inserted by scientists have different values, and thus no correlation pattern can be detected based on the raw values. However, by *generalizing* the annotations to a common concept—the *Red Flag* annotation in our case—we can detect the correlation pattern between them and the experiment Id 105. Therefore, building a generalization hierarchy on top of the annotations is an important step.

(2) *Integration with the Annotation Manager:* We propose to build a coherent integration between the association rule mining module and the Annotation Manager component in contrast to the *offline* mining techniques. As a result, the Annotation Manager can take informed actions based on the discovered rules, e.g., discover potential missing attachments and report them for verification (Motivation Scenario 1), and annotate newly inserted data tuples with existing annotations (Motivation Scenario 2). Moreover, since the Annotation Manager cannot guarantee with 100% confidence that the predicted attachments are correct, we propose developing a verification module that enables domain experts to verify the predicted attachments.

(3) *Incremental Maintenance under Annotation Addition:* In annotated databases, the discovered correlations and association rules need to be incrementally updated under two scenarios, i.e., the addition of new data tuples, and the addition of new annotations. The former case can be handled by existing techniques that address the incremental update of association rules, e.g., [16]. These techniques assume that the new delta batch changes the size of the database, i.e., the number of data tuples increases. In contrast, in

the latter case, the new annotation batches will not change the number of data tuples, instead they change the content of the tuples—assuming the annotations are part of the tuples. Therefore, the existing incremental techniques need to be extended to handle the latter case.

In this work, we develop an end-to-end solution that addresses the above challenges in the context of a real-world application and annotation repository, which is a data warehouse for the *Caenorhabditis elegans* (*C. elegans*) Worm from biological sciences. To facilitate scientists’ usage of the developed system, we designed an Excel-based GUI—A tool that most scientists are familiar with—through which all of the proposed functionalities can be performed.

The rest of the paper is organized as follows. In Section 2, we present the needed background, preliminaries, and our case study. In Sections 3, and 4, we present the techniques for the discovery and maintenance of the annotation-related correlations, and their exploitation, respectively. Section 5 overviews the related work while Section 6 contains the experimental evaluation. Finally, the conclusion remarks are included in Section 7.

2. PRELIMINARIES

In this section, we give a brief overview on annotation management and association rule mining techniques, and then present our case study.

2.1 Background

Annotation Management in Relational DBs: Annotation management techniques in relational databases enable end-users to attach auxiliary information to the data stored in the relational tables [9, 15, 17, 21, 24, 46]. Annotations can be attached to individual table cells, rows, columns, or arbitrary sets and combinations of them. Some systems provide a GUI through which the annotations can be added [17, 25], while other systems extend the SQL language with new commands and clauses to enable annotation addition [17, 21, 25]. For example, the work in [21] introduces a new `Add Annotation` command to SQL as follows:

```
Add Annotation
[Value <text-value> | Link <path-to-file>]
On <sql-statement>;
```

This command will first trigger the execution of the specified `<sql-statement>` to identify the data tuples and the attributes to which the annotation will be attached. The annotation can be provided as a text value (using the `Value` clause), or as a link to a file (using the `Link` clause). In all of these systems, the organization of annotations, i.e., storage scheme and indexing, is fully transparent to end-users.

At query time, when a standard SQL query is submitted, the underlying database engine will not only compute the data tuples involved in the answer set, but will also compute the related annotations that should be reported along with the answer set. This is not straightforward since the data may go through complex transformations, e.g., projection, join, grouping and aggregations. Therefore, the semantics of the query operators have been extended to manipulate the data as well as their attached annotations in a systematic way. For example, one possible semantic is to union the annotations when performing grouping, joining, or duplicate elimination over a group of tuples. According to this semantic, the SQL query in Figure 2 produces the illustrated output—assuming duplicate annotations on the same tuple are eliminated.

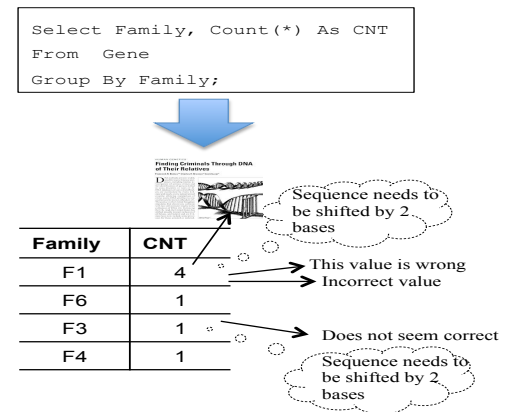

Figure 2: Automatic Propagation of Annotations at Query Time.

Since in large-scale annotated databases, the number of reported annotations on a single output tuple can be large, the work in [32, 50] proposed summarizing the annotations using data mining techniques, e.g., clustering, classification, and text summarization, and reporting the summarize instead of the raw annotations. The proposed work of discovering the correlations in annotated databases is complementary to the existing techniques and can be integrated with any of the existing systems.

Association Rule Mining: Association rule mining is a well-known problem in data mining that concerns the discovery of correlation patterns within large datasets [8, 44, 45, 52]. An association rule in the form of “ $X \implies Y$, support = α , confidence = β ” means that the presence of the L.H.S itemset X implies the presence of the R.H.S itemset Y (in the same transaction or tuple) with support equals to α and confidence equals to β . Typically, $X \cap Y = \emptyset$, and the support is computed as the fraction of transactions (or tuples) containing $X \cup Y$ relative to the database size, while the confidence is computed as $\text{support}(X \cup Y) / \text{support}(X)$. Therefore, given a minimum support min_supp and minimum confidence min_conf , the association rule mining technique discovers all rules having support and confidence above the specified min_supp and min_conf , respectively.

It has been observed in many real-world applications, that the number of generated rules can be very large and many of them may not be interesting. Therefore, additional measures have been proposed in [31, 44], which include the *lift* and *conviction* measures. The former is computed as $\frac{\text{support}(X \cup Y)}{\text{support}(X) * \text{support}(Y)}$, and the latter is computed as $\frac{1 - \text{support}(Y)}{1 - \text{confidence}(X \implies Y)}$. The higher these measures, the more interesting the rule. Another related extension to the standard association rule mining problem is the mining of multi-level rules [44, 45]. In this extension, the technique is given a domain generalization hierarchy over one or more attributes, and we need to discover the association rules that may span different levels of the hierarchy. For example, in market analysis, the items “*pants*”, “*shirts*”, and “*t-shirts*” can be generalized to “*clothes*”. Because of this generalization, some rules may hold at the higher level(s) of the hierarchy which may not be true for the lower more-detailed levels. Association rule mining has numerous applications in various domains including market analysis, biology, healthcare, environmental sciences, and beyond [31]. The proposed work extends these applications to the emerging domain of annotated databases.

(a) *Caenorhabditis elegans*. Lives in garden soil and feeds on bacteria, e.g., *E. coli*.

(b) Time course of intestinal distention in *C. elegans* worms exposed to *S. cerevisiae*. Worms were exposed to RFP-marked, wildtype yeast from hatching and photographed on day 3 (A and D), day 4 (B and E), and day 5 (C and F). The experiment was done three times, and 60 to 75 worms were observed over a 3-day period. (A to C) Anterior region of the worm; (D to F) posterior region of the worm. Accumulation of yeast began in the pharynx region (compare panels A and D) and proceeded to the posterior. (G to I) *S. cerevisiae* also induces vulval swelling in the worms. Worms exposed to *S. cerevisiae* (H to I) show abnormal vulval swelling (white circles) compared to the control sample grown on *E. coli* (G). Bars: A to G, 50 μ m; H and I, 20 μ m.

Figure 3: Case Study: Building Data-Annotation Repository for *Caenorhabditis elegans* (*C. elegans*) Worm.

2.2 Case Study: Annotated Repository for *C. elegans* Worm

Although the proposed work is applicable to annotated databases in general, we consider one case study as an example. This case study focuses on building a database repository for the *Caenorhabditis elegans* (*C. elegans*) worm, which integrates data from multiple databases and labs studying the genetics and fungal pathogenesis of the organism (Refer to Figure 3). Some of these sources maintain relational databases, while other use excel sheets to store their data. Each of the sources maintains various types of curation information and annotations related to the data records, e.g., images, publications, observations, corrections, and experimental setups. In these data sources the curation information is not modeled as *annotations*. Instead, they are modeled as regular data with relationships to the data tuples, e.g., in the relational databases, the images and observations are stored in separate tables linked to the primary data tables through PK-FK constraints.

The disadvantage of this modeling scheme, i.e., modeling the annotations as data, is that applications lose the benefits of annotation management. That is, annotation management tasks are entirely delegated to end-users and higher-level applications starting from the storage and indexing of annotations and ending by explicitly encoding the propagation semantics within each of the users' queries. Both tasks have been shown to be very complex and sophisticated. For example, the storage and indexing mechanisms need to deal with the combinatorial relationship between annotations and data, e.g., annotations can be attached to single table cells (attributes), rows, columns, arbitrary sets and combinations of them, or even attached to sub-attributes [21, 24]. Moreover, manually encoding the annotations' propagation within each query is not only error-prone, and lacks optimizations, but also renders even simple queries very complex [9, 13, 26, 46]. That is why annotation management engines have been proposed to efficiently and transparently manage such complexities across applications.

To address the above limitations, we opt for leveraging our previous systems and work in annotation management [21, 50] to model the metadata information as annotations. These systems are built on top of PostgreSQL DBMS, and thus the repository will acquire the benefits of both a DBMS and an annotation management engine. We developed an Excel-based user interface to enable seamless visualization of the data as well as the annotations (See Figure 4). For the purpose of this project, the annotations are categorized into three basic types, which are: (1) Regular comments or observations, which covers any free-text values, (2) Articles and

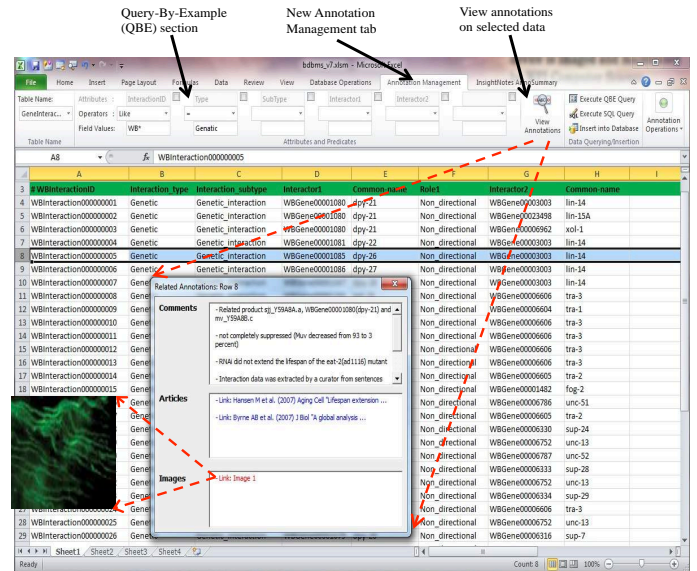

Figure 4: Excel-Based GUI for Annotation Management.

documents, and (3) Images. In the Excel-based GUI, scientists can query their data either by writing direct SQL queries, or through a QBE interface as illustrated in Figure 4. Then, they can select specific rows or table cells of interest, and click the *View Annotation* button, which reports the annotations related to the selected datasets in a new window. This window has three sections for the three annotation types mentioned above as shown in the figure. For the articles and images, they are uploaded to a web-server and can be opened by clicking the corresponding link.

3. DISCOVERY OF CORRELATIONS

Given an annotated database, the primary challenge is to discover and incrementally maintain the hidden annotation-related correlations within the database, which is the focus of this section. The basic unit in an annotated database is an "*annotated relation*". In the following, we formally define an annotated relation and the target correlations.

Definition 3.1 (Annotated Relation). An annotated relation \mathcal{R} is defined as $\mathcal{R} = \{r = \langle x_1, x_2, \dots, x_n, a_1, a_2, a_3, \dots \rangle\}$, where

each data tuple $r \in \mathcal{R}$ consists of n data values x_1, x_2, \dots, x_n , and a variable number of attached annotations a_1, a_2, \dots, a_k .

Definition 3.2 (Data-to-Annotation Correlations). *Given an annotated relation \mathcal{R} , a minimum support α , and a minimum confidence β , the data-to-annotation correlations over \mathcal{R} is the problem of discovering all association rules in the form of: $x_1:v_1, x_2:v_2, \dots, x_k:v_k \Rightarrow a$, where the L.H.S is a set of column names (x_i) and corresponding data value (v_i), the R.H.S is a single annotation, the rule's support $\geq \alpha$, and the rule's confidence $\geq \beta$.*

Definition 3.3 (Annotation-to-Annotation Correlations). *Given an annotated relation \mathcal{R} , a minimum support α , and a minimum confidence β , the annotation-to-annotation correlations over \mathcal{R} is the problem of discovering all association rules in the form of: $a_1 a_2 \dots a_k \Rightarrow a$, where the L.H.S is a set of annotations, the R.H.S is a single annotation, the rule's support $\geq \alpha$, and the rule's confidence $\geq \beta$.*

According to Definitions 3.2 and 3.3, the rules to be discovered must involve an annotation in the R.H.S of the rule. In addition, these rules focus on the raw annotations without generalization. This is applicable especially for annotations of type *image* or *publication*, where a single image or publication can be attached to many data tuples. Discovering these rules is straightforward using any of the state-of-art techniques, e.g., the A-priori [8], or FP-Tree [30] algorithms. The only modification that we introduced to these algorithms is the early elimination of candidate patterns that do not include at least one annotation value.

3.1 Incremental Maintenance of Correlations

An annotated database may evolve and change in three different ways, which are: (1) Adding new un-annotated data tuples (refer to it as $\Delta_{unannotated}$), (2) Adding new annotated data tuples (refer to it as $\Delta_{annotated}$), and (3) Adding new annotations to existing data tuples (refer to it as δ). Each of these changes may affect the discovered association rules as summarized in Figure 5. The maintenance of association rules under incremental data updates has been studied in existing work [16, 41]. However, these existing techniques can handle only the first two cases mentioned above, i.e., the $\Delta_{unannotated}$ and $\Delta_{annotated}$ cases, but not the third case, i.e., the δ case. The reason is that the assumption in these techniques is that the number of data tuples change (get increased), which is true for the first two cases. In contrast, in the third case, the number of the data tuples is fixed, but their content changes due to the addition of new annotations.

Figure 5 summarizes the three cases mentioned above and their effect on the association rules. The $\Delta_{unannotated}$ case does not add any new rules since no new annotations are added. For the existing rules, both the support and confidence of the data-to-annotation rules may get decreased and need to be re-computed (Column 2 in Figure 5). Nevertheless, for the annotation-to-annotation rules, only the support may decrease and need to be re-computed, but the confidence remains unchanged (Column 3 in Figure 5). The $\Delta_{annotated}$ case may introduce new association rules since the new data tuples are annotated. Moreover, all of the existing rules may get affected positively or negatively. For these two cases, the existing techniques in [29, 44] can be directly applied to efficiently and incrementally update the association rules.

The third case—which is not handled by existing techniques—concerns the addition of new annotations to existing data tuples. For this case, all existing data-to-annotation rules are guaranteed to remain valid because the support and confidence of these rules

$\Delta_{unannotated}$	New un-annotated data tuples	$=$ Remain Fixed $\downarrow \uparrow$ May increase or decrease \downarrow May only decrease \uparrow May only increase
$\Delta_{annotated}$	New annotated data tuples	
δ	New annotations on existing data tuples	

Effect Change	New Rules	Existing Rules	
		$x_1, x_2, \dots, x_k \Rightarrow a$	$a_1, a_2, \dots, a_k \Rightarrow a$
$\Delta_{unannotated}$	✗	$S \downarrow$ & $C \downarrow$	$S \downarrow$ & $C =$
$\Delta_{annotated}$	✓	$S \downarrow \uparrow$ & $C \downarrow \uparrow$	$S \downarrow \uparrow$ & $C \downarrow \uparrow$
δ	✓	$S \uparrow$ & $C \uparrow$	<u>In L.H.S:</u> $S \uparrow$ & $C \downarrow \uparrow$ <u>In R.H.S:</u> $S \uparrow$ & $C \uparrow$

Figure 5: Effect of Evolving Data on Support (S) and Confidence (C).

cannot be decreased. The same intuition applies to the annotation-to-annotation rules if the new annotation appears in the R.H.S of the rule, i.e., the support and confidence may only increase. However, if the new annotation appears in the L.H.S of a rule, then the confidence of this rule needs to be re-computed because it may decrease and becomes below the *min_conf* threshold. Finally, this third case may introduce new association rules that need to be discovered as indicated in Figure 5. In the following, we present a pseudocode on how these changes take place incrementally.

The algorithm depicted in Figure 6 presents the main steps of updating the existing rules. In Step 1, the data-to-annotation rules are updated. Basically, the denominator in the support and confidence of these rules does not change, and thus only the numerator values need to be re-computed. This update can be performed by checking only the newly annotated data tuples and counting the number of new occurrences of the rule's pattern ($L.H.S \cup R.H.S$). This count will be added to the old numerator to compute the new values. Since all of these rules are guaranteed to be in the output set U' , they are directly copied to U' after updating their support and confidence values.

In Step 2, the annotation-to-annotation rules are updated. The first **For...End For** loop handles the case where the new annotations do not appear in the L.H.S of an existing rule, but appear on the R.H.S. This case is very similar to Step 1, where all the rules will get their support and confidence updated (only the numerator values), and then copied to the output set U' . The second **For...End For** loop handles the case where the new annotations appear on the L.H.S of the rules. In this case both the numerator and the denominator values of the confidence may change and hence, it may increase or decrease. Fortunately, updating these values can be also performed by only checking only the newly annotated data tuples and counting the number of new occurrences that will be added to either of the numerator or denominator values. Depending on the new confidence, if the rule is still valid, then it will be copied to the output set U' . It is worth highlighting that in updating the existing association rules (Steps 1 & 2 in Figure 6), we only need to process the newly annotated data tuples without touching the rest of the database.

The addition of the new annotations (the δ batch) may also create new association rules. The algorithm depicted in Figure 7 outlines the procedure of incrementally discovering the new rules. In Step 1, the new data-to-annotation rules in the form of $x_1 x_2 \dots x_k \Rightarrow a$ will be discovered, where $a \in \delta$. First, a must be a frequent an-

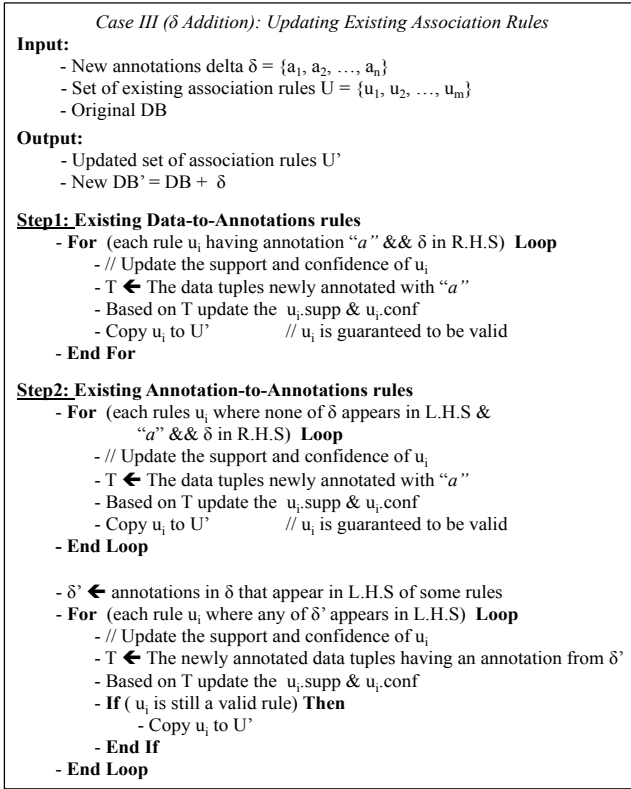

Figure 6: Case III (δ Addition): Updating Existing Rules.

notation by itself. To perform this check efficiently, the system maintains a table containing the frequency of each annotation, and it is updated whenever a new annotation is added. If a is frequent, then from the newly annotated tuples, denoted as T , we extract the data-value patterns that are already frequent, say $x_1 x_2 \dots x_k$. Notice that since $x_1 x_2 \dots x_k$ is already frequent, then the denominator for the support and confidence of rule $x_1 x_2 \dots x_k \Rightarrow a$ is already known. What is left is to compute the frequency of pattern $x_1 x_2 \dots x_k, a$, which can be performed by checking only the data tuples in the database annotated with a . As illustrated in Figure 7, a similar procedure will be taken in Step 2, i.e., discovering the new annotation-to-annotation rules where the new annotations $a \in \delta$ contribute only to the R.H.S of the rule.

Discovering the new annotation-to-annotation rules where the new annotations $a \in \delta$ contribute to the L.H.S is slightly different (Step 3). This is because the denominator of the new rules is no longer known and it has to be computed. The procedure works by considering each new annotation $a \in \delta$, and verifying first that it is frequent (if not, then the process stops). And then, for each data tuple t that is receiving a as a new annotation, we extract the already-frequent annotation patterns, say $p = a'_1, a'_2, \dots, a'_k$, i.e., p is already frequent and attached to t . By augmenting a to p , we generate several candidate new rules in the form of $a'_1, a, \dots, a'_k \Rightarrow a'_i$. Notice that a can be a new annotation over tuple t , but it is an already-existing annotation over many other tuples in the database. Therefore, to compute the support and confidence of these rules, we need to check all data tuples in the database having annotation a . This is enough to compute the support and the confidence of the rule and to verify whether or not it is a valid rule.

It is clear that the algorithm of maintaining the existing rules (Figure 6) is less expensive than that of discovering new rules (Fig-

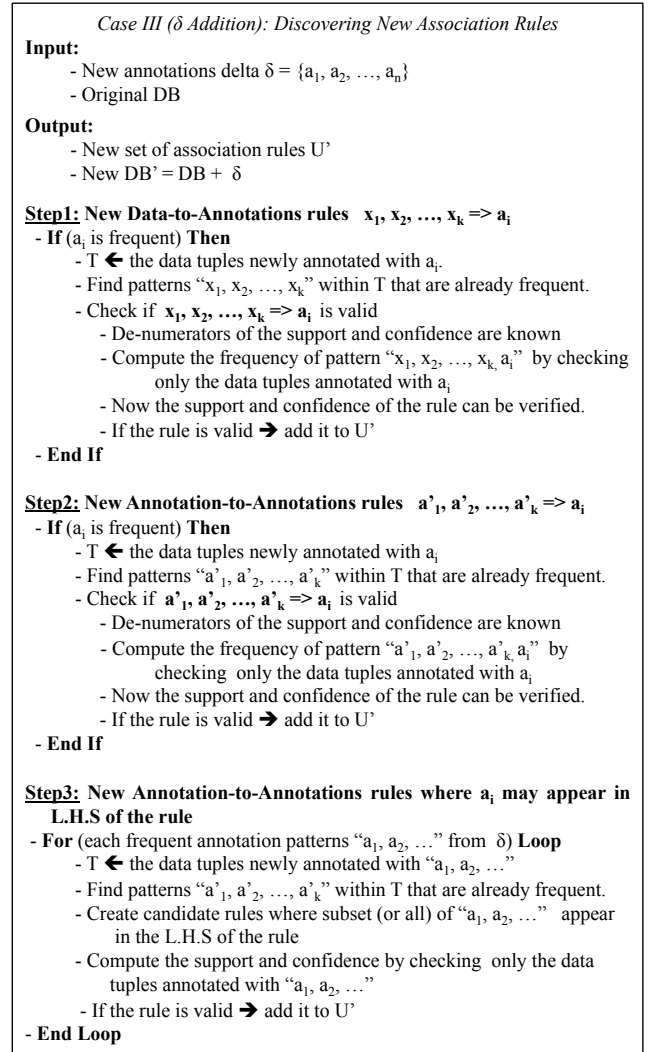

Figure 7: Case III (δ Addition): Discovering New Rules.

ure 7). This is because the former requires access to only the newly annotated data tuples, whereas the latter requires access to all data tuples that have annotation $a \in \delta$ (even if the tuples are not newly annotated with a). To efficiently support the latter case, the system indexes the annotations such that given a query annotation, we can efficiently find all data tuples having this annotation. In all cases, there is no need for full database processing or re-discovering the rules from scratch.

3.2 Generalization-Based Correlations

Generalizing the raw annotation values to higher concepts may lead to discovering important association rules that cannot be discovered from the raw values. The *Red-Flag* annotation in Figure 1 is a good example of this case. The reason this case is important in annotated databases is that the annotations can be added by many curators, and they may not follow specific ontology. And thus, multiple annotations may carry the same semantics but differ in their raw values. There are extensions to association rule mining techniques that can discover the rules under the presence of a generalization hierarchy [29, 44, 45]. However, these techniques assume that the hierarchy, and the assignments between the raw values to

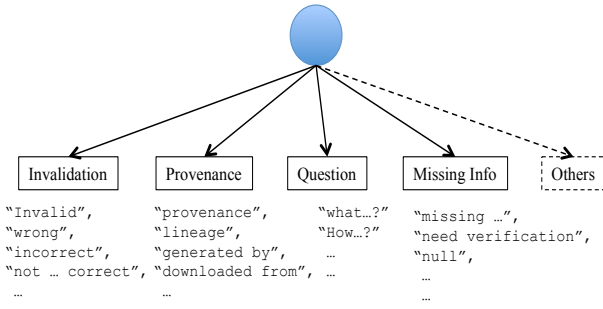

Figure 8: Example of Annotation-Generalization Hierarchy.

the hierarchy elements are given as input, which is usually not the case in annotated databases.

In this work, we assume the more practical case where the domain experts know the generalization hierarchy, i.e., the generic types of annotations of interest, but the raw annotations are not yet labeled. An example of this hierarchy is illustrated in Figure 8, where several types can be of interest, e.g., “*Invalidation*” (comments that highlight errors or invalid values), “*Provenance*” (comments capturing the source of data or how it is generated), “*Question*” (comments including questions), and “*Missing Info*” (comments highlighting missing values or more investigation). The hierarchy will always include a separate class, called “*Others*” to which any un-generalized annotation will belong.

In general, any text classification technique can be used. As a proof of concept, we use the technique proposed in [18]. Since we assume no training set or classifier model is given, the model is first created as follows:

- 1- Select α real annotations at random and manually label them to build the 1st classifier model.
- 2- Select $\beta\%$ of the real annotations at random and classify them using the trained classifier.
- 3- Manually verify the results, and re-label the wrong classification to refine the model.
- 4- Repeat Steps 2 & 3 until achieving an acceptable accuracy.

In Step 1, in addition to manually labeling an initial set of α annotations, we also create synthetic annotations to each class capturing the keywords in that class. For example, as highlighted in Figure 8, keywords like “*wrong*”, “*incorrect*”, “*invalid*” are embedded in synthetic annotations under the 1st class label, while keywords like “*source*”, “*generated from*” are added under the 2nd class label. The creation process iterates between labeling and verifying a small subset of annotations ($\beta\%$) until the classifier reaches an acceptable accuracy (Step 4).

After building the classifier model, it is applied over all annotations in the dataset, and data tuples get annotated with the class labels corresponding to their raw annotations—Except for “*Others*” label for which its annotations are not generalized. A data tuple can have a given label at most once even if there are multiple raw annotations mapping to the same label. This is the same model used in association rule mining techniques that handle a generalization hierarchy [29, 44, 45]. For example, the top data tuple in Figure 9 has two attached annotations classified into the “*Invalidation*” label, i.e., the *Red Flag*, and thus after attaching the classification decision, it generates the tuple at the bottom of the figure.

After building the extended annotated database, existing tech-

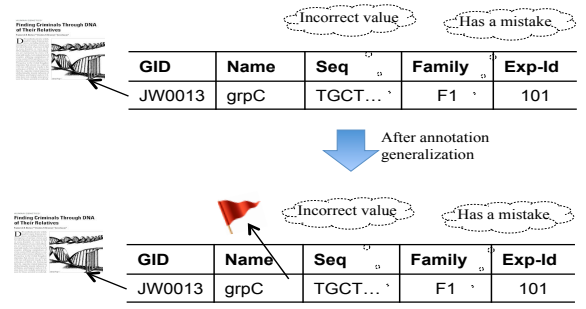

Figure 9: Applying Annotation-Generalization over Example Tuple.

niques can mine and extract the data-to-annotation association rules in the form of: $x_1 x_2 \dots x_k \implies \mathbb{b}$, where \mathbb{b} is either a raw annotation or an annotation’s class label. The same applies for annotation-to-annotation rules, which are in the form of: $\mathbb{b}_1 \mathbb{b}_2 \dots \mathbb{b}_k \implies \mathbb{b}$, where none of the L.H.S or R.H.S values (either raw or class label values) have an ancestor-descendant relationship in the generalization hierarchy.

4. EXPLOITATION OF CORRELATIONS

As discussed in Section 1, one of our goals is to exploit the discovered correlations to enhance the quality of the annotated database. We consider two exploitation scenarios: (1) The prediction of related annotations to newly inserted tuples (Motivation Scenario 2), and (2) The discovery of missing attachments when new association rules are found (Motivation Scenario 1).

Insertion of New Data Tuples: For this case, an automatic database trigger (at *After Insert at Row Level*) is created for each database table. The trigger forwards a newly inserted tuple t to the Annotation Manager, which checks t against the available association rules. If the L.H.S pattern of a rule is present in t without the R.H.S annotation, then the system creates a recommendation that the R.H.S annotation is potentially applicable to t . For example, referring to the motivation example in Figure 1, the following rule can be derived from the data:

Exp-Id:101 \implies “Sequence need to be shifted by 2 bases.”

The newly added tuple JW0027 contains the L.H.S of the rule, and hence the system predicts and creates a recommendation that the R.H.S annotation may be related to the new tuple. The end-user will be notified that the system has created annotation predictions for the new tuple, and the prediction(s) will be stored in a system table along with its supporting rule (the rule generated the recommendation) for later verification and approval as explained in sequel.

To enable efficient searching for the association rules matching the newly inserted tuple, the L.H.S of the rules are indexed. Since the L.H.S may contain several pairs in the form of `columnName:value`, we first itemize and store the L.H.S in a normalized form, i.e., one record for each pair, and then index them using a B-Tree index. In this case, given a new data tuple, the *After Insert* database trigger will create lookup keys from the new tuple, i.e., each column name and its value will form one lookup key, and then search the normalized table to find a “superset” of the candidate rules. The tuple will be checked against this candidate set to find the actual matches.

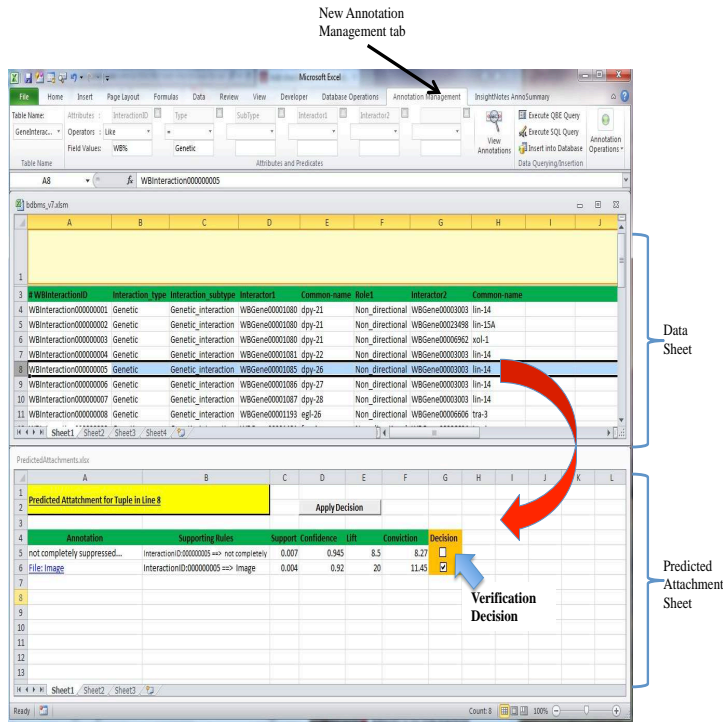

Figure 10: Exploitation of Correlations and Annotation-Related Recommendations.

Updating the Association Rules: As presented in Section 3.1, the annotation-related association rules may change periodically when new batches of data or annotations are applied. The change may take three forms: (1) Valid rules remain valid, (2) Valid rules become invalid, and (3) New rules are discovered. In the 1st case, nothing will change in the system. In the 2nd case, the pending recommendations awaiting verification whose supporting rules become invalid will be eliminated. This is because the system will not recommend attachments without rules supporting available as evidences.¹ In the 3rd case, the discovery of new rules will trigger the system to search for data tuples matching the L.H.S of the new association rules, but missing the R.H.S annotation in the rule. If a matching is found, then a new pending recommendation will be added to the system table. Given a newly discovered rule having a L.H.S in the form of: " $C_1 : v_1, C_2 : v_2, \dots, C_m : v_m$ ", where C_i is a column name and v_i is the column's value, the searching for the matching data tuples is performed as follows. A query on the same table to which the new rule is related is formed, and it consists of a set of conjunctive predicates in the form of $C_i = v_i \forall 1 \leq i \leq m$. The returned tuples will be then checked if they are missing the R.H.S of the rule, i.e., the annotation value, and if so, then a new recommendation is generated.

It is worth highlighting that the number of discovered rules by considering solely the *support* and *confidence* thresholds is in most cases very high [31, 44]. This will result in many uninteresting predictions and recommendation. To overcome this problem, we integrate additional properties such as *lift* and *conviction* measures that measure how interesting the rule is (See Section 2). That is,

¹Recommended attachments that have been approved by the end-users will remain in the system even if their supporting rules become invalid at a later point in time. This is because an approved attachment is viewed as a correct and permanent one.

among all the rules that satisfy the support and confidence requirements, we use in the exploitation process only a subset of these rules that also satisfy the lift and conviction requirements.

Manipulation Interface: To seamlessly enable the verification process, we extend the Excel-based GUI presented in Section 2.2 such that domain experts can visualize the recommendations from the tool and decide whether or not each prediction will be accepted (See Figure 10). The tool enables reporting and visualizing the pending predictions either by providing a database table name, or by specifying a select statement to limit the scope of interest. The reported predictions can be then sorted according to various criteria, e.g., the confidence of the association rule suggested the prediction. As Figure 10 illustrates, the data tuples from a given table (or a select statement) are reported on the top-level excel sheet, and then when a tuple is selected, its related predictions and recommendations are dynamically reported on the bottom-level sheet. For each prediction, the supporting association rule is displayed along with its properties, e.g., the support, confidence, lift, and conviction. Curators can then use the checkbox highlighted in the figure to decide on whether or not to accept the recommendation.

5. RELATED WORK

Annotation management is widely applicable to a broad range of applications, yet it gained a significant importance within the context of scientific applications [27, 35, 40]. Therefore, to help scientists in their scientific exterminations and to boost the discovery process, several generic annotation management frameworks have been proposed for annotating and curating scientific data in relational DBMSs [9, 17, 24, 25, 26, 46]. Several of these systems, e.g., [9, 17, 24, 46], focus on extending the relational algebra and query semantics for propagating the annotations along with the queries' answers at query time. The techniques presented in [46] address the annotation propagation for containment queries, while the techniques [13] address the propagation in the presence of logical database views. They address, for example, the minimum amount of data that need to be annotated in the base table(s) in order for the annotation to appear (propagate) to the logical view. The work in [21] proposed compact storage mechanisms for storing multi-granular annotations at the raw-, cell-, column-, and table-levels, as well as defining behaviors for annotations under the different database operations. Moreover, the techniques proposed in [21, 36] enable registering annotations in the database system and automatically applying them to newly inserted data tuples if they satisfy pre-defined predicates.

Other systems have addressed special types of annotations, e.g., [15, 23]. For example, the work in [15] have addressed the ability to annotate the annotations, and hence they proposed a hierarchical approach that treats annotations as data. On the other hand, the BeliefDB system in [23] introduced a special type of annotations, i.e., the *belief annotation*, that captures the different users' beliefs either about the data or others' beliefs. In both systems, the query engine is extended to efficiently propagate/query these annotations. It have been also recognized in [28, 34] that annotations may have semantics and based on these semantics the propagation in the query pipeline may differ, e.g., instead of getting the union of annotations under the join operation, getting the intersection makes more sense under some annotation semantics. In our previous work [50], we addressed the challenge of managing number of annotations that can be orders of magnitude larger than the number of base data tuples. In this case, reporting the raw annotations will be overwhelming and useless. Instead, we proposed summarizing the annotations into concise forms, and then proposed an extended query engine to efficiently propagate these summaries.

Figure 11: Annotation Generalization and Rule Generation.

Although the above systems provide efficient query processing for annotations, none of them have addressed the facet of mining the rich repositories of annotations to discover interesting patterns, e.g., discovering the annotation-related correlations proposed in this paper. Therefore, the proposed work is complementary to existing systems and creates an automated mechanism for enhancing the quality of annotated databases, which is currently handled through a manual curation process [2, 6]. In this process, domain experts manually curate the data, ensure correct and high-quality annotations are attached to the data, and potentially add or remove further attachments between the annotations and the data. Certainly, this curation process is very time consuming, error-prone and does not scale well, and more importantly consumes valuable cycles from domain experts and scientists. With the proposed work, a significant effort in discovering missing attachments and relationships between the data and the annotations can be automated.

Annotations have been supported in contexts other than relational databases, e.g., annotating web documents [10, 33, 37, 51], and pdf files [38, 39, 48]. These techniques focus mostly on annotating different pieces within a document (or across documents) with useful information, e.g., extracting the key objects or providing links to other related objects. In the domains of e-commerce, social networks, and entertainment systems [22, 42], the annotations are usually referred to as *tags*. These systems deploy advanced mining and summarization techniques for extracting the best insight possible from the annotations to enhance users' experience. They use such extracted knowledge to take actions, e.g., providing recommendations and targeted advertisements [7, 19, 42]. However, none of these systems focus on mining and discovering correlations within the annotation repositories.

6. EXPERIMENTS

Setup and Dataset: The experiments are performed using our annotation management engines [21, 50], which are based on the open-source PostgreSQL DBMS. The experiments are conducted using an AMD Opteron Quadputer compute server with two 16-core AMD CPUs, 128GB memory, and 2 TBs SATA hard drive. Our objectives are: (1) To quantify the effectiveness of the annotation generalization technique, (2) The performance of discovering the annotation-based association rules over static data, and (3) The efficiency of the proposed incremental techniques to update the rules under new batches of annotations. The experimental dataset represent the *C. elegans* repository, which we are building on site. The repository consists of 27 database tables, where the main table of our focus is the *Gene* table that contains approximately 17,500 genes integrated from multiple sources. The table has nine

columns, e.g., *Gene Id*, *Locus*, *Strain*, *Stage*, *Location*, and *Length*. The table has a total number of 43,000 publications attached to the genes in addition to other 8,120 free-text comments. These publications and comments represent the annotations attached to the *Gene* table. In the dataset, each record has between 0 annotations (the minimum) and 16 annotations (the maximum).

In Figure 11, we study the effect of annotation generalization on the generation of interesting annotation-related association rules. Figure 11(a) illustrates the accuracy of the generalization algorithm presented in Section 3.2. The x-axis indicates the number of iterations from 1 to 4, while the y-axis represents the obtained accuracy from the manual verification step (Step 3 of the algorithm). As the figure shows, there is a big jump in accuracy from Iteration 1 to Iteration 2, and then as more iterations are performed the accuracy slightly increases. This is mostly because our generalization model is simple and consists of one level only. However, as the generalization model becomes more complex, we expect to more iterations will be needed to reach the desired accuracy. In the subsequent experiments, we will use the results obtained after performing 4 iterations.

In Figure 11(b), we present the number of interesting association rules discovered in the entire dataset under varying confidence and support degrees (the x-axis). Since the expected rules are not necessarily globally frequent, we use very low support, e.g., 0.1% to 0.4%, while setting the confidence to a very high threshold as indicated in the figure. As expected, as the support or confidence thresholds increase, less number of interesting rules are discovered. The number of discovered rules is relatively manageable and not very large because we also enforce minimum lift and conviction thresholds to narrow down the reported rules to the strongest ones only. Both thresholds are set to value 5. In the remaining experiments, we will consider the dataset under the annotation generalization case, i.e., the annotations have been generalized to enable the discovery of more rules.

In Figure 12, we study the execution time of discovering the annotation-related rules in the entire dataset. We vary the confidence and support thresholds as depicted in the figure. In this experiment that dataset is static, i.e., there are no new batches of data or annotations. As the figure illustrates the execution time ranges from 8 secs to 22 secs depending on the used thresholds. We have also studied the execution time of the mining algorithm without annotation generalization and the observed differences are not significant, e.g., the technique without generalization are faster by 1% to 7% compared to the other case.

In Figure 13, we study the execution time under the addition of new annotation batches. We focus on the 3rd case presented in

Figure 12: Evaluation of Execution Time.

Figure 13: Execution Time of Incremental vs. Non-Incremental Algorithms (Case III).

Figure 14: Number of Rules Yielding Approved Recommendations.

Figure 15: Percentage of Rules Yielding Approved Recommendations.

Section 3.1 since this case is not supported by existing association rule mining techniques. In the experiment, we set the confidence and support thresholds to values 95%, and 0.2%, respectively. In the x-axis of the figure, we vary the number of newly added annotations (δ) between 200 and 1,600. This is performed by isolating *delta* annotations (publications) from the original dataset, discovering the association rules on the modified dataset, and then adding the isolated annotations back as the new delta batch. We perform the experiment on three different dataset sizes, i.e., small (20% of the entire dataset), medium (40% of the entire dataset), and large (the entire dataset). We compared between a naive non-incremental A-priori technique [8] versus the incremental technique proposed in Section 3.1. As the results show, the incremental algorithm outperforms the non-incremental one by up to two orders of magnitude while producing the same exact results.

In Figures 14 and 15, we investigate the virtue of the exploitation process within which the system proactively uses the discovered association rules and provides recommendations to enrich the annotated database. In the experiment, we set the confidence and support thresholds to 95% and 0.2%, respectively (resulting in 64 discovered rules as illustrated in Figure 11(b)). We then, in Figures 14 and 15 select the top K strongest rules for generating recommendations. The K varies over the values between 10 to 64 as indicated on the x-axis. Each rule, may generate many recommendations, e.g., attaching a specific annotations to some data tuples, and each recommendation is supported by some evidences (Refer to Figure 10). The results presented in Figure 14 and 15 illustrate for each K , the number, and percentage, respectively, of the rules that yield to at least one recommendation being approved by the database admin. This means that these rules were valuable as they

Figure 16: Searching for Matching Rules under New Tuples Insertions.

helped discovering missing attachments. The results show that a fair number of rules have yielded to approved recommendations. Moreover, the strongest rules, e.g., Top 10 or 20, usually yield to more realistic recommendations compared to the weaker rules, e.g., Top 50, or 60. The results in Figures 14 and 15 are interesting as they show that we may not even use all the discovered interesting rules for recommendation purposes. We can depend on only the top ranked ones to achieve high acceptance rate while reducing the domain experts' efforts in the verification process.

In Figure 16, we study the performance of searching for matching association rules under the insertion of new data tuples. We compare the two cases where the search does not use an index, i.e., scanning all existing rules, versus the use of index, i.e., the rules

are normalized and indexed using the B-Tree index (Refer to Section 4). In the experiment, we varied the number of rules from 10 to 10,000 (the x axis), and measured the search time (the y axis). The experiment is repeated 10 times, and the average values are presented in the figure. As expected, the “*With Index*” case scales much better and remains stable as the number of association rules gets larger. Whereas, the “*Without Index*” case has slightly better performance when the number of rules is very small. This is because the key lookups over the index—which are multiple lookups per tuple—add unnecessary overhead when the number of rules is very small. In this case, one scan over all rules becomes faster.

7. CONCLUSION

In this paper, we investigated a new facet of annotation management, which is the discovery and exploitation of the hidden annotation-related correlations. The addressed problem is driven by the emerging real-world applications that create and maintain large-scale repositories of annotated databases. The proposed work opens a new application domain to which the well-known association rule mining can be applied. We show cased several scenarios specific to annotated databases that cannot be efficiently handled by the state-of-art in association rule mining. We then proposed algorithms for efficient and incremental maintenance of the discovered association rules under these scenarios. We proposed two important applications for leveraging the discovered annotation-related correlations and enhancing the quality of the underlying database, which are the discovery of missing attachments, and the recommendation of applicable annotations to newly inserted data. To enable seamless use by scientists, we integrated the proposed algorithms within the annotation management engine and developed an end-to-end system including an Excel-based GUI through which all of the proposed functionalities can be performed.

ABSTRACT

Database query performance problem determination is often performed by analyzing query execution plans (QEPs) in addition to other performance data. As the query workloads that organizations run have become larger and more complex, analyzing QEPs manually even by experts has become a very time consuming and cumbersome task. Most performance diagnostic tools help with identifying problematic queries and most query tuning tools address a limited number of known problems and recommendations. We present the OptImatch system that offers a way to (a) look for varied user defined problem patterns in QEPs and (b) automatically get recommendations from an expert provided and user customizable knowledge base. Existing approaches do not provide the ability to perform workload analysis with flexible user defined patterns, as they lack the ability to impose a proper structure on QEPs. We introduce a novel semantic web system that allows a relatively naive user to search for arbitrary patterns and to get solution recommendations stored in a knowledge base. Our methodology includes transforming a QEP into an RDF graph and transforming a GUI based user-defined pattern into a SPARQL query through handlers. The SPARQL query is matched against the abstracted RDF graph, and any matched portion of the abstracted RDF graph is relayed back to the user. With the knowledge base, the OptImatch system automatically scans and matches interesting stored patterns in a statistical way as appropriate and returns the corresponding recommendations. Although the knowledge base patterns and solution recommendations are not in the context of the user supplied QEPs, the context is adapted automatically through the handler tagging interface. We test the performance and scalability of our framework to demonstrate its efficiency using a real query workload. We also perform a user study to quantify the benefits of the approach in terms of precision and time compared to manually searching for patterns.

1. INTRODUCTION

1.1 Background and Motivation

Much of the world's high-valuable data remain in relational databases (e.g., operational databases and data warehouses [12]). Access to this data is gained through relational query languages such as Structured Query Language (SQL). Complex analytic queries on large data warehouse system are not only done as weekend or end of period canned batch reports. Ad hoc complex queries are increasingly run as part of business operations. As such it is critical to pay attention to performance of these queries.

Database systems themselves are certainly increasingly becoming more sophisticated and able to automatically tune the environments they operate in. General query performance problem determination tools [4], [6], [23], [24] also offer an automated way to database administrators to analyze performance issues that neither requires mastery of an optimizer, nor deep knowledge about the query execution plans (QEPs). However, due to the complexity while the general approach has merit, there is a lack of customization and many refinements are needed, so that the problem determination and tuning process can be truly effective and consumable by the general end-user. Given the specific circumstances and limitations of existing tools, performance analysis today is often best done by manually analyzing optimizer QEPs that provide detail of how queries are executed. Manually analyzing these QEPs can be very demanding and often requires deep expertise particularly with complex queries that are often seen in data warehouse environments. Very often the end users and database administrators resign themselves to opening problem reports to the database vendors so that experts who are well versed in both SQL and analyzing optimizer QEPs can provide recommendations. This can be a time consuming exercise and does not scale well.

Existing tools such as IBM® Optim Query Tuner® and IBM Optim Workload Tuner® provide tuning recommendations for specific known problems. While very effective, they do not, however, provide the ability to perform query performance problem determination with flexible user-defined patterns (examples listed below). This is mainly because these tools are agnostic to the

complex structure of QEPs. There does not exist a general purpose automated system that would allow for interactive analysis and diagnosis of performance problems by searching for arbitrary patterns within a large number of QEPs. A user not so experienced with QEPs may want to answer simple questions. For example, after searching and determining the cost of a table scan on a particular table, the user may want to know how many queries in the workload do an index scan access on the table and get a sense of the implications of dropping the index by comparing the index access cost to that of the table scan. Even with more experienced database administrators, often there are clues from monitoring data that provide hints of certain characteristics of QEPs that are not easily found by using typical search tools like *grep*. For instance, given a large number of queries, say 1000 queries, and the corresponding workload QEPs:

- Find all the queries in the workload that might have a spilling hash join below an aggregation and the cost is more than a constant N .
- Find all the subqueries that have a cost that is more than 50% of the total cost of the query and provide details of the subquery operators (name, cost, and input operators).
- Find all the queries that have an outer join involving the same table somewhere in the plan below both sides of a hash join.
- Perform cost based clustering and correlate results of applying expert patterns to each cluster.

We consider making it easier and faster to automatically answer questions like the above in our work. We provide a flexible system OptImatch that performs analysis over large and complex query workloads, in order to help diagnosis optimizer problems and retrieve solutions that were previously provided by experts. The optImatch system drastically lowers the skill level required for optimizer access plan problem determination through advanced automated pattern matching and retrieving of solution recommendations of previously discovered performance problems for single queries and large query workloads. OptImatch is very well received and is proving to be very valuable in the IBM support

of business clients and database optimizer development organization.

At the enterprise level, major commercial state-of-the-art relational database systems such as IBM DB2®, Oracle®, and Microsoft® SQL Server® are deployed in environments where finding all available optimizations and performance tuning strategies becomes necessary to maintain the usability of the database. Traditional optimization methods often fail to apply when logical subtleties in queries and database schemas circumvent them. The examples of this include cases, where the recommended performance enhancement is to index a table in a particular way, prescribe an integrity constraint such as functional dependency [16] or order dependency [17], create a materialized view [7] or to rewrite manually the proposed SQL query, where orthogonal approach with machine optimization [5], [21], [25] failed to rewrite the query to get the same answer but with a better performance.

The problem pattern comprises a list of operators having particular properties that are of interest to a user, as exemplified in some of the aforementioned problems. By incorporating our query performance problem determination system many optimization problems could be automatically identified and resolved. Figure 1 depicts an example of a text graph version of a snippet of a QEP from IBM DB2. The snippet shows a nested loop join (NLJOIN) of the SALES_FACT table accessed using an index scan (IXSCAN) with other columns fetched (FETCH) from the table and then joined to the CUST_DIM table. The numbers immediately above the operator or table name show the estimated number of rows flowing out (cardinality). The numbers in parenthesis show the operator number. Operators are also referred to as Plan Operators (pop) or LOW LEVEL Plan Operators (LOLEPOP) in this paper. Each operator has an estimated Input/Output (I/O) cost, the bottom number below the operator number, and a cumulative cost for itself and all operator below it, the number immediately below the operator number. In the depicted example, a user could be concerned with NLJOIN that has an inner stream of type table scan (TBSCAN). Such query is costly as the NLJOIN operator scans the entire inner table CUST_DIM for each of the rows from the outer SALES_FACT table. An example of a solution recommendation might be to provide a recommendation to create an index of the target table of the TBSCAN, in this case CUST_DIM.

In recent years, more and more customer queries are generated automatically by query managers (such as IBM Cognos®) with business users providing only specific parameters through graphical interfaces [9], [10]. Specific parameters are then automatically translated by query managers into executable SQL queries. Based on analyzing IBM customer workloads there is essentially no limit to the length of the query generated automatically by query managers. It is quite usual to find queries with over one thousand lines of SQL code (hundreds of operators). Such queries are very complex and time consuming to analyze with nesting and stitching of several subqueries into a larger query being a common characteristic. Another common feature is repetitiveness, where similar (or even identical) expressions appear in several different parts of the same query, for instance, in the queries referring to the same view or nested query block multiple times [15], [22]. If there is need to improve the performance of such complex queries, when optimizer failed, it could be time consuming to do this manually. It could take hours or even days to analyze a large query workload. Our goal is automate this process as much as possible, and therefore save significant amount of time spent by users on query performance problem determination. The OptImatch system makes this process easier. While optimizers are constantly improving, OptImatch allows experts through their

experience to create the interesting problem patterns and recommendations to overcome issues.

We decided to use the RDF format as it allows one to easily retrieve information with the SPARQL query language. SPARQL has the capability for querying optional and required graph patterns. Another powerful feature exploited in SPARQL is that of property paths. A property path is a possible route through a graph between two graph nodes. SPARQL property paths provide a succinct way to write parts of graph patterns and to also extend matching patterns to arbitrary length paths. With property paths, we can handle recursive queries, for instance, search for a descendant operator that does not necessarily have an immediate relationship (connection) with its parent. We can also search for patterns that appear multiple times in the same QEP. Last but not least, SPARQL allows graph traversal and pattern matching in a very efficient way [3], enabling analysis of a large number of complex QEPs in a short period of time.

While the focus of this work is on query performance problem determination, our methodology can be applied to other general software problem determination [26], assuming that there exists automatically or dynamically generated diagnostic information that needs to be further analyzed by an expert. Broadly, the contemplated diagnostic data may be human-readable and intended for review by human users of the system to which the diagnostic data relates. Examples of possible diagnostic data include log data relating to network usage, security, or compiling software, as well as software debug data or sensor data relating to some physical external system. In these scenarios, the problem pattern may correspond to any sequence of data points or interrelationships of data points that are of diagnostic interest.

1.2 Contributions

The main contributions of this paper appear in Section 2 and Section 3 as follows.

1. We developed a semantic web tool to transform a QEP into an abstracted artefact structure (RDF graph). We propose in our framework to model features of the QEP into a set of entities containing properties with relationships established between them. (Section 2.1)
2. We provide a web-based graphical interface for the user to describe a problem pattern (pattern builder). The tool transforms this pattern into a SPARQL query through handlers. Handlers provide the functionality of automatically generating variable names used as part of the SPARQL query. The SPARQL query is executed against the abstracted RDF structure and any matched portions of RDF structure are relayed back to the user. We present a suite of real-world IBM customer problem patterns that illustrate the issues related to query performance, which are then used in Section 3 for experimental performance evaluation. (Section 2.2).
3. We added a knowledge base capability within the tool that could be populated with some expert provided patterns and solution recommendations as well as allow users to add their own patterns and recommendations. The system automatically matches problem patterns in knowledge base to the QEPs and if there are any search results ranks them using statistical correlation analysis. OptImatch distinguishes between a pattern builder and a tagging handler interface to achieve generality and extensibility. In a nutshell, the pattern builder allows the users to specify what is wrong with the query execution plan (static semantics), and the handler tagging interface defines how to report and fix it (dynamic semantics) through automatically adopting the context. Since

the knowledge base patterns and solution recommendations are not in the context of the user supplied QEPs, we have defined the language that users can use to add dynamic context to the recommendations. (Section 2.3)

4. An experimental evaluation showing the performance and effectiveness of our techniques was carried out using real IBM customer datasets. We experimented with different problem patterns, and show that our framework runs efficiently over large and complex query workloads. Our performance evaluation reveals that the time needed to compute a search over a specified problem pattern against a QEP increases linearly with the size of the workload, the number of operators in the QEP and the number of pattern/recommendations in the knowledge base. Finally, we show through a user study that our system is able to save a significant amount of time to analyze QEPs. Moreover, we quantify in the user study the benefits of our approach in terms of precision over manual pattern searching. (Section 3)

In Section 4, we discuss related work. We conclude and consider future work in Section 5.

To the best of our knowledge, we are the first to provide a system for query performance problem determination by applying QEP feature transformation through RDF and SPARQL. This work we feel opens exciting venues for future work to develop a powerful new family of problem determination techniques over existing optimizer performance analysis tools and other diagnostic data exploiting graph databases.

2. SYSTEM

2.1 Transforming Diagnostic Data

Even though optimizer diagnostic data may differ in some ways between various database management systems, their major characteristics remain the same. Query performance diagnostic information is usually in the form of QEPs formatted in readable text form. An example of the portion of the QEP generated by the IBM DB2 database engine is presented in Figure 1. A QEP includes diagnostic information about base objects (e.g., tables, views and indexes), operators (e.g., join, sort and group-by) as well as costs and characteristics associated with each operator.

Some properties of operators are included in a QEP in the tree diagram as in Figure 1 (e.g., cardinality total cost, Input/Output cost, cumulative cost), wherein other properties appear as separate textual blocks identified by operator number (e.g., cumulative CPU cost, cumulative first row cost and estimated bufferpool buffers). Furthermore, some properties are common between different types of operators (e.g., cardinality, total cost and CPU cost), while others are specific to certain operators. For instance, NLJOIN has a property fetch max, and TBSCAN has a property max pages, but not vice versa. A QEP also contains some other detailed diagnostic data, including information about the DBMS instance and environment settings. All of the techniques described in this paper have been implemented given IBM DB2 QEPs. Hence, much of the discussion through the rest of the paper is framed in the terminology and characteristics of IBM DB2. However, the techniques that are described have general applicability, and can be used with any other DBMS product or other diagnostic data that lends itself to property graph representation.

A QEP can be viewed as a directed graph that indicates the flow of operations processing data within the plan. QEPs resemble a tree structure, where each node (operator) possesses numerous properties and is considered as one of the inputs to a derived

Figure 2 Generated RDF in textual representation

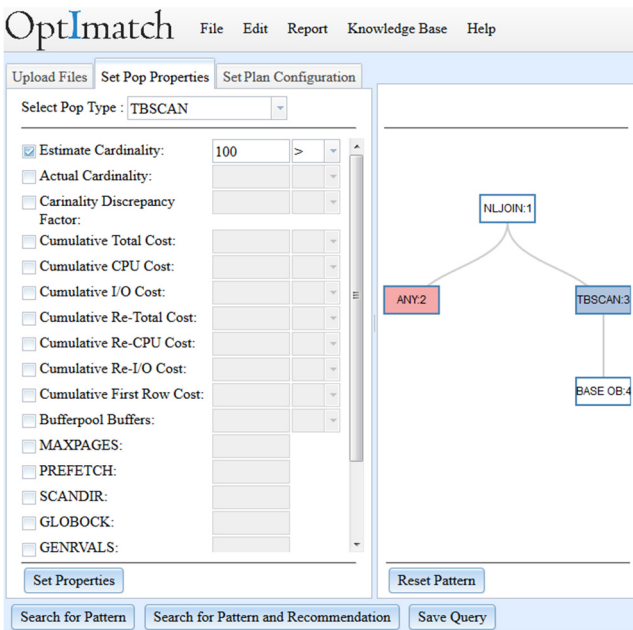

Figure 3 Web-based Graphical Interface (Pattern Builder)

ancestor node. LOLEPOPs in a QEP are connected to their parents as inputs streams. These inputs can be identified with three different types 1) outer input (left input of the parent operator) 2) inner input (right input of the parent operator) and 3) general input stream (generic input used for any kind of operator).

The LOLEPOPs may be understood, at the level of abstraction of the DBMS user, as indivisible operations that are directly executed by the DBMS, with each LOLEPOP carrying a stated cost. The stated cost for each LOLEPOP represents an estimate of server resources, generated by the DBMS system based on a proposed SQL query by taking into account the particular properties of the database. The overall QEP is machine-generated by the DBMS Optimizer [14]. It is machine-optimized to gravitate towards the lowest total cost LOLEPOPs attainable by the DBMS's optimizer. The plan structure is highly dynamic and can change based on configuration, statistics of the data associated with referenced base objects and other factors even if query characteristics remain similar. However, plan changes are difficult to spot manually as they tend to spawn thousands of lines of informative details for more complex queries in the workload.

RDF is a labeled directed graph built out of triples, each containing subject (resource), predicate (property or relationship) and object (resource or value). RDF does not enforce specific schema, hence, two resources in addition to sharing properties and relationships, can also be described by their own unique predicates. This property of RDF is beneficial to describe and preserve various types of complex diagnostic information about QEPs. Even though RDF inherently does not possess a particular structure, such structure can be enforced by specifying predicates (for example, defining predicates, such as *hasInputStreamPop* or *hasOutputStreamPop*, and *hasInnerInputStreamPop* or *hasOuterInputStreamPop* and using them to establish relationships between resources (LOLEPOPs)). This allows one to recreate the tree structure and characteristics used in QEPs.

Algorithm 1 TransformingQEPs

Input: query execution plan files *QEPFs*[]

Output: execution plans represented as RDF Graphs, *RDFGs*[]

```

1: forall qepf in QEPFs[ ]
2:   i := 0
3:   rdg := convert qepf into RDF graph model by traversing
      through base objects, operators and relationship
      (input streams) with Jena RDF API
4:   RDFGs[i] := rdg
5:   i := i + 1
6: end forall
7: return RDFGs[ ]

```

We propose in our framework to model features of the QEP into a set of entities containing properties with relationships established between them. In these terms, a QEP can be modelled into LOLEPOPs (entities), type, cardinality and costs (properties) and input/output streams (relationships). This model, represented in our framework by means of Apache Jena RDF API, is applied to QEPs provided by the user and persisted in a transformation engine (Algorithm 1). Jena is a Java API which can be used to create and manipulate RDF graphs. Jena has object classes to represent graphs, resources, properties and literals. The result is a transformation of the QEP into an RDF graph, where each LOLEPOP represents an RDF Resource, each property and relationship represents an RDF Predicate and each property value is represented by an RDF Object. During the transformation from the QEP file to the RDF graph additional derived properties can be defined by analyzing resource properties. For instance, the *hasTotalCostIncrease* predicate allows us to calculate and store the total cost of the LOLEPOP by subtracting the cost of the input LOLEPOPs from currently LOLEPOP being analyzed. The

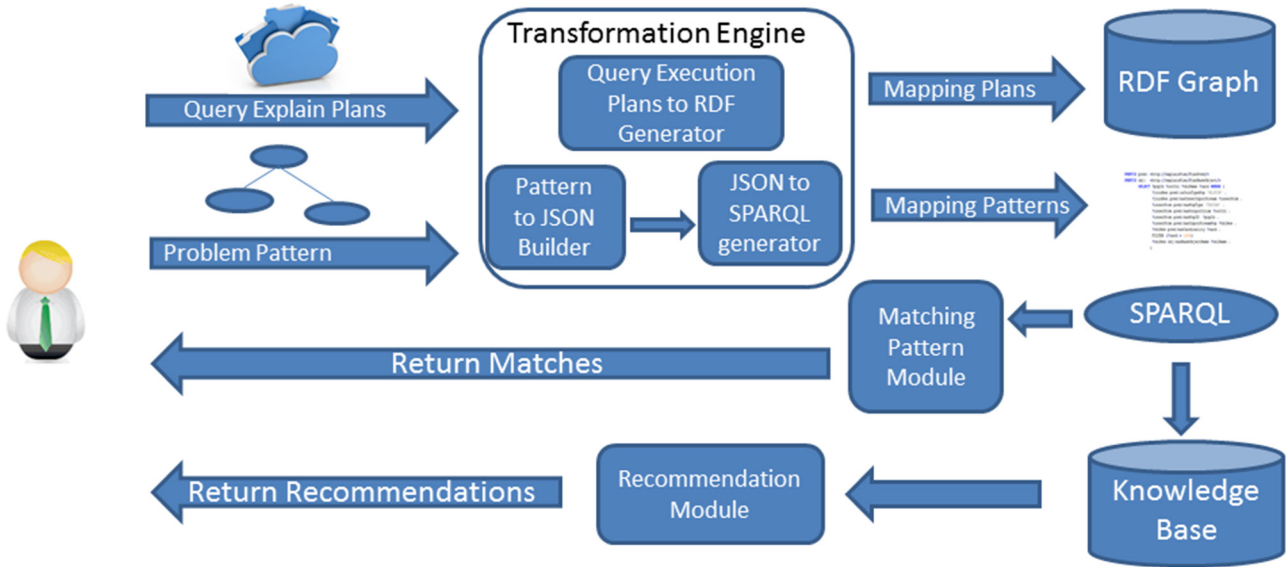

Figure 4 System Architecture

Generated RDF graph can then be preserved in memory ready for analysis by the transformation engine. The OptImatch System architecture is illustrated in Figure 4.

An example of an auto-generated RDF graph in textual representation is presented in Figure 2. Figure 2 depicts an RDF representation of the LOLEPOPs shown in Figure 1. Each RDF statement is in the form of a triplet including a resource, a predicate and an object. In the code presented, statements referring to the resource “http://explainPlan/PlanPop/5” represents LOLEPOP #5. Various predicates are shown, each encoding a piece of information from the QEP. For example, there are predicates that specify LOLEPOP #5’s total cost (15771) and estimated cardinality (4043). The RDF representation of all other LOLEPOPs is generated accordingly.

2.2 Searching for Problem Patterns

SPARQL is the RDF Query Language. The SPARQL standard is maintained by the W3C. Our system can accomplish the step of searching for user-defined problem patterns in QEPs by transforming patterns into SPARQL queries directed to the abstracted RDF derived from the QEPs. SPARQL performs graph traversal and pattern matching efficiently. This allows one to analyze complex patterns over large query workloads in a short period of time.

We decided to use RDF and SPARQL as SPARQL contains the capability for querying optional and required patterns of the graph with arbitrary length paths, and moreover, SPARQL property paths provide a succinct way to match patterns in the RDF graph. This includes recursive queries, such as looking for descendants operators that do not necessarily have an immediate connection with their parent (see Pattern B in Section 2.3), and searching for patterns that appear multiple times in the same query execution plan. We decided to use RDF and SPARQL as SPARQL contains the capability for querying optional and required patterns of the graph with arbitrary length paths, and moreover, SPARQL property paths provide a succinct way to match patterns in the RDF graph. While one could consider using any property graph representation framework, RDF was used also for convenience since DB2

supports RDF file format and SPARQL querying across all editions from DB2 10.1, when the RDF specific layer, DB2 RDF Store, was added. The DB2 RDF Store is optimized for graph pattern matching.

Algorithm 2 TransformingProblemPattern

Input: problem pattern *probPat*

Output: problem pattern *probPat* transformed to SPARQL query

- 1: *probPatJSON*[] := translate problem pattern *probPat* into JSON Object (an array)
- 2: *sparql* := initialize prefixes
- 3: **forall** *probPat* in *probPatJSON*[]
- 4: *sparql* += transform an element *probPat* from JSON object *probPatJSON* with handlers into the SPARQL query
- 5: **return** *sparql*

Query performance problems can usually be described as problem patterns in the QEP. A problem pattern is a set of optimizer plan features and characteristics specified in a particular order and containing properties with predefined values. Figure 3 displays a web-based graphical user interface (pattern builder) used in our system wherein a user can express the problem pattern by selecting various properties of LOLEPOPs and plan properties that a user might be interested in within the QEP. In the depicted example of problem pattern (**Pattern A**), the user is concerned with a LOLEPOP that: (i) is of type NLJOIN; (ii) has an outer input stream of type any (ANY) with cardinality greater than one (meaning that the outer is likely to be more than one row and consequently the inner will be accessed multiple times; (iii) has an inner input stream of type TBSCAN; and (iv) the inner input stream has large cardinality (greater than 100). The depicted graphical user interface generates an example structure of a LOLEPOP that matches the selected properties. In this case, the described LOLEPOP is a nested loop join operator (NLJOIN) with some operator (ANY) on the outer input stream and a table scan (TBSCAN) on the inner input stream. Such a pattern is costly as deduced by satisfying the cardinality conditions. The NLJOIN operator scans the entire table (TBSCAN) for each of the rows from the outer operator ANY. It would likely be of value for a subject

matter expert to spend time and attention to try to optimize queries matching this problem pattern in the QEP. (System recommendations are described in details in Section 2.3.)

When specifying a problem pattern using the graphical user interface (GUI) for generality and flexibility sake, the user can choose between two types of relationships: immediate and descendant. Descendants are operators that are successors but not necessarily immediately below the current LOLEPOP. In that case, the path between the parent and the descendant child is the portion of the graph that in the general case can contain any arbitrary number of operators. For instance, in Figure 1, LOLEPOP #4 is an immediate child of LOLEPOP #3 and LOLEPOP #4 is a descendant child of LOLEPOP #2.

Once the desired problem pattern is defined by the user by describing LOLEPOPs, their characteristics and relationships, it is then automatically translated (Algorithm 2) into a JavaScript Object Notation (JSON). This object is constructed to contain a transformation of the properties specified in the pattern builder to the RDF resources and the predicates defined in the model used in the QEP. In Figure 5, we present an example JSON Object that contains properties specified in the pattern builder (Figure 3). The generated JSON Object is an array of objects describing each resource operator and its relationships. For instance, the portion of JSON Object describing LOLEPOP with ID 1 has specified type NLJOIN, an estimated cardinality value of more than 100 and relationship with two immediate children operators, LOLEPOP with ID 2 and LOLEPOP with ID 3.

```

        {
          "id": "hasOutputStream", "value": 3
        }
      }
    }
  ],
  "planDetails": []
}
```

Figure 5 JSON Object

The transformation engine uses JSON Objects to auto-generate an executable SPARQL query. An example of the autogenerated SPARQL query is presented in Figure 6. The URIs broadly match the RDF graph generated based on the QEP in Figure 1, and various SPARQL query operators and operands match the elements of the problem pattern indicated by the user.

An autogenerated SPARQL query is composed of two main parts, the SELECT clause that defines variables that appear in the query results, and the WHERE clause that defines resource properties that should be matched against the specified RDF graph. The variables that appear in query results are specified by prefixing variable name with “?” symbol, i.e., “?variable_name” (and can be referenced multiple times in the WHERE clause). The same convention is used to define variables to establish relationship between resources and the ones used to filter retrieved resources.

Our framework allows us to autogenerate SPARQL queries with a wide range of characteristics, including nesting, filtering, multiple resource mapping, and specifying property paths as well as blank nodes. Blank nodes in RDF indicate the existence of unnamed or previously undefined resources. We introduce the concept of *handlers* to facilitate this. Handlers provide the functionality of automatically generated variable names used for the retrieval of query results, filtering of retrieved values, and establishing relationships between resources and blank nodes.

Handler generation is performed in a modular manner, by building the SPARQL query one layer (one operator) at the time over portions of JSON Object. In order to generate the SPARQL query, we define four types of handler variables: *result handlers*, *internal handlers*, *relationship handlers* and *blank node handlers*. Result handlers are created based on identifiers (sequential identifiers assigned to each LOLEPOP as shown in the graphical user interface in Figure 3), i.e., ?pop1 and ?pop2 etc. For instance, in our SPARQL query, the result handler ?pop1 is a resource returned to the user, and is also used in the WHERE clause to identify this resource as NLJOIN by adding the predicate *hasPopType*.

```
PREFIX popURI: <http://explainPlan/PlanPop/>
SELECT (?pop1 AS ?TOP) (?pop2 AS ?ANY2)
      (?pop4 AS ?BASE4)
WHERE {
  ?pop1 predURI:hasPopType "NLJOIN" .
  ?pop1 predURI:hasOuterInputStream
    ?BNodeOfpop2_to_pop1 .
  ?BNodeOfpop2_to_pop1 predURI:hasOuterInputStream
    ?pop2 .
  ?pop2 predURI:hasOutputStream ?BNodeOfpop2_to_pop1 .
  ?BNodeOfpop2_to_pop1 predURI:hasOutputStream ?pop1 .
  ?pop1 predURI:hasInnerInputStream
    ?BNodeOfpop3_to_pop1 .
  ?BNodeOfpop3_to_pop1 predURI:hasInnerInputStream
    ?pop3 .
  ?pop3 predURI:hasOutputStream ?BNodeOfpop3_to_pop1 .
  ?BNodeOfpop3_to_pop1 predURI:hasOutputStream ?pop1 .
  ?pop3 predURI:hasPopType "TBSCAN" .
  ?pop3 predURI:hasEstimateCardinality ?internalHandler1 .
  FILTER ( ?internalHandler1 > 100 ) .
  ?pop3 predURI:hasInputStream ?BNodeOfpop4_to_pop3 .
  ?BNodeOfpop4_to_pop3 predURI:hasInputStream ?pop4 .
  ?pop4 predURI:hasOutputStream ?BNodeOfpop4_to_pop3 .
  ?BNodeOfpop4_to_pop3 predURI:hasOutputStream ?pop3 .
  ?pop4 predURI:isABaseObj ?internalHandler2 .
} ORDER BY ?pop1
```

Figure 6 Autogenerated SPARQL Executable Query

Internal handlers are used to filter results. Identifiers of internal handlers are not tied to a specific resource. Their identifiers are automatically incremented on the server. For instance, the handler *?internalHandler1* is generated to provide the filtering of cardinality property by first associating it with ?pop1 (?pop1 predURI:hasEstimatedCardinality ?internalHandler1) and then

utilizing it in the FILTER clause (FILTER (?internalHandler1 > 100)).

Relationship handlers establish connection between resources based on information about the hierarchy of operators retrieved from the JSON Object (e.g., {"id": "hasOuterInputStream", "value": 2, "sign": "Immediate Child"}). The relationship handlers are used in conjunction with blank node handlers to resolve ambiguity problems. Ambiguity problems are encountered when the same LOLEPOP is absorbed in the different parts of the QEP. Such a LOLEPOP, for example, a common sub expression with a temporary table (TEMP) that has multiple consumers, has the same cardinality in all the consumers which may produce different results. This might be the case, for example, when a common sub expression TEMP is consumed by both a NLJOIN and a HSJOIN in the different parts of the QEP applying different predicates. In such a case, the output columns of NLJOIN and HSJOIN might differ even though the input common sub expression TEMP into each of them is the same. In the above example, *?pop1* resource has the predicate *hasOuterInputStream* connecting it to *?pop2* via the blank node *?BnodeOfPop2_to_pop1* (*?pop1* predURI: *hasOuterInputStream* *?BnodeOfPop2_to_pop1*). This design ensures the uniqueness of each resource instance in the received QEP.

The autogenerated SPARQL query through handlers is matched against the abstracted RDF structure containing information about the QEP. It maps any matched portions of the abstracted RDF structure back to the corresponding diagnostic data (Algorithm 3). Figure 1 represents an example of the DBMS QEP that contains problem pattern specified in Figure 3.

Algorithm 3 FindingMatches

Input: problem pattern *probPat*,
query execution plan files *QEPFs*[]
Output: matches found in query execution plans
1: *RDFGs*[] := TransformingQEPs(*QEPFs*[])
2: *sparql* := TransformingProblemPattern(*probPat*)
3: **forall** *rdfg* in *RDFGs*[]
4: *matchProbPat*[] := match abstracted problem pattern *sparql*
 against query execution plan *rdfg*
5: **if** (*matchProbPat* != empty)
6: *matchProbPatDet*[] := detransformation by relating
 any matched portions of RDF structure
 matchProbPat back to corresponding query plan
7: *MATCHES*[].append(*matchProbPatDet*[])
8: **endif**
9: **end forall**
10: return *MATCHES*[]

Matching problem patterns against diagnostic data allows for dynamic analysis of ad-hoc patterns. However, beyond single pattern matching, the tool usage can vary from problem identification and analysis to solution recommendations as described in the following section.

2.3 Finding Solutions in Knowledge Base

The OptImatch system has the ability to access the knowledge base to provide solutions to the known problems (Algorithm 4 and Algorithm 5). The knowledge base is populated with predetermined problem patterns and associated query plan recommendations by subject matter experts (e.g. IBM employees or expert database administrators). The OptImatch system promotes and supports collaboration among developers, experts and database administrators to create library of patterns and recommendations.

Once defined, the problem pattern is preserved in the knowledge base in two forms: an executable SPARQL query that is applied to the QEP provided by the user and as an RDF structure describing this pattern. Although the knowledge base problem patterns and solution recommendations are not in the context of the user supplied QEPs, the context for problem patterns is adapted automatically through the handlers tagging with the defined language.

Once a problem pattern to be stored in the knowledge base is described by an expert, it is translated into the SPARQL query that includes result handlers (Section 2.2). The result handlers can have *aliases* associated with them. Looking at the example SPARQL snippet we can see that the result handler *?pop1* has been assigned an alias *?TOP* and *?pop4* an alias *?BASE4*. These aliases are used to tag the recommendation to the specified result handlers. Tagging allows for identifying a specific result handler or a set of result handlers to be returned. This allows OptImatch to list table names, column names and predicates etc., in the context of the QEP provided by the user even though these are not available when the recommendations were created.

Algorithm 4 SavingRecommendationsKB

Input: problem patter *probPat*
suggested recommendations *recomms*[]
current knowledge base *KB*[]
Output: updated knowledge base *KB*[]
1: *sparql* := TransformingProblemPattern(*probPat*)
2: save abstracted problem *sparql*, problem pattern represented
as RDF and corresponding recommendations *recomms*[]
in knowledge base *KB*[] with handlers tagging interface
3: **return** *KB*[]

Our language allows for surrounding static parts of recommendations with dynamic components generated through aliases by preceding each alias of the handler with an “@” sign. This approach is also used to limit the number of resource handlers returned to the user since in complex queries there can be large number or result handlers generated, however, only some of them might be significant to the recommendation.

Algorithm 5 FindingRecommendationsKB

Input: query execution plan files *QEPFs*[]
knowledge base *KB*[]
Output: solution recommendations for queries that match *QEPFs*[]
1: **forall** *qepf* in *QEPFs*[]
2: *queryRecommendation*[] := match specified qepf against
 knowledge base *KB*[] using statistical analysis and
 provide recommendations to diagnostic data through tags
 of handlers
3: **if** (*queryRecommendation* != empty)
4: *queryRecommendations*[].
 append(*queryRecommendation*)
5: **else**
6: *queryRecommendations*[].
 append(“There is currently no recommendation in
 knowledge base”)
7: **endif**
8: **end forall**
9: **return** *queryRecommendations*[]

A user may include multiple result handlers and apply the same rules to each of them by using array brackets e.g., [*@TOP*, *@ANY2*]. For common patterns (appearing multiple times in the same QEP) a user may limit the number of occurrences of the

Figure 7 Query with Left Outer Join

pattern that is returned in recommendation results. In the following example, [@TOP, @ANY2]:1, only the first occurrence of @TOP and @ANY2 is returned and the specifics of the LOLEPOP types and names are obtained from the context of each occurrence.

Furthermore, a user can make use of various *helper functions* constructed to allow for interactions with base tables, indexes and materialized query tables (MQTs). These functions provide means to list column predicates and table names specific to each occurrence of the pattern in the context of the user provided query execution plan. For instance, a following expression @TOP.listColumns("PREDICATE") lists columns from an alias handler in the predicate indicated by the keyword PREDICATE.

An expert can also use ?TOP alias tagging handler to indicate that when such pattern is encountered all input columns (using keyword INPUT) coming from ?BASE4 object into the NLJOIN should be listed and are valid candidates for the index creation. This can be accomplished by tagging recommendation with following expression:

```

"Create index on table @BASE4 on columns
@TOP.listColumns("INPUT")",

```

and adding it to the knowledge base with the corresponding pattern.

Our system can look through all the QEPs supplied and iterate through both the user-defined problem patterns and the library of expert provided patterns with corresponding recommendations. If there is a match between the problem pattern in the knowledge base and the QEP, one or more query plan recommendations are returned with the appropriate context.

Our system returns ranked recommendations by using statistical correlation analysis. QEPs typically have operators, estimated or actual cost, frequency or priority metrics associated with them (as described in more details in Section 2.1). These characteristics are critical to the database system in terms of performance. Based on these characteristics a prioritized list of recommendations is provided by the system. The ranked recommendations are provided

with a confidence score. For instance, in the example described in Section 2.2 with NLJOIN, the query plan problem determination program could output the recommendation (by automatically generating context) to create an index of the CUST_DIM table that is the source for the TBSCAN, as this could be the recommendation stored in the knowledge base created by the experts. An example of the syntax for creating index is illustrated in the previous paragraph. An alternate recommendation may be to collect column group statistics in order to get better cardinality estimates so that the optimizer may choose a hash join instead of a nested loop join. Ranking between these two recommendations can be aided with statistical correlation analysis comparing the QEP context of cardinality and cost estimates with that in the expert provided patterns.

OptImatch can provide advanced guidance with a variety of recommendations for example, changing database configuration, improving statistics quality, recommending materialized views, suggesting alternate query and schema design changes, and recommending integrity constraints that promote performance. We illustrate some examples of these below.

As an example of a problem related to query rewrite, we describe the pattern that represents the problem of poor join order. This pattern (**Pattern B**) is given by the following properties: (i) LOLEPOP of type JOIN (which means any type of JOIN method, e.g. NLJOIN, hash join (HSJOIN) and merge scan join (MSJOIN)); (ii) has a descendant (i.e., not necessarily immediately below) outer input stream of type JOIN; (iii) the descendant outer input stream join is a Left Outer Join; (iv) descendant inner input stream join is a Left Outer Join. The recommendation for this pattern is to rewrite the query from the following structure (T1 LOJ T2) ... JOIN ... (T3 LOJ T4) to ((T1 LOJ T2).... JOINT3) LOJ T4 as the rewritten query is more efficient. This optimization is now automatically done in DB2 but was found to be a limitation in early versions of DB2. This illustrates the usefulness of the tool in database optimizer development as well as supporting clients that use previous version of the DB2 system. We found QEPs matching this problem pattern in the real customer workload used in experiments, since the customer uses previous version of DB2. Figure 7 represents an example of the DBMS QEP that contains specified problem pattern. (Left outer join operators are prefixed in a QEP with ">" symbol, e.g. >HSJOIN and >NLJOIN.) This pattern is an example of the recursive problem pattern, since descendant outer and inner input stream of type LOJ do not have to be necessary immediate child of JOIN. (For instance, see LOLEPOP #5 and LOLEPOP #15) in Figure 7.

An alternate recommendation for this pattern, in case T1 = T3, is to materialize the column(s) from table T4 into table T1 and change the order of the operators from (T1 LOJ T2) ... JOIN ... (T1 LOJ

T4) to ((T1 LOJ T2).... JOINT1), eventually allowing to eliminate T4 as well as one instance of T1, because it had a unique key join to itself. This optimization is not automatically done in current version of DB2 optimizer.

The next pattern (**Pattern C**) represents the problem related to estimation of the execution cost by optimizer. This pattern is given by the following properties: (i) LOLEPOP of type index Scan (IXSCAN) or table scan (TBSCAN) (ii) has cardinality smaller than 0.001; (iii) has a generic input stream of type Base Object (BASE OB); (iv) the generic input stream has cardinality bigger than 100000. The recommendation in this case is to create column group statistics (CGS) on equality local predicate columns and CGS on equality join predicate columns of the Base Object. Figure 8 represents an example of the DBMS query explain plan that contains specified problem pattern. With column group statistics, the optimizer can determine a better QEP and improve query performance. This is a common tuning recommendation when there is statistical correlation between column values associated with multiple equality local predicates or equality join predicates.

A user can also encounter a problem related to SORT spilling (**Pattern D**) given by the following properties: (i) LOLEPOP of type SORT; (ii) has an input stream immediately below with an I/O cost less than the I/O cost of the SORT. The recommendation may be to change the database memory configuration to increase sort memory if the number of QEPs containing this pattern is large enough to benefit the performance of many queries in the workload.

With expert or user provided patterns and recommendations in the knowledge base, OptImatch can iterate over all of the predetermined problem patterns in the knowledge base. Specifically, each problem pattern may, in such cases, be understood as being received from the knowledge base. If matched, OptImatch recalls and returns the recommendations corresponding to the particular problem pattern. Such a technique enables query plan checks to be routinized – a user can, with no particular knowledge or training, run a general test of all predetermined problem patterns against a given query workload.

3. EXPERIMENTAL STUDY

In this section, we present an experimental evaluation of our techniques. Our evaluation focuses on three objectives.

- a) An evaluation of the effectiveness of our approach using real IBM customer query workload (1000 QEP files). (Section 3.2 and Section 3.3)
- b) Scalability and performance over different problem characteristics: sizes of the query workload (Section 3.2.1), number of LOLEPOPs (Section 3.2.2) and number of recommendations in the knowledge base (Section 3.2.3).
- c) A comparative study with manual search for patterns by experts, quantifying the benefits of our approach in terms of time and precision. (Section 3.3)

3.1 Setup

Our experiments were run on an Intel® Core™ i5-4330M machine with 2.80GHz processor and 8GB of memory. For all the conducted experiments, we used three patterns created by IBM experts. Each pattern has associated recommendations for the user (stored in the knowledge base), providing a diagnosis of the artefact. The patterns used throughout the experimental study and their respective recommendations are as follows (detailed description of each pattern can be found in Section 2).

- a) **Pattern #1 – Pattern A** (Section 2.2) that represents a problem with recommendation related to indexing.

- b) **Pattern #2 – Pattern B** (Section 2.3) of a problem with a recommendation related to rewriting the query.

- c) **Pattern #3 – Pattern C** (Section 2.3) that represents problem with a recommendation related to statistics for better cardinality (and consequently cost) estimation.

We measure the performance by computing system time for running OptImatch over the IBM customer query workload. We demonstrate the benefits of our framework by quantifying the running time against the size of the query workload (number of QEPs), number of LOLEPOPs (complexity of individual QEPs) and number of recommendations in the knowledge base.

3.2 Performance and Scalability

3.2.1 Size of Query Workload

In the first experiment, we measure the performance of our tool by dividing the IBM customer query workload into ten buckets, each containing a different number of execution files. The first bucket contains 100 QEP files, and for each following bucket another 100 unique QEP files is added up to 1000. In other words, the distribution of the QEP files over buckets is as follows: [100, 200, ..., 1000].

The purpose of this experiment is to verify how efficient our tool is to search for portions of QEP files that match the prescribed pattern against different sizes of the query workload. The test was repeated six times (for each pattern), by dividing the QEP files into buckets randomly. (The average time is reported.)

Figure 9 reveals that the time needed to compute the search increases *linearly* with the number of QEP files. The linear dependence allows our problem determination tool to scale well to large query workloads. (There is a possibility to even further reduce the time by optimizing the communication between the client and server in our system.) Furthermore, the time to perform the search even for a large query workload with 1000 QEPs (with hundreds of operators each) that involves complex SPARQL recursion is less than 70 seconds. Therefore, we can conclude that our tool allows for efficient search for patterns over complex diagnostic data.

Note that Pattern #2 takes more time to be searched for than the others (around two times more). This is because Pattern #2 is more complex, as it contains descendant nodes. Therefore, recursion is used to analyze all LOLEPOPs inside the query explain plans which are fairly complex involving on average 100+ operators in the experimental workload.

3.2.2 Number of LOLEPOPs

In the second experiment, we measured the performance of our system over QEPs with varying number of LOLEPOPs. We divided the IBM customer query workload into eleven buckets. The first bucket contains QEPs with the number of LOLEPOPs from 0 to 50, the second one from 50 to 100, and so on, until the last bucket that contains from 500 to 550 LOLEPOPs. (The maximum number of LOLEPOPs encountered in the workload was 550.) However, buckets 7-10 with the number of LOLEPOPs from 250 to 500 turned out to be empty, because the tested query workload contains only query explain plans with number of LOLEPOPs below 250 or above 500. Hence, as a consequence we report numbers for six buckets, 1-5 and 11. In other words, the distribution of the buckets is [0-50], [50-100], [100-150], [150-200], [200-250], and [500-550]. The number of pops is tied to the size of the explain file, the larger number of pops, the larger the size of the file.

The objective to run this experiment is to verify how efficient searching for patterns is as a function of number of pops. The experiment was repeated 6 times for each pattern, and the average

Figure 9 Search time versus number of QEP files

Figure 10 Search time versus number of LOLEPOPs

Figure 11 Matching recommendations in knowledge base

Figure 12 Comparative user study

time is reported. For each bucket, we report the average time in milliseconds, to analyze a single explain plan.

The results of this experiment are presented in Figure 10. As expected, the time spent to analyze QEPs increases as the number of LOLEPOPs increases. However, the time spent to analyze the QEPs increases in a linear fashion. Therefore, our system scales well for complex queries with a large number of LOLEPOPs. Moreover, even large and complex queries (with around 500 LOLEPOPs) can be processed efficiently by our tool (less than 400 milliseconds).

3.2.3 Number of Recommendations in Knowledge Base

In the next experiment, we quantify the performance of our system against the number of recommendations in the knowledge base. We measure the running time to analyze 1000 QEP files against 1, 10, 100 and 250 recommendations in the knowledge base, respectively.

We perform this experiment to simulate the important use case for our system described in Section 2.3 to routinize query plan checks with expert provided predetermined problem patterns and corresponding recommendations against a given complex query workload. Instead of taking a specific problem pattern defined by the user, the system iterates over all of the predetermined problem patterns in the query plan knowledge base and provides matching solutions to known problems.

We report the results of this experiment in Figure 11. Our framework adapts well, with linear dependence over the number of recommendations in the knowledge base. The linear dependence allows our system to scale well to large knowledge databases. Our tool can process a 1000 query workload against 250 problem patterns and recommendations in around 70 minutes.

3.3 Comparative User Study

In the last experiment, we measure the time to perform pattern search both manually by experts and automatically with Optlmatch. We also looked at the search quality. For each of the three patterns, we provide users the workload with 100 distinct QEP files. Out of 100 QEP files, 15, 12 and 18 QEP files match the three prescribed patterns #1, #2, and #3, respectively. Three experts participated in this experiment. We report the aggregated average statistics.

The purpose of this experiment is to quantify the benefits of our automatic approach against cumbersome manual search by experts that is prone to human error. The time comparison is shown in Figure 12. It can be observed that our tool drastically reduces the time to search for a pattern against even a sample of the query workload. (We perform this experiment over a sample of the query workload due to the limited time experts could spend to participate in the experiment.) Overall, our tool is around 40 times faster than the manual search by IBM experts. To simulate real world environment during the manual search for patterns experts were

Table 1 Precision for manual search

Pattern #	#1	#2	#3
Precision	88%	71%	81%

allowed to access the tools that they use in their daily problem determination tasks. An example of this includes the *grep* command-line utility for searching plain-text data sets for lines matching a regular expression.

When we measure the running time for automatic search with our tool, we include the time both for specifying the pattern using graphical interface in our tool (on average around 60 seconds), as well as, performing the actual search by our system. Based, on this experiment, it can be inferred that manual search for a larger query workload (1000 queries) would take approximately 5 hours, whereas, with our tool this can be performed in around 2 minutes (around 150 times faster). Note that an automatically searched pattern has to be specified only once by the user.

Last but not least, we report the quality of the search results in our comparative study. We measure the precision as the function of missed QEP files that contain the prescribed pattern. As predicted, manual search has been prone to human error. The precision for manual search by experts is on average 80%. Details are provided in Table 1. The common errors include misinterpreting information stored in the QEP file as well as formatting errors, e.g., using *grep* on operand value 0.001 while this information is represented in the QEP in either the decimal form or with an exponent as 10^{-3} . Obviously, since our tool is fully automatic and immune to such differences, it provided 100% precision. Our system does not only perform significantly faster than a manual search but it also guarantees correctness. Often, high precision may be very important in problem determination analysis, as such, this experiment emphasizes another important benefit of Optlmatch.

4. RELATED WORK

The SQL programming language is declarative in nature. Therefore, it is enough to specify what data we want to retrieve, without actually specifying how to get data. This is one of the main strengths of SQL, as it means that it should not make a difference to the query optimizer how a query is written as long as the different versions are semantically equivalent. However, in practice this is only partially true, as there is only a limited number of machine-generated query rewrites that a database optimizer can perform [9]. As the complexity of SQL grows, there is an increasing need to have tools help with performance problem determination.

Many different formalisms have been proposed in query optimization. We cite here only the most pertinent references. Join, sort and group by are at the heart of many database operations. The importance of these operators for query processing has been recognized very early on. Right from the beginning, the query optimizer of System R paid particular attention to interesting orders by keeping track of indexes, ordered sets and pipelining operators throughout the process of query optimization, as described in Selinger et al. [14]. Within query plans, group-by, order-by and join operators can be accomplished either by a partition operation (such as by the use of a hash index), or by the use of an ordered tuple stream, as provided by a tree-index scan or by a sort operation (if appropriate indexes are not prescribed).

In Guravannavar et al. [11], authors explored the use of sorted sets for executing nested queries. The importance of sorted sets in query optimization has prompted the researchers to look beyond the sets

that have been explicitly generated. In Szlichta et al. [17], authors show how to use relationship between sorted attributes discovered by reasoning over the physical schema via integrity constraints to avoid potentially expensive join operator. The inference system presented in follow-up work provides a formal way of reasoning about previously unknown or hidden sorted sets [18], [19]. Based on that work, many other optimization techniques from relational query processing can also be adapted to optimize group by, order by and case expressions [2], [20].

Optimization strategies described above hold the promise for good improvement. Their weakness, however, is that often the indexes, views and constraints that would be useful for optimization for a given database and workload is not explicitly available and there is only a limited number of types of query transformations that the optimizer can perform. Therefore, problem determination tools [23], [24] offer an alternative automated way to analyze QEPs and provide recommendations, such as re-write the query, create an index or materialized view or prescribe an integrity constraints. However, existing automatic tools for query performance problem determination do not provide the ability to perform workload analysis with flexible user defined patterns, as they lack the ability to impose proper structure on QEPs (as described in details in Section 1).

5. CONCLUSIONS

Query performance problem determination is a complex process. It is a tedious manual task that requires one to analyze a large number of QEPs that could span thousands of lines. It also necessitates a high level of skill and in-depth optimizer knowledge from users. Identification of even known issues is a very time and resource consuming and prone to human error.

To the best of our knowledge, we are the first to provide the system that performs interactive analysis in a structured manner of potentially a large number of QEPs in order to diagnose and match optimizer problem patterns and retrieve corresponding recommendations that are provided by experts. Our semantic system combines and applies the benefits of RDF model and SPARQL query language in query performance problem determination and QEP analysis. Optlmatch is very well received and is proving to be very valuable in the IBM support of clients and database optimizer development organization by providing quick work around solutions through the use of a well-defined knowledge base.

Our methodology can certainly be applied to other general software determination problems (e.g., log data relating to network usage, security, or software compiling, as well as software debug data or sensor data relating to some physical system external to the system). Our framework can be applied to other general software problem determination, assuming that there exists automatically generated structured diagnostic information in the form of the graph that needs to be further analyzed by an expert or general user. This is the direction that we would like to explore in the future work.

6. ACKNOWLEDGMENTS

The authors would like to thank members of the DB2 optimizer development and support teams for their feedback and guidance through the development of the Optlmatch system. Special thanks in particular to Shu Lin, Vincent Corvinelli and Manopalan Kandiah.

Scalable Public Transportation Queries on the Database

Alexandros Efentakis
Research Center "Athena"
Artemidos 6 & Epidavrou,
Marousi 15125, Greece
efentakis@imis.athena-innovation.gr

ABSTRACT

Recent scientific literature focuses on answering Earliest Arrival (EA), Latest Departure (LD) and Shortest Duration (SD) queries in (schedule-based) public transportation networks. Unfortunately, most of the existing solutions operate in main memory, making the proposed methods hard to scale for larger instances and difficult to integrate in a multi-user environment. This work proposes PTLDB (Public Transportation Labels on the DataBase), a novel, scalable, pure-SQL framework for answering EA, LD and SD queries, implemented entirely on an open-source database system. Moreover, we formulate four new types of queries targeting public transportation networks, namely the Earliest Arrival and Latest Departure k -Nearest Neighbor (k NN) and One-to-many queries and propose novel ways to efficiently answer them within PTLDB. Our experimentation will show that the proposed solution is fast, scalable and easy to use, making our PTLDB framework a serious contender for use in real-world applications.

1. INTRODUCTION

Recent algorithmic advances have been very efficient in solving vertex-to-vertex queries on graphs, for a variety of different graph types and instances. For road networks, latest papers focused on supporting additional types of shortest-path (SP) queries, including *one-to-all* (finding SP distances

from a source vertex s to all other graph vertices) [8, 15], *one-to-many* (computing the SP distances between the source vertex s and all vertices of a set of targets T) [11, 15], *range* (find all nodes reachable from s within a given timespan) [15], *many-to-many* (calculate a distance table between two sets of vertices S and T) [11] and k -Nearest Neighbor (k NN) queries in [12, 17, 21]. For large-scale networks, the works of [4, 9, 20], proposed methods for solving vertex-to-vertex queries, whereas the works of [16] and [14] deal with more complex queries, such as k -Nearest Neighbor, Reverse k -Nearest Neighbor (R k NN) and one-to-many queries, either on main memory or inside a database. Finally, for schedule-based public transportation networks recent works, either expand existing shortest-path techniques originally used for road networks, or work directly on the provided timetable. Most of the recent methods targeting public transit networks are surveyed in the latest literature overview on transportation networks of [5].

Despite the inherent different characteristics between those three types of graph networks (road, large-scale and public transportation networks), the prevailing technique that excels at all of them is the 2-hop labeling or hub labeling (HL) algorithm of [18],[6], in which we store a two-part label $L(v)$ for every vertex v : a forward label $L_f(v)$ and a backward label $L_b(v)$. These labels are then used to very fast answer vertex-to-vertex shortest-path queries. This technique has been adapted successfully to (i) road networks [2, 3, 10], (ii) undirected, unweighted graphs in [4, 9, 20] and (iii) has also been extended to public transportation networks in [7] and [23]. The HL method has also been applied successfully for one-to-many, many-to-many and k NN queries in road networks [11, 12] and k NN and R k NN queries in the context of large-scale networks in [16].

Although hub labeling is an extremely efficient shortest-path technique on main memory, there are very few works that extend those results for secondary storage. HLDB [13] stores the precomputed labels for road networks in a commercial database system and translated the hub labeling, vertex-to-vertex distance query to plain SQL commands. Moreover, it showed how to answer k NN queries and k -best via points, again with simple SQL queries. The work of [20] proposed HopDB, a C++ customized solution that utilizes secondary storage during preprocessing for large-scale networks. Efentakis et al. proposed the COLD framework [14] that stores hub-labels for large-scale networks in an open-source database engine and answers vertex-to-vertex, one-to-many, k NN and R k NN queries, using SQL commands.

In this work, we focus on timetable, public transporta-

tion networks and present a novel database framework that may service several route-planning queries on such networks. Our pure-SQL, *PTLDB* (Public Transportation Labels on the DataBase) framework, extends the hub labeling technique for public transportation networks, as presented in Timetable Labeling (TTL) [23] and may answer multiple variations (Earliest Arrival, Latest Departure and Shortest-Duration) of vertex-to-vertex queries, entirely within a database. Moreover, we formulate four new types of route-planning queries for public transit, namely the *Earliest Arrival* and *Latest Departure* k -Nearest Neighbor (k NN) queries and their *one-to-many* versions, i.e., namely the *Earliest Arrival* and *Latest Departure one-to-many* queries. These newly defined public-transit queries may be very useful for a variety of applications utilizing public transport, such as mobile travel guides, transportation and urban planning or geomarketing applications. Our experimentation will show that the proposed *PTLDB* framework may answer all those different types of queries efficiently, while its implementation with an open-source database engine makes *PTLDB* very easy to integrate into existing multi-user, real-world applications. Additionally, each type of query may be answered with a simple SQL command, making our results easily reproducible by anyone. Thus, the *PTLDB* framework is the only database solution that focuses on public-transportation networks, while ensuring excellent performance that is fast-enough for real-time applications.

The outline of the remainder of this work is as follows. Section 2 presents related work. Section 3 describes the novel *PTLDB* framework and its implementation details. Experiments establishing the benefits of *PTLDB* are provided in Section 4. Finally, Section 5 gives conclusions and directions for future work.

2. BACKGROUND AND RELATED WORK

In this section we will present related work, relative to the hub labeling method for directed weighted graphs $G(V, E, w)$, where V is the set of vertices, $E \subseteq V \times V$ is the set of arcs and w is a positive weight function $E \rightarrow \mathbb{R}^+$. We will also discuss the latest adaptations of this specific technique for public transportation networks.

2.1 Hub Labeling

In the 2-hop labeling or Hub Labeling (HL) algorithm of [18, 6], preprocessing stores at every vertex v a forward $L_f(v)$ and a backward label $L_b(v)$. The forward label $L_f(v)$ is a vector of pairs $(u, \text{dist}(v, u))$, with $u \in V$. Likewise, the backward label $L_b(v)$ contains pairs $(w, \text{dist}(w, v))$. Vertices u and w are denoted as the *hubs* of v . The generated labels conform to the *cover property*, i.e., for any s and g , the set $L_f(s) \cap L_b(g)$ must contain at least one hub that is on the shortest $s - g$ path. To find the network distance $\text{dist}(s, g)$ between any two vertices s and g , a HL query seeks the hub $v \in L_f(s) \cap L_b(g)$ that minimizes the sum $\text{dist}(s, v) + \text{dist}(v, g)$. By sorting the pairs in each label by hub, this takes linear time by employing a coordinated sweep over both labels. The HL technique has been successfully adapted for road networks in [2, 3, 10]. In the case of large-scale graphs, the Pruned Landmark Labeling (PLL) algorithm of [4] orders vertices by degree and then during preprocessing, performs one BFS per graph vertex, starting from the highest-order / degree vertices. At each iteration, each individual BFS is pruned by using the hub labels cal-

culated from the previous searches. Later, Delling et al. [9] improve the suggested vertex ordering and the storage of the hub labels for maximum compression. The HL method has also been extended to one-to-many, many-to-many and k NN queries on road networks in [11] and [12] respectively. The recent work of [16] has also proposed *ReHub*, a novel main-memory algorithm that extends the Hub Labeling approach to efficiently handle Reverse k -Nearest Neighbor (RkNN) queries on large-scale networks.

Regarding secondary-storage solutions, Jiang et al. [20] propose their HopDB algorithm for constructing an efficient HL index when the given graphs and the corresponding index are too large to fit into main memory. Abraham et al. [1] introduced the HLDB system, which answers distance and k NN queries in road networks entirely within a database by storing the hub labels in database tables and translating the corresponding HL queries to SQL commands. In [14], Efentakis et al. presented the pure-SQL *COLD* framework (Compressed Labels on the Database) for answering multiple exact distance queries (vertex-to-vertex, k NN, RkNN and *one-to-many*) for large-scale networks, in a open-source database engine. Despite the fact that each type of query was translated to just few lines of SQL code, experiments have showed that COLD provides excellent performance and is thus, fast enough for real-time applications.

2.2 Public transportation networks

For methods targeting public transportation networks before 2015, one can refer to the latest related literature overview of [5]. In this section, we will mainly focus on the latest research works that appeared in 2015.

Recently, the hub labeling method has also been extended for public transportation networks, in Public Transit Labeling presented in [7] and Timetable Labeling (TTL) presented in [23]. Since our work builds on Timetable Labeling (TTL), we will follow the notation presented there. A schedule-based, public transportation network may be modeled as a multigraph G , where each vertex is associated with a station or stop (i.e., “distinct locations where one may board a transit vehicle” [7]) and each arc from a vertex u to a vertex v represents a trip b that departs from stop u at timestamp t_d and arrives at v at timestamp t_a . Thus, each arc e may be represented with a tuple $\langle u, v, t_d, t_a, b \rangle$, where b, t_d, t_a are the trip, departure time and arrival time of e respectively and $t_a - t_d$ is the corresponding duration of the arc. The arc e is an outgoing arc for vertex-stop u and an incoming arc for vertex-stop v . Thus, there are multiple arcs connecting the same pair of vertices-stops that correspond to the different trips connecting those two stops together.

Timetable labelling (TTL) is an extension of Hierarchical Hub Labeling [3] for public transportation networks. The TTL index preprocessing, computes two sets of labels, $L_{in}(v)$ and $L_{out}(v)$, for each vertex-stop v , such that each label in $L_{in}(v)$ (or $L_{out}(v)$) is a tuple describing a “fast” path that ends at (starts from) v . TTL assumes there is a strict vertex ordering, which, defines the relative importance of each vertex with respect to the others. Hence, the rank $r(v)$ of a vertex v is an integer $\in [1, |V|]$. It is assumed that the vertex v ranks lower (i.e., is less important) than u , when $r(v) > r(u)$. When given a timetable graph G and a node order r , the TTL index can be uniquely constructed. The output of TTL preprocessing is two sets of labels, $L_{in}(v)$ and $L_{out}(v)$ for each vertex-stop v , whereas

each label contains tuples $\langle hub, t_d, t_a, pivot, b \rangle$ representing a fast transit path between stops v and hub , passing through stop $pivot$, using trip b and departing at t_d and arriving at t_a . The pivot information is required for reconstructing the full path, when it is comprised of multiple trips and is set to *null*, when the corresponding tuple describes a direct trip between stops v and hub (i.e., $b \neq null$). Note, that the label sets $L_{in}(v)$ and $L_{out}(v)$ for a vertex v only contain paths between v and vertices of higher order.

The labels calculated during the TTL preprocessing may be used for answering the following three types of queries:

- *Earliest Arrival* (EA). Given two stops s and $g \in G$ and a starting timestamp t , the earliest arrival $EA(s, g, t)$ query seeks the path with the earliest arrival time among those paths that (i) start from s no sooner than t and (ii) end at g .
- *Latest Departure* (LD). Given two stops s and g and an ending timestamp t' , the latest departure $LD(s, g, t')$ query seeks the path with the latest departure time among those paths that (i) start from u and (ii) end at v no later than t' .
- *Shortest Duration* (SD). Given two stops s and g , a starting t and an ending t' timestamp, the shortest duration $SD(s, g, t, t')$ query seeks the path with the shortest duration among those that (i) start from s no sooner than t and (ii) end at g no later than t' .

During the query phase, TTL only has to visit the labels of stops s and g (without accessing the original graph G) and select the best solution from three candidate cases: (i) Tuples in $L_{out}(s)$ where $hub = g$, (ii) Tuples in $L_{in}(g)$ where $hub = s$ and (iii) Combining all tuples $l_1 \in L_{out}(s)$ and $l_2 \in L_{in}(g)$ where $l_1.hub = l_2.hub$ and $l_1.ta \leq l_2.td$. The experimentation in [23], showed that TTL may answer EA, LD and SD queries in less than $30\mu s$, while requiring preprocessing time of less than $17min$ for all datasets.

In this work, based on the lessons learnt from the previous COLD database framework [14], that answers multiple distance queries on large-scale graphs, we will: (i) show how to efficiently store the labels created from Timetable labelling for public transportation networks into a database, (ii) translate the corresponding EA, LD and SD queries into simple SQL commands (iii) formulate four new types of queries for public transportation networks, namely the *Earliest Arrival* and *Latest Departure k*-Nearest Neighbor (kNN) and the *Earliest Arrival* and *Latest Departure one-to-many* queries and (iv) show how to efficiently answer those additional queries, by using simple SQL commands within the same database framework, implemented entirely on a popular, open-source database engine. The resulting *PTLDB* (Public Transportation Labels on the DataBase) framework will be described in the following section.

3. THE PTLDB FRAMEWORK

This section presents the PTLDB (Public Transportation Labels on the DataBase) database framework. *PTLDB* can answer multiple route-planning queries (Earliest Arrival [EA], Latest Departure [LD], Shortest Duration [SD] vertex-to-vertex, EA, LD k -Nearest Neighbor and EA, LD *one-to-many*) for public transportation networks using SQL commands. Since *PTLDB* builds on the Timetable Labeling

Figure 1: An example timetable graph G with 7 vertices (stops) and 4 trips (each highlighted with a different color). Timestamps are in 100s, i.e., 360 \Rightarrow 36,000s (10:00h). Vertex 0 is the highest order vertex, followed by vertices 1,2,3,4

Table 1: The created labels for the example graph G

v	$L_{out}(v)$	$L_{in}(v)$
	$\langle hub, t_d, t_a, pivot, b \rangle$	$\langle hub, t_d, t_a, pivot, b \rangle$
0	$\langle 0, 360, 360, -1, -1 \rangle$	$\langle 0, 360, 360, -1, -1 \rangle$
1	$\langle 0, 324, 360, 0, 1 \rangle$ $\langle 1, 324, 324, -1, -1 \rangle$ $\langle 1, 396, 396, -1, -1 \rangle$	$\langle 0, 360, 396, 0, 2 \rangle$ $\langle 1, 324, 324, -1, -1 \rangle$ $\langle 1, 396, 396, -1, -1 \rangle$
2	$\langle 0, 324, 360, 0, 2 \rangle$ $\langle 2, 324, 324, -1, -1 \rangle$ $\langle 2, 396, 396, -1, -1 \rangle$	$\langle 0, 360, 396, 0, 1 \rangle$ $\langle 2, 324, 324, -1, -1 \rangle$ $\langle 2, 396, 396, -1, -1 \rangle$
3	$\langle 0, 324, 360, 0, 3 \rangle$ $\langle 3, 396, 396, -1, -1 \rangle$	$\langle 0, 360, 396, 0, 4 \rangle$ $\langle 3, 396, 396, -1, -1 \rangle$
4	$\langle 0, 324, 360, 0, 4 \rangle$ $\langle 4, 396, 396, -1, -1 \rangle$	$\langle 0, 360, 396, 0, 4 \rangle$ $\langle 4, 396, 396, -1, -1 \rangle$
5	$\langle 0, 288, 360, 1, 1 \rangle$ $\langle 1, 288, 324, 1, 1 \rangle$ $\langle 5, 432, 432, -1, -1 \rangle$	$\langle 0, 360, 432, 1, 2 \rangle$ $\langle 1, 396, 432, 1, 2 \rangle$ $\langle 5, 432, 432, -1, -1 \rangle$
6	$\langle 0, 288, 360, 2, 2 \rangle$ $\langle 2, 288, 324, 2, 2 \rangle$ $\langle 6, 432, 432, -1, -1 \rangle$	$\langle 0, 360, 432, 2, 1 \rangle$ $\langle 2, 396, 432, 2, 1 \rangle$ $\langle 6, 432, 432, -1, -1 \rangle$

(TTL) [23], we will explain the basic concepts presented there. We chose PostgreSQL [22] for our implementation, given that it is a popular, open-source RDBMS. Although we use some PostgreSQL-specific data-types (namely arrays) and SQL extensions, we use only features included in its standard installation, without any third-party extensions.

3.1 Vertex-to-Vertex (v2v) queries

The *PTLDB* framework uses the labels generated by the Timetable Labeling (TTL) of [23] for public transportation networks. The respective TTL implementation (and the respective datasets) were made publicly available by the authors at [24]. To highlight the results of this process, the labels for the example timetable graph G of Figure 1 are shown in Table 1. The labels $L_{out}(v)$ and $L_{in}(v)$ for each vertex / stop v is a vector of tuples $\langle hub, t_d, t_a, pivot, b \rangle$ sorted by hub, t_d (see Section 2). To answer vertex-to-vertex (v2v) queries between two stop s and g , TTL only has to visit the labels $L_{out}(s)$ and $L_{in}(g)$ and select the best solution from three candidate cases: (i) Tuples in $L_{out}(s)$ where $hub = g$, (ii) Tuples in $L_{in}(g)$ where $hub = s$ and (iii) Combining all tuples $l_1 \in L_{out}(s)$ and $l_2 \in L_{in}(g)$ where $l_1.hub = l_2.hub$ and $l_1.ta \leq l_2.td$. Although selecting between those three cases is trivial for a main memory algorithm, it is complex to adapt in a database context. Thus, we need to generate for every $v \in G$, some extra “dummy” tuples in both

$L_{out}(v)$ and $L_{in}(v)$ with $hub = v$ and $t_d = t_a$ for every DISTINCT (hub, t_d) combination existing in $L_{out}(u)$ and for every DISTINCT (hub, t_a) combination existing in $L_{in}(u)$. Those dummy tuples for our example graph are highlighted in bold. Note that, those dummy tuples are only a small fraction ($< 10\%$) of the total number of tuples and hence, they add minimal overhead to the PTLDB framework's performance. By generating those dummy tuples, we can ensure that each vertex-to-vertex query may be answered by combining exactly one tuple $l_1 \in L_{out}(s)$ and one tuple $l_2 \in L_{in}(g)$ where $l_1.hub = l_2.hub$ and $l_1.ta \leq l_2.td$, i.e., we unified the three separate cases of TTL query processing into one. Thus, the answer to the $EA(1, 1, 324)$ query is 324 by combining the tuples $\langle 1, 324, 324, \dots \rangle$, present in both $L_{out}(1)$ and $L_{in}(1)$.

Code 1: Vertex-to-vertex (v2v) queries for PTLDB

```

1 WITH outp AS
2   (SELECT UNNEST(hubs) AS hub,
3          UNNEST(tds) AS td,
4          UNNEST(tas) AS ta
5   FROM lout WHERE v=s),
6 inp AS
7   (SELECT UNNEST(hubs) AS hub,
8          UNNEST(tds) AS td,
9          UNNEST(tas) AS ta
10  FROM lin WHERE v=g)
11 /* For EA queries */
12 SELECT MIN(inp.ta)
13 /* For LD queries */
14 SELECT MAX(outp.td)
15 /* For SD queries */
16 SELECT MIN(inp.ta-outp.td)
17 FROM outp,
18      inp
19 WHERE outp.hub=inp.hub AND outp.ta<=inp.td
20 /* For EA,SD queries */
21 AND outp.td>=t
22 /* For LD,SD queries */
23 AND inp.ta<=t'

```

After generating the additional dummy tuples for simplifying the TTL vertex-to-vertex queries, we need to store the respective $L_{out}(v)$ and $L_{in}(v)$ labels in the database, as two separate DB tables denoted *lout* and *lin*, respectively. Similar to the previous work COLD [14], we take advantage of the fact that PostgreSQL features an array data type that allows columns of a DB table to be defined as variable-length arrays. Hence, in PTLDB we store hubs, departure timestamps t_d and arrival timestamps t_a for a vertex (all ordered by hub, t_d) as arrays in three separate columns (i.e., hubs, tds and tas) in a single row. The resulting *lout* and *lin* DB tables are shown in Tables 2 and 3. Similar to COLD, this approach has considerable advantages: (i) The *lout* and *lin* DB tables have exactly $|V|$ rows (ii) Each of those DB tables has the column v as primary key, minimizing the size of the respective index. (iii) For any v2v query, PTLDB needs to access exactly two rows, regardless of the sizes of $|L_{out}(s)|$ and $|L_{in}(g)|$, thus minimizing the secondary-storage utilization, even working inside a database. In case of timetables changing depending on the weekday (e.g., weekdays vs weekends) or the time of the year (e.g., on holidays) in PTLDB we would need to have different versions of the *lout* and *lin* DB tables, for servicing each different period. Also note

that in PTLDB, we do not need to store the pivot or the trip information, since if we wanted to reconstruct the full path, it would make more sense to store on the database the expanded path for each tuple generated by the TTL preprocessing. After all, this is another advantage of databases, also suggested by previous efforts like [1].

The resulting SQL commands for all types (Earliest Arrival, Latest Departure and Shortest Duration) of vertex-to-vertex queries for PTLDB are shown in Code 1, where the user may choose between the lines 12, 14 and 16 and lines 21, 23 depending on the specific type of query. We use Common Table Expressions (CTEs) for greater readability and we exploit the fact that PostgreSQL “guarantees that parallel unnesting” for *hubs*, *tds* and *tas* for each nested query “will be in sync”, i.e., each tuple $\langle hub, td, ta \rangle$ is expanded correctly since for the same v the respective arrays have the same number of elements¹. It is obvious that the PTLDB vertex-to-vertex query is very simple, since it is implemented with just a few lines of SQL code and at the same time, it is highly optimized since it only has to fetch only one row from each *lout* and *lin* DB tables.

THEOREM 3.1.1. *The PTLDB v2v query is correct.*

PROOF. By adding the dummy tuples to the *lout* and *lin* DB tables, we can guarantee that the solution to any vertex-to-vertex query is a combination of one tuple $l1 \in lout$ and one tuple $l2 \in lin$ with $l1.hub = l2.hub$ and $l1.ta \leq l2.td$ (Line 19). Considering the fact that PostgreSQL guarantees correct unnesting of the hubs, tds and tas arrays (line 2-4, 7-9) for the respective rows for u and v and the extra conditions specific for each type of query (Lines 12,14 and 16 and lines 21, 23) then the resulting PTLDB vertex-to-vertex query is correct. \square

3.2 EA and LD kNN queries

The k -Nearest Neighbour (kNN) query, either for Euclidean space or for network databases, is a very well-studied problem in database systems due to its wide range of applications. Unfortunately, it has not been extended yet, to public transportation networks. To this propose, we formulate the Earliest Arrival and Latest Departure k -Nearest Neighbour (kNN) queries for schedule-based timetable networks, according to the following definitions:

- **Earliest Arrival kNN query (EA- kNN).** Given a stop q , a set of target-stops T and a starting timestamp t , the earliest arrival $EA-kNN(q, T, t, k)$ query seeks the k -distinct stops $\in T$ with the earliest arrival time among the paths that (i) start from q no sooner than t and (ii) end in any stop $\in T$.
- **Latest Departure kNN query (LD- kNN).** Given a stop q , a set of target-stops T and an ending timestamp t , the latest departure $LD-kNN(q, T, t, k)$ query seeks the k -distinct stops $\in T$ with the latest departure time from stop q from among the paths that (i) start from q and (ii) end in any stop $\in T$ no later than t .

Both these type of queries may be used in a wide range of useful applications, such as an tourist deciding to visit the nearest Point of Interest (POI) using public transport

¹<http://stackoverflow.com/a/23838131>

Table 2: The *lout* table used in *PTLDB* for the example graph *G*

v	hubs	tds	tas
...
1	{0, 1, 1}	{324, 324, 396}	{360, 324, 396}
...
4	{0, 4}	{324, 396}	{360, 396}
...

Table 4: The *ea_knn_naive* table for the example graph *G*, $T = \{4, 6\}$ and $k = 1$

hub	td	vs	tds
0	360	{4, 6}	{396, 432}
2	396	{6}	{432}
4	396	{4}	{396}
6	432	{6}	{432}

(EA-*k*NN) or how a city visitor may determine his remaining time for finishing his breakfast, before reaching one of his preferred POI-destinations by 11:00 (LD-*k*NN). To the best of our knowledge, *this is the first time that these queries have been formalized for public transit networks* and therefore we are not aware of any previous approach tackling them. Throughout this work we assume that targets are not changing, which is a reasonable assumption for public transportation networks, since, e.g., for location based services we already know the stops that are located near attractive POIs or the most visited city-landmarks. In the following sections, we will show how to efficiently solve those queries within *PTLDB*. For our example graph *G* (Figure 1) and the remainder of this section, we assume that target stops are 4 and 6, i.e., $T = \{4, 6\}$

3.2.1 Implementation

In this section, we will mainly discuss EA-*k*NN queries. The solution to LD-*k*NN queries will be directly analogous. Typically, to solve *k*NN queries with the hub labeling method, we need to group the L_{in} tuples of the targets by hub [1, 16, 14] and keep the *k*-best entries per hub. Unfortunately, this approach cannot be extended directly to public transportation networks, due to the condition $l_1.ta \leq l_2.td$ that must always hold. A naive solution to this problem, would be to group the L_{in} tuples of the targets per *hub* and *td* instead, and again keep the best distinct *k*-entries per *hub*, *td* ordered by *ta*, with ties broken arbitrarily. The results of this process would then be stored in the DB table *ea_knn_naive*, with the data structure shown in Table 4. As seen there, for $k = 1$, *hub* = 0 and *td* = 360 we only need to keep the best entry that corresponds to $v = 4$ and *td* = 396. The primary key of *ea_knn_naive* table will be the (*hub*, *td*) combination. After building this table, the EA-*k*NN(*q*, *T*, *t*, *k*) query may be solved by the SQL of Code 2, that combines the row of *lout* DB table that corresponds to vertex *q*, with the *ea_knn_naive* table. Therefore the EA-*k*NN(0, {4, 6}, 360, 1) will have the correct answer (4, 396), i.e., the NN of vertex 0 for departure time 360 or later is the vertex 4 with arrival time 396. As showcased in [14], it makes sense to create one large *ea_knn_naive* table for the maximum value *kmax* of *k* (e.g., for $k = 16$) that may be serviced by the DB framework and that same table will be used for all *k*NN queries up to $k = kmax$. In this case, we only need to retrieve *k*-entries per (*hub*, *td*) combination and thus we only expand *vs*[1 : *k*] and *tas*[1 : *k*]

Table 3: The *lin* table used for *PTLDB* for the example graph *G*

v	hubs	tds	tas
...
1	{0, 1, 1}	{360, 324, 396}	{396, 324, 396}
...
4	{0, 4}	{360, 396}	{396, 396}
...

(Lines 14-15) for $k < kmax$.

Code 2: EA-*k*NN naive query for *PTLDB*

```

1 WITH n1 AS
2   (SELECT v, hub, td, ta
3    FROM
4     (SELECT v AS v,
5            UNNEST(hubs) AS hub,
6            UNNEST(tds) AS td,
7            UNNEST(tas) AS ta
8     FROM lout
9     WHERE v=q) n1a
10    WHERE td >= t)
11 SELECT v2, MIN(n2.ta)
12 FROM n1,
13      (SELECT hub, td,
14             UNNEST(vs[1:k]) AS v2,
15             UNNEST(tas[1:k]) AS ta
16      FROM ea_knn_naive) n2
17 WHERE n1.hub=n2.hub
18 AND n2.td >= n1.ta
19 GROUP BY v2
20 ORDER BY MIN(n2.ta), v2
21 LIMIT k;

```

THEOREM 3.2.1. *The naive EA-*k*NN query is correct.*

PROOF. The naive EA-*k*NN query joins the *l1* tuples in *q* row of DB table *lout*, with the *l2* tuples of *ea_knn_naive* DB table with $l1.hub = l2.hub$ and $l1.ta \leq l2.td$. Since for each individual (*hub*, *td*) combination the *ea_knn_naive* DB table stores the top-*k* (earliest arrival) entries, this ensures that the naive EA-*k*NN query provides correct results. \square

Although the EA-*k*NN naive query is very simple, it cannot scale well for large metropolitan networks. In a realistic setting, multiple buses or trains leave the same *hub* every few minutes and therefore for each hub we will have multiple *td* entries. Thus, the size of *ea_knn_naive* DB table and its primary key index will vastly increase (even after keeping only the best *k*-entries per *hub*, *td*). The number of rows that should be joined will also grow, making queries too slow for real-time applications. Hence, we must further group entries per hub and create a condensed *knn_ea* DB table. Ideally, each tuple contained in the *q* row of *lout* DB table should be joined with only a single row in the *knn_ea* table, during a EA-*k*NN query. To achieve that, we can group hub entries per hour of departure, i.e., making a separate entry per hub and hour of departure for the available timestamp ranges of *td* in *lin* DB table. The resulting *knn_ea* table will have the data structure showcased in Table 5 and the combination of *hub*, *dephour* as a primary key. For a specific hub and hour, e.g., *hub* = 0, *dephour* = 10, (i) the columns *tds-exp*, *vs-exp* and *tas-exp*, contain ALL tuples of *lin*

Table 5: The *knn_ea* table data structure

hub	dephour	vs	tas	tds-exp	vs-exp	tas-exp
0	0	top-k entries (v) $hub = 0, hour \geq 1$	top-k entries (ta) $hub = 0, hour \geq 1$	all entries (td) $hub = 0, 0 \leq hour \leq 1$	all entries (v) $hub = 0, 0 \leq hour \leq 1$	all entries (ta) $hub = 0, 0 \leq hour \leq 1$
0	1	top-k entries (v) $hub = 0, hour \geq 2$	top-k entries (ta) $hub = 0, hour \geq 2$	all entries (td) $hub = 0, 1 \leq hour \leq 2$	all entries (v) $hub = 0, 1 \leq hour \leq 2$	all entries (ta) $hub = 0, 1 \leq hour \leq 2$
...
1	0	top-k entries (v) $hub = 1, hour \geq 1$	top-k entries (ta) $hub = 1, hour \geq 1$	all entries (td) $hub = 1, 0 \leq hour \leq 1$	all entries (v) $hub = 1, 0 \leq hour \leq 1$	all entries (ta) $hub = 1, 0 \leq hour \leq 1$
1	1	top-k entries (v) $hub = 1, hour \geq 2$	top-k entries (ta) $hub = 1, hour \geq 2$	all entries (td) $hub = 1, 1 \leq hour \leq 2$	all entries (v) $hub = 1, 1 \leq hour \leq 2$	all entries (ta) $hub = 1, 1 \leq hour \leq 2$

for targets T , with $hub = 0$ and t_d between 10:00 and 11:00 ordered by t_d , whereas (ii) the columns *vs* and *tas* contain only the best top-k (earliest arrival) distinct entries for targets T and $hub = 0, t_d \geq 11:00$.

Thus, the optimized EA- k NN query must implement those two separate cases: (i) Expanding the $l2$ tuples for a specific hub between e.g., 10:00 and 11:00 contained in DB columns *tds-exp*, *vs-exp* and *tas-exp* (still checking that $l1.ta \leq l2.td$ for those entries) and (ii) Expanding the $l3$ tuples that leave the specific hub after 11:00. As showcased earlier, both cases are included in a single row per hub of the *knn_ea* DB table. The resulting query is shown in Code 3. For combining those aforementioned cases we still have to use the UNION operator (Line 30) and for increasing performance, the JOIN between the *lout* and *knn_ea* DB tables happens AFTER expanding the *lout* tuples for q row and BEFORE expanding the tuples in *knn_ea* DB table (Lines 1-18). Note, that if each row in *lout* DB table contains on average $|L_{out}|/|V|$ tuples, then the optimized EA- k NN query will always access at most $|L_{out}|/|V|$ rows from the *knn_ea* DB table, thus minimizing secondary storage utilization.

THEOREM 3.2.2. *The construction of the *knn_ea* DB table and the corresponding EA- k NN query are correct.*

PROOF. For the EA- k NN query (q, T, t) , assume there is a tuple $l1 = \langle h, td, ta \rangle$ with $td \geq t$ for the query vertex q , included in the *lout* DB table. The EA- k NN query will join this tuple with exactly one row in the *knn_ea* DB table for which $hub = h$ and $dephour = FLOOR(ta/3600)$. This specific *knn_ea* row contains (i) all $l2$ tuples of targets T for $hub = h$ and $dephour$ between $FLOOR(ta/3600)$ and $FLOOR(ta/3600)+1$ (we still need to check for those entries that $l1.ta \leq l2.td$) but (ii) only the best top-k (earliest arrival) distinct $l3$ tuples for targets T that leave $hub = h$ after $FLOOR(ta/3600) + 1$. There is no need to search for any other tuples for $hub = h$ after $FLOOR(ta/3600) + 1$ because all other tuples will have worst arrival time than the $l3$ tuples. Also, there is no need to look for any other tuples for $hub = h$ before $FLOOR(ta/3600)$, because the $l1$ trip arrives at hub h after $FLOOR(ta/3600)$. Since the EA- k NN query will similarly join all tuples in *lout* DB that leave query vertex q after timestamp t , the resulting EA- k NN query is correct. \square

Considering the choice of an hour as the tuning parameter for grouping the *knn_ea* DB table entries, we could have chosen any other valid time interval to that purpose. In fact, we have even experimented with other intervals (smaller or larger than an hour) but (i) when smaller intervals are used, the respective *knn_ea* table has more rows (which makes queries slower) and (ii) when larger intervals are used (e.g., 3 hours) the number of tuples stored in *tds-exp*, *vs-exp*

and *tas-exp* columns vastly increases, which counteracts the benefit of the smaller number of total rows. Thus, a time interval of an hour seems like the best compromise between those two scenarios and worked well for all tested datasets. However, it can be tuned according to the specific use-cases and user needs for a particular public transit network.

In the case of LD- k NN queries, the corresponding *knn_ld* table will have a similar data structure to the *knn_ea* table. There are some main differences though: (i) Entries are grouped by hub and hour of ARRIVAL, i.e., for a specific hub and hour, e.g., $hub = 0, arrhour = 10$, the columns *tds-exp*, *vs-exp* and *tas-exp*, contain all tuples of *lin* for targets T , with $hub = 0$ and t_a between 10:00 and 11:00 ordered by t_d . Likewise, the combination of *hub, arrhour* will be the primary key. (ii) The columns *vs* and *tds* (and not *tas* as before) contain only the best top-k (latest departure) distinct entries for targets T and $hub = 0, t_a \leq 10:00$. The corresponding LD- k NN query (see Code 4) will also be slightly different (e.g., $MIN(n3.ta)$, $MIN(n2.ta)$ will be replaced by $MAX(n1.td)$ or the DESC ordering) but it will still offer the same performance benefits as before.

3.3 EA and LD One-to-many queries

Similar to k NN, we formulate the Earliest Arrival and Latest Departure One-to-many queries for schedule-based timetable networks, according to the following definitions:

- *Earliest Arrival One-to-many query* (EA-OTM). Given a stop q , a set of target-stops T and a starting timestamp t , the earliest arrival $EA-OTM(q, T, t)$ query seeks the earliest arrival time for all target-stops for trips that start from q no sooner than t .
- *Latest Departure One-to-many query* (LD-OTM). Given a stop q , a set of target-stops T and an ending timestamp t , the latest departure $LD-OTM(q, T, t)$ query seeks the latest departure times for trips starting from q and end in any stop $\in T$ no later than t .

Again the EA-OTM and LD-OTM queries have a wide range of useful applications, such as transportation planning (e.g., find faraway stops) or geomarketing applications (e.g., nearby what stop one must build a franchise store to be more easily reachable by clients). To the best of our knowledge, *this is also the first time that these queries have been formalized for public transportation*. How to efficiently solve them within *PTLDB*, will be shown in the following.

For answering the EA-OTM query, we need to build a new *otm_ea* DB table that will have the data structure showcased in Table 6. In the *otm_ea* table the columns *hub*, *dephour* (= hour of departure), *tds-exp*, *vs-exp* and *tas-exp* are identical to the *knn_ea* DB table and

```

Table 6: The *otm_ea* table data structure

hub	dephour	vs	tas	tds-exp	vs-exp	tas-exp
0	0	best entry per target (v) $hub = 0, hour \geq 1$	best entry per target (ta) $hub = 0, hour \geq 1$	all entries (td) $hub = 0, 0 \leq hour \leq 1$	all entries (v) $hub = 0, 0 \leq hour \leq 1$	all entries (ta) $hub = 0, 0 \leq hour \leq 1$
0	1	best entry per target (v) $hub = 0, hour \geq 2$	best entry per target (ta) $hub = 0, hour \geq 2$	all entries (td) $hub = 0, 1 \leq hour \leq 2$	all entries (v) $hub = 0, 1 \leq hour \leq 2$	all entries (ta) $hub = 0, 1 \leq hour \leq 2$
...
1	0	best entry per target (v) $hub = 1, hour \geq 1$	best entry per target (ta) $hub = 1, hour \geq 1$	all entries (td) $hub = 1, 0 \leq hour \leq 1$	all entries (v) $hub = 1, 0 \leq hour \leq 1$	all entries (ta) $hub = 1, 0 \leq hour \leq 1$
1	1	best entry per target (v) $hub = 1, hour \geq 2$	best entry per target (ta) $hub = 1, hour \geq 2$	all entries (td) $hub = 1, 1 \leq hour \leq 2$	all entries (v) $hub = 1, 1 \leq hour \leq 2$	all entries (ta) $hub = 1, 1 \leq hour \leq 2$

the combination (*hub*, *dephour*) again serves as the primary key. The only difference is in the *vs* and *tas* columns, where we must store the best tuple (earliest arrival) per vertex for the following hours, instead of only the top-*k* entries over all targets (as in *knn_ea* table), i.e., the *vs* and *tas* columns will store at-most $|V|$ tuples per row, instead of only *k*. Although this makes the resulting EA-OTM query slower, its SQL implementation is practically identical to the EA-*k*NN query (see Code 3). We only need to replace the *knn_ea* table with *otm_ea* (Line 16), remove the LIMIT *k* clauses (Lines 36,51,56) and use UNNEST(*tas*), UNNEST(*vs*) (Lines 30,31) instead of the lines 27,28.

Likewise, for LD-OTM queries we need to build the corresponding *otm_ld* DB table that follows the same structure as *knn_ld* DB table, except that in the *vs* and *tds* columns, we must store the best tuple (latest departure) per vertex for the PREVIOUS hours, instead of only the top-*k* entries over all targets (as in *knn_ld* table). The respective LD-OTM query is very similar to the previous LD-*k*NN query, as showcased in Code 4.

Conclusively, for any query vertex *q* (containing on average $|L_{out}|/|V|$ tuples), then the proposed *k*NN and *One-to-many* queries will always access at most $|L_{out}|/|V|$ rows from the respective *knn* or *otm* DB tables. Thus, it will be hard to achieve better secondary storage utilization inside a database. It is important to note that once we load the TTL labels and create the *lout* and *lin* DB tables, all the auxiliary DB tables within *PTLDB* (namely the *knn_ea*, *knn_ld*, *otm_ea* and *otm_ld*) may also be created by simple SQL commands (the corresponding queries were omitted due to space restrictions). This fact also demonstrates that *PTLDB* is truly a pure-SQL framework for servicing multiple route-planning queries on public transportation graphs. In the following experimentation section, we will benchmark *PTLDB*'s performance for various real-world datasets.

4. EXPERIMENTAL EVALUATION

To assess the performance of *PTLDB* on various public transportation graphs, we conducted experiments on a workstation with a 4-core Intel i7-4771 processor clocked at 3.5GHz and 32Gb of RAM, running Ubuntu 14.04. In our experiments, we use the same 11 public transportation networks from [19], as in Timetable Labeling (TTL) [23], where “each dataset records the timetable of the public transportation network of a major city or country on a weekday” [23]. The characteristics of these networks and the necessary TTL preprocessing (using the vertex ordering files provided by its authors) for creating the labels are presented in Table 7. The graphs’ average degree is between 53 and 413 and the TTL algorithm creates 630 – 7,230 tuples per vertex, requiring 4.5 – 353.6s for the labels’ construction.

Table 7: Public transportation graphs statistics

Graph	V	E	Avg degr.	HL / V	TTL Preproc. Time (s)
Austin	2K	317K	119	1,600	11.3
Berlin	12K	2,081K	153	1,734	184.7
Budapest	5K	1,446K	252	2,486	54.4
Denver	10K	7,11K	75	1,190	27.3
Houston	10K	1,113K	113	2,196	72.6
Los Angeles	15K	1928K	127	2,572	194.5
Madrid	4K	1,913K	413	7,230	338.5
Roma	9K	2,281K	258	4,370	353.6
Salt Lake City	6K	330K	53	630	4.5
Sweden	51K	4,072K	76	775	179.1
Toronto	10K	3,300K	305	2,987	262.1

PTLDB was implemented in PostgreSQL 9.3.6, 64bit with the same settings used in [14] (8192Mb *shared buffers* and 64Mb *temp buffers*). We conducted experiments belonging to the following query types: (i) Earliest Arrival (EA), Latest Departure (LD) and Shortest Duration (SD) *vertex-to-vertex*, (ii) Earliest Arrival (EA) and Latest Departure *k*NN and (iii) Earliest Arrival (EA), Latest Departure (LD) *one-to-many*. For each experiment, we used 1,000 random start vertices (and goal vertices for vertex-to-vertex queries), reporting the average running time. Starting timestamps for EA and SD queries are randomly selected from the first quarter of timestamp ranges, whereas ending timestamps for LD and SD queries are randomly selected from the fourth quarter of timestamp ranges, to ensure that in the majority of the cases we actually get trip results that service a particular type of query. Contrarily, selecting timestamps randomly from all available ranges would significantly lower query times, since a significant percent of those queries would provide no results (no trip would fill the suggested criteria). Before each experiment, we restart the PostgreSQL server for clearing its internal query cache and we also clear the operating system’s cache for accurate benchmarking. All *k*NN and one-to-many charts are plotted in logarithmic scale. Note that (i) *PTLDB* is the only pure-SQL framework tailored for servicing public transportation queries and (ii) to the best of our knowledge there is no previous work or any working system trying to tackle EA, LD *k*NN and one-to-many queries for such networks. Thus, we only present our results, since there is no previous secondary-storage work for comparison.

4.1 Performance on HDD

In our first round of experiments, we ran experiments on an HDD, specifically a SATA3, ST3000DM001, 7200rpm Seagate Barracuda disk with 64Mb cache.

Figure 2: EA, LD and SD v2v queries on a HDD

4.1.1 Vertex-to-vertex queries

Figure 2 shows results for vertex-to-vertex (v2v) queries for *PTLDB*. Results show that LD queries are 35% faster than EA queries, because in the LD queries we select timestamps from the fourth quarter of timestamp ranges where there are less trips than the beginning of the day (as in EA queries). SD queries are on average 26% slower than EA queries, due to the increased complexity of the query. In all cases, EA and SD queries take less than 19.2ms and LD queries take less than 7.7ms, which is an considerable achievement, since even main memory solutions (before TTL) would require a few ms for vertex-to-vertex queries and the suggested datasets [23]. Moreover, we may answer such queries with a simple SQL command inside a database, which ensures scalability, regardless of the numbers of users or the size of the datasets and with a performance that is fast enough for real-time online applications.

4.1.2 k NN queries

In this section, we provide the *PTLDB*'s results for EA and LD k NN queries. Similar to previous works [14], we will experiment with varying values of k and *target density* D , i.e., the ratio $|T|/|V|$, where T is the set of target-stops in the graph and V is the total number of vertices. As explained in Section 3.2.1, for database frameworks it makes sense to create large knn tables for the maximum value $kmax$ of k that will be serviced by the respective framework. Thus, we have created two versions of k NN DB tables for *PTLDB*, one for $kmax = 4$ and one for $kmax = 16$. Then, the k NN DB table for $kmax = 4$ is used for answering k NN queries for $k = 1$, $k = 2$ and $k = 4$ and the k NN table for $kmax = 16$ is used for answering k NN queries for $k = 8$ and $k = 16$.

In our first set of k NN experiments, we compare our optimized EA- k NN and LD- k NN queries (see Codes 3, 4) in comparison to the corresponding naive k NN implementation (Code 2) for varying values of k . Results are presented in Figure 3. Results show that the optimized versions are 11 – 53× faster than their naive counterparts. Thus, it really pays off to group tuples in the knn_ea (and knn_ld) DB tables by departure (arrival) hour. For the remainder of the paper, we will only provide results for the optimized EA- k NN and LD- k NN queries, since those queries provide significantly superior performance.

Figure 4 shows the absolute times of optimized EA- k NN and LD- k NN queries for the same scenario, i.e., for $D = 0.01$ and varying values of k . Results show that the EA- k NN queries require <64ms for all values of k (except the highest ratio $|HLL|/|V|$ dataset of Madrid and $k = 8, 16$). LD- k NN

Figure 7: EA, LD and SD v2v queries on a SSD

queries are even faster, requiring less than 32ms on all cases.

In our third set of k NN experiments, we assess the performance of *PTLDB* for varying values of D . For each value for D , we have build separate versions of knn_ea and knn_ld DB tables for $D \cdot |V|$ targets selected at random from each dataset and $kmax = 4$. Figure 5 shows results for $k = 4$ and $D = \{0.001, 0.005, 0.01, 0.05, 0.1\}$. Results show, that although *PTLDB*'s performance degrades for larger values of D , k NN queries may still be answered in less than 128ms (with the exception of Madrid for EA queries and Toronto for LD queries and $D = 0.1$). For the smaller datasets (Austin, Berlin, Budapest, Denver, Houston, Los Angeles, Salt Lake City, even Sweden) k NN queries always take less than 32ms. Moreover, EA- k NN queries are more robust to increasing values of D than LD- k NN queries that perform significantly worse for denser targets (i.e., for $D = 0.1$). Conclusively, the *PTLDB* framework provides excellent k NN query performance for all values of D and k .

4.1.3 One-to-Many queries

In our third round of experiments, we assess the performance of *PTLDB* for one-to-many queries. Figure 6 presents the corresponding results for varying values of D ($D = \{0.001, 0.005, 0.01, 0.05, 0.1\}$). *PTLDB* answers EA-OTM queries in less than 512ms for all datasets and values of D (except the Madrid and Toronto datasets that require 1084ms and 751ms respectively for $D = 0.1$). For LD-OTM queries *PTLDB* requires less than 256ms for all datasets and values of D (except the Madrid, Roma and Toronto datasets that require 303ms, 325ms and 349ms respectively for $D = 0.1$). Note, that for such high values of D , the *one-to-many* query almost degrades to the *one-to-all* query and hence, it cannot get any faster on a secondary storage device.

4.2 Performance on SSD

Having established *PTLDB*'s performance in the HDD, we repeat most previous experiments on a SSD (a SATA3 Crucial CT512MX100SSD1 MX100 512GB 2.5") to measure how the secondary-storage device type impacts results.

4.2.1 Vertex-to-vertex queries

Results for all variants of vertex-to-vertex queries on the SSD are shown in Figure 7. Results show that by using the SSD, *PTLDB* is 3 - 20× faster for EA, 6 - 17× faster for LD and 3 - 19× faster for SD vertex-to-vertex queries. Thus, EA queries may now be answered in less than 2.5ms, SD queries may now be answered in less than 3.2ms and LD queries may now be answered in less than 0.6ms. Conclusively, the usage

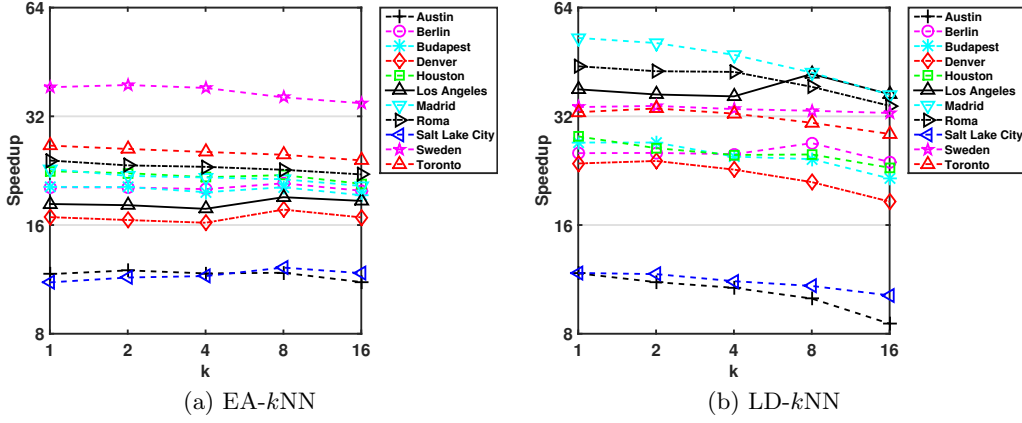

Figure 3: Speedup of optimized k NN queries, in comparison to the naive versions for $D = 0.01$ and varying values of k

Figure 4: k NN queries for $D = 0.01$ and varying values of k

Figure 5: k NN queries for $k = 4$ and varying values of D

of SSD benefits significantly all vertex-to-vertex variations within *PTLDB* and therefore *PTLDB* may easily be used for public-transit real-time applications and such queries, since query times always require less than $3.2ms$.

4.2.2 k NN and One-to-many queries

In this section, we repeated all the k NN and one-to-many experiments performed in Sections 4.1.2 and 4.1.3 on the SSD. Results for k NN queries, $D = 0.01$ and varying values

of k are presented in Figure 8. Results show that for k NN queries, the usage of the SSD does not provide any further benefits (in fact sometimes the SSD performs slightly worse), meaning that in *PTLDB* we have effectively minimized secondary storage utilization for k NN queries and thus, adding a faster storage medium adds no performance benefits. The same pattern was encountered on all experiments, for different values of D or k , including the respective one-to-many queries and therefore the resulting figures are omitted.

4.3 Summary

Our experimentation has shown that our proposed *PTLDB* framework provides excellent performance for all public transportation planning queries. Using HDDs, *PTLDB* may answer vertex-to-vertex queries in less than $19.2ms$. For SSDs, this time drops down to $3.2ms$. For the newly formulated EA and LD k NN queries, *PTLDB* requires less than $64ms$ and $32ms$, for $k = 16$ and $D = 0.01$ for the vast majority of the tested datasets. Even the EA and LD One-to-many queries require less than $512ms$ and $256ms$ respectively, for most datasets and varying values of D . Regarding memory requirements, *PTLDB* is very modest, since all DB tables and primary key indexes, including the *lout*, *lin*, *knn_ea*, *knn_ld* (for all values of D and $kmax = 4, 16$) and the *otm_ea*, *otm_ld* tables (for all available values of D) for all tested datasets, require less than $12GB$. Hence, *PTLDB* may easily scale to even significantly larger datasets. Overall, not only *PTLDB* is the only pure-SQL framework tailored for multiple public-transportation queries, offering excellent performance for real-time applications but the simplicity of its SQL queries, makes its integration with existing real-world applications very easy and seamless.

5. CONCLUSION

This work presented *PTLDB*, a novel SQL framework for answering multiple route-planning queries for public transportation graphs on a database. Our results showed that *PTLDB* provides excellent query performance, minimum secondary storage utilization and maximum scalability. Moreover, we have extended k NN and one-to-many queries for public transportation networks and proposed how to efficiently answer them within *PTLDB*, with a few lines of SQL code. This establishes *PTLDB* as a competitive database-driven solution for querying public transportation networks.

The paper gives the complete design and implementation details of *PTLDB* using a popular, open-source database engine, along with the exact SQL queries used in our implementation. This easily allows the replication of our results and might provide the necessary foundation for other researchers to expand the *PTLDB* framework towards handling additional types of queries and novel use-cases. In terms of future work, currently the *PTLDB* framework aims at optimizing travel times, without taking the number of transfers as an additional optimization criterion. Integrating this additional constraint would further improve the use-cases and marketability of the *PTLDB* framework.

ABSTRACT

The analysis of temporal behavioral patterns of home network users can reveal important information to Internet Service Providers (ISPs) and help them to optimize their networks and offer new services (e.g., remote software upgrades, troubleshooting, energy savings). This study uses time series analysis of continuous traffic data from wireless home networks, to extract traffic patterns recurring within, or across homes, and assess the impact of different device types (fixed or portable) on home traffic. Traditional techniques for time series analysis are not suited in this respect, due to the limited stationary and evolving distribution properties of wireless home traffic data. We propose a novel framework that relies on a *correlation-based similarity* measure of time series, as well as a notion of *strong stationarity* to define *motifs* and *dominant devices*. Using this framework, we analyze the wireless traffic collected from 196 home gateways over two months. The proposed approach goes beyond existing application-specific analysis techniques, such as analysis of wireless traffic, which mainly rely on data aggregated across hundreds, or thousands of users. Our framework, enables the extraction of recurring patterns (motifs) from traffic time series of individual homes, leading to a much more fine-grained analysis of the behavior patterns of the users. We also determine the best time aggregation policy w.r.t. to the number and statistical importance of the extracted motifs, as well as the device types dominating these motifs and the overall gateway traffic. Our results show that ISPs can exceed the simple observation of the aggregated gateway traffic and better understand their networks.

1. INTRODUCTION

The increasing diversity of home devices and network technologies have added layers of complexity to the connected home environment. Residential gateways (RGWs), Smart TVs, smartphones and tablets are just a few of the devices in today's connected home. Furthermore, several "over-the-top" services, such as video streaming (e.g., Netflix) and conferencing (e.g., Skype), are being delivered to a variety of devices and users using wireless home networks. Managing the connected home environment, and indeed optimizing the Quality of Experience (QoE) of residential users, emerges as a critical differentiator for Internet and Communication Service providers (ISPs and CSPs, respectively) and heavily relies on the analysis of home networks.

Although RGWs technology has been considerably improved to deliver IP-based, whole-home services as well as advanced WiFi capabilities as "Community WiFi" hotspots, ISPs still have little information about what lies beyond the subscribed RGW and how home network resources (e.g. bandwidth) are actually consumed by the underlying device ecosystem. For this reason, RGWs have been extended with continuous home network measurement capabilities under normal service operation and provide fine-grained connectivity, usage and performance data of home networks and devices¹. Mining recurring patterns from these home traffic time series can enable a *data-driven* paradigm in network management [13] in order, for instance, to reduce the cost for *serving* and *diagnosing* remotely home networks [3, 22, 11], or even to improve residential QoE via home-specific *bandwidth sharing* [1] and *prioritization* [21] policies.

More precisely, home networks troubleshooting is almost always reactively initiated by residential users, requires a human intervention and as a consequence is a time consuming (e.g., 38 min. average time of a technical support call [26]) and not always feasible task (e.g., user's problem is solved in only 14% of technical support calls, partially solved in 24%

¹Home network monitoring is of course subject of different low restrictions in different countries, and thus we are interested in non-intrusive passive probing techniques that guarantee anonymity.

and not solved at all in 62% [26]). One of the reasons of low efficiency of remote technical support is that technicians cannot completely understand the problem and home network settings, mainly due to limited and sometimes inaccurate information that residential users provide. Extracting previously unknown recurring patterns (aka motifs [19, 7]) from residential traffic time series will bring strong evidence of regular user activity in homes that can be contrasted to the trouble description reported by users. In particular, traffic patterns enriched with detailed home device information is a valuable input for root cause diagnosis. Moreover, in their majority, ISPs typically broadcast firmware and software updates to all gateways at nights (some operators even on a daily basis). This may cause service outages, given that some gateways may exhibit an active network usage during night time. A fine-grained temporal characterization of residential bandwidth consumption will enable ISPs to differentiate RGWs firmware update policies according to the least cumbersome time window per home, thus, improving the overall QoE of residential users.

In addition, home network resources (bandwidth) are shared not only among residents using an increasing number of on-line applications (e.g., social networking, gaming, uploading/downloading, etc.) and real time services (TV on demand, teleconferencing), but also with guests, neighbors, or even the occasional passersby. Existing methods for bandwidth sharing and traffic prioritization are static and coarse. ISPs usually allocate a fixed percentage of home bandwidth to non-residential users, while traffic prioritization in commodity gateways is at best based on the network port on which traffic is sent or received. We believe that behavioral patterns extracted by gateway traffic time series can be used to support dynamic policies for sharing home bandwidth that consider the online habits of residential users. For example, in-home traffic congestion can be avoided by ordering the traffic patterns of different devices observed especially during afternoon and weekends. These patterns reveal the bandwidth consumption behavior of different groups of residential users (adults and children employ different devices during the same time-slots) while the comparison of traffic domination help us to distinguish between residents and guests (pattern-specific vs global traffic dominant devices).

To the best of our knowledge, this paper presents the first thorough analysis of traffic dynamics of heterogeneous wireless (WiFi) devices connected to 196 real RGWs, which are subscribers of a major European ISP. We focus on a time-oriented analysis of *continuous traffic data* to extract *previously unknown patterns* recurring of internet consumption that happen within, or across homes. We also assess the impact of different types of devices, such as laptops, desktops (classified as “fixed” devices), and tablets, smartphones (classified as “portables”), on these patterns. Unsupervised learning techniques are used for patterns discovery as the ground truth data regarding home activities are not available. Rather than partitioning homes or devices into distinct behavioral clusters, we are looking to extract *informative motifs of bandwidth consumption* within or across homes. Different from a previous analysis of the same dataset [23], which focused on coarsely aggregated gateway traffic, in this paper we conduct various types of time series analysis, including a per-device analysis, motif extraction, and search of dominant devices.

In our study, we develop a framework for analyzing the

distribution properties of traffic data, the stationarity and predictability of usage patterns within and across homes, the similarity of device specific traffic to the overall home traffic, and others. We demonstrate that traditional techniques of time series analysis [20] are not suitable in our setting due to restricted stationarity of traffic time series. This is caused also by the fact that low-valued non-active traffic occupies the most of the probability mass of the traffic distribution, while the values of active traffic are detected as outliers. In contrast to Euclidean Distance and Dynamic Time Warping (DTW), the proposed approach better fits the requirements of our applications: (a) it correctly identifies similar trends, both when absolute values are important and when they are not; (b) it restricts the matches to time-aligned sequences; and (c) it provides a similarity measure, whose values (between -1 and 1) we know how to interpret based on the theory of statistics.

The main contributions of this paper are:

- 1) We propose a novel analysis framework for wireless home traffic data, namely: (a) a *correlation-based similarity* measure, which exploits the evolution characteristics, rather than the absolute traffic values, and is invariant to scaling; (b) a notion of *strong stationarity* that in addition to the similarity of data distributions imposes a correlation similarity across non-overlapping time windows; and (d) a definition of *dominant devices* based on the correlation similarity, that enables an intuitive and statistically grounded interpretation of the results.

- 2) We evaluate the effectiveness of the proposed framework using real data of wireless traffic observations and report the main findings: (a) there are many repetitive patterns within and across RGWs which describe the intrinsic user behavior of users and valuable to ISPs; (a) as networking time series are not stationary certain aggregation should be performed in order to find statistically significant patterns. The best time windows to aggregate home traffic data is found to be 8 hours for weekly patterns and 3 hours for daily patterns; (b) frequent weekly patterns correspond to heavy bandwidth usage both during weekdays and weekends, and frequent daily patterns correspond to (mostly) evening usage, (c) weekend usage tends to rely on portable devices, weekday usage relies more on fixed devices, while discontinuous usage within a day (mostly active in the evening or the morning) is still due to portable devices; and (d) almost every RGW involves a device that dominates its overall traffic, thus the behavior of this device should be mainly considered by ISPs while planning the updates.

The paper is organized as follows. Sections 2 and 3 describe the related work and our dataset. Section 4 shows the preliminary analysis of the wireless traffic. Section 5 describes the proposed methodology. Section 6 correlates the wireless traffic with home devices. Section 7 presents in detail the time aggregation and motifs analysis. Section 8 concludes the paper.

2. RELATED WORK

We consider several directions of related work that cover the specifics of analysis of wireless devices in home.

Wireless traffic analysis. The analysis of wireless traffic dynamics has been widely used to provide energy savings [12, 24], to build collaborative wireless networks [27], and to accommodate traffic offloading [16]. For example, recent proposals seek to power off idle Access Points (APs) [12]

or cellular base stations [24] to save energy. SEAR [12] forms clusters of WiFi APs and powers on/off APs of the same cluster based on the traffic demand that the cluster needs to serve. In a similar fashion, the system proposed in [24] powers off under-utilized cellular base stations when their traffic load is light, and power them on when the traffic load becomes heavy. Collaboration among APs has been explored in [27] to offer energy savings and load balancing in WiFi APs. The above designs though, are based on two key assumptions, which may not hold in RGWs. First, they are based on wireless traffic stationarity to predict idle times (e.g., the traffic volume is stable over short-term (2 hours), which can remain stable over several consecutive days [24]). Second, a set of devices (e.g., APs or base stations) show very similar temporal traffic characteristics. Our analysis shows that these assumptions do not hold in our case.

Human behavior. Multiple works demonstrate that the behavior of humans can be described through recurrent activity patterns. This is shown in the work [4] for social network data, in the work [31] for user behavior in microblog and in the work [10] for moving trajectories using mobile phone data. According to the results of work [10] the patterns of human mobility behavior are very regular. Home traffic data which we focus on is also determined by human behavior, but unlike previous studies it is not defined by a single individual but by a group of individuals who share one home. This leads to less repetability an large variety of possible activity patterns, making the analysis of RGWs more challenging.

Work [14] analyzes human correspondence behavior via mobile phone data. As in the other human activity studies [15, 9, 5], the data show high inhomogeneous in activities, meaning that periods of active events are much shorter than inactivity silence. This leads to the bursty time series with long tails in the probability density function. We observe this property for our data as well while pattern extraction is needed to take place on more regular data. Study [14] checks whether the inhomogeneous of correspondence behavior is due to daily or weekly periodical patterns or it is due to the nature of the behavior of human task execution. According to the results of this study, even after de-seasoning when daily and weekly periodical patterns are excluded, the data remains inhomogeneous, which means that the character of human activities is one of the main sources of bursty time series. Unlike mobile phone data, where long silence periods were observed in night time and during weekends, our networking data for certain homes have peak activities exactly in this “silence” periods. This means that in our case de-seasoning is not applicable as there are no strong daily and weekly silence period for all homes into consideration. Thus, we safely assume that the heterogeneity of our data is caused by human activities even to larger extend than for phone call data. In our work we concentrate on reducing inhomogeneous data characteristics by other means, such as by excluding background traffic from consideration and by specially devised distance measure for traffic time series. Then, we extract recurrent activity patterns of usage behavior using the technique of motifs.

Motifs. Mining of motifs or sequential patterns is an important task in time series analysis [19], [7]. As far as we know this kind of analysis has not been applied to the internet traffic data before as most of the studies use aggregated traffic values instead of time series. For this task, we

considered several state-of-the-art tools for motif discovery, such as GrammarViz [17] and VizTree [18]. However, these tools are not suitable for our analysis for the following reasons. (a) These tools (and many other techniques available online) use Symbolic Aggregate approXimation (SAX) to represent time series, assuming that the distribution of time series values is normal [19]. This is not true for our traffic time series though, as their values follow the Zipf’s law (we note that, contrary to the claims in [19], z-normalization does not lead to normal distribution if the initial distribution of the time series is not normal). At the same time we do not have ground truth data about the motifs in order to tune the alphabet size of SAX, which assigns more symbols near the value of zero, while in our case this region should have been coded with only one symbol. (b) GrammarViz seeks to discover motifs of different lengths, and exploits grammar distance for this. On the other hand, our data has clear time semantics, and we would like to discover motifs for week- and day shifting (i.e., non-overlapping) windows of fixed length, that is not enabled with GrammarViz.

3. DATASET DESCRIPTION

We analyze wireless traffic data collected from 196 residential gateways under normal service operation, involving subscribers of a large European ISP that are distributed over a large geographic area spanning 10 cities. The residential subscribers participate on a voluntary basis to our large scale data collection campaign. For privacy reasons, we do not collect data regarding running applications of home devices, demographics and activities users are engaged in.

The gateway platforms of our deployment have the following specifications: (i) ADSL2+ modem or fiber WAN access link, (ii) 4 ethernet ports, (iii) a WiFi access point enabled by a Broadcom 802.11b/g/n 2x2 radio. The 802.11 interface operates at the 2.4GHz band and supports PHY rates up to 300 Mbps. The most (67%) of our deployment’s gateways are fiber (92% of the fiber plans provide 100/10 Mbps downstream/upstream speed, and for the rest it is 30/3 Mbps) and the rest are ADSL (with 24/1 Mbps downstream/upstream speeds). Each gateway logs the traffic counters at all network interfaces on the IP layer, and reports in bytes the cumulative outgoing (transmitted) and incoming (received) traffic of each connected device to the gateway. The focus of this work is the WiFi traffic. The gateway further reports the aggregated gateway traffic, which is the sum of the corresponding outgoing and incoming traffic of all its devices. These data measurements are automatically reported every minute by each gateway to a central server. Note that the wireless traffic reported by a gateway depends on the running applications’ data rates and is bounded by the wireless effective throughput or the access link throughput (for traffic exiting/entering the home). A recent study though [23] has shown that wireless (and wired) network throughput is rarely the bottleneck.

Our dataset includes more than 20 million measurement reports collected over a 2-month period (starting from March 17, 2014). We were able to identify a total of 2147 distinct wireless devices (a device is defined by its MAC address). Using a heuristic-based algorithm [25], we were able to infer the type of a wireless device. The heuristic algorithm leverages the device MAC address (revealing manufacturer name) and the device names typically assigned by the user, which are reported by the gateway. For example, “Nintendo

Co., Ltd.” is known to produce game consoles, “EPSON” – peripheral devices, while “Katy’s-iPhone”, indicates a smartphone manufactured by Apple. We have validated the effectiveness of the algorithm using ground truth data collected from surveys at 49 homes of our deployment. All ‘light’ devices such as smartphones, tablets and others are labeled as “portable”, while laptops and desktops fall under the “fixed” category. There is also a category of “network equipment” that includes devices such as WiFi extenders, and additionally there is a small amount of “game consoles”.

4. STANDARD DATA ANALYSIS

In this section, we study the main data characteristics (distribution and stationarity) of the traffic time series observed by the RGWs in our deployment, and discuss the challenges arising in this task when using traditional analytical techniques.

4.1 Traffic Data Distribution

We first conduct a preliminary analysis using the wireless traffic data of the 10 most representative gateways with the highest number of observations for a single week period. Our analysis aims to answer the questions: (a) What are the main properties of the distribution of traffic values? Are probability density functions of traffic counters similar across gateways? (b) Which kind of traffic (outgoing, incoming, or overall) provides the most meaningful description of a gateway? To answer these questions, we exploit the following methods:

- 1) *boxplots* in order to visualize general probability distribution and outliers of time series, and
- 2) *estimation of probability density function (PDF)* using Kernel Density Estimators in order to assess and compare the probability distributions of time series.

The above methods lead to the following results: (a) The distribution of incoming and outgoing traffic of gateways follows Zipf’s law (see Figure 1a), which means that the concentration of low traffic values is much larger than the amount of medium and high traffic values. The periods of really active traffic are very small, and thus detected as outliers in data distribution plots and boxplots. As an example, we show a typical time series in Figure 1b, an approximation of its PDF using Kernel Density Estimation zoomed around 0 of the y-axis in Figure 1a, and its boxplots with and without outliers in Figures 1c and 1d. This phenomena is also called inhomogeneity of data and as we mentioned in Section 2 it is typical for data describing human activities. (b) According to our results, there is a strong correlation between the incoming and outgoing traffic (mean = 0.92, median = 0.95, stddev = 0.08) of the gateways in our deployment. Since they are strongly correlated, we consider that the overall traffic of a gateway reflects the active behavior of a user without artifacts.

Summary. Since low traffic values account for most of the probability mass, the traffic values reported when devices are actually used are essentially detected as outliers in data distribution plots and boxplots considered by traditional time series analysis techniques. This motivates us to characterize the background traffic (Section 6.1) and remove it when looking for recurring patterns of active internet consumption. In this context, z-normalization alone does not help, as we want to consider also similarity of rankings of traffic values.

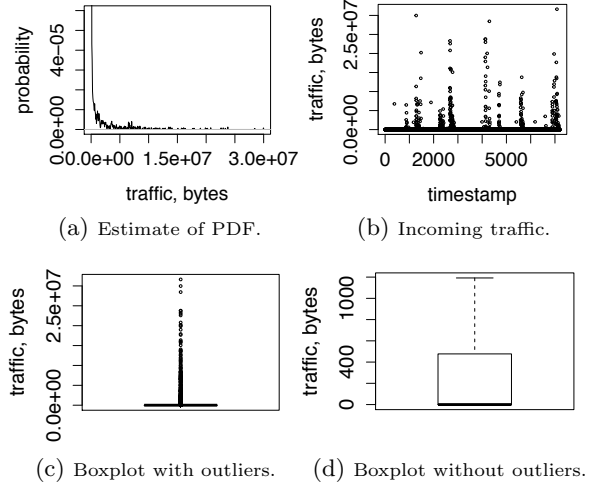

Figure 1: Statistical analysis of a typical gateway.

4.2 Traffic Correlation and Stationarity

We now turn our attention to the following questions regarding the characteristics of the data: (a) Is the behavior of traffic counters similar among gateways? (b) Is there significant autocorrelation in the traffic of a gateway, or significant cross (lag-)correlation between gateways, or in general, what is the predictive power of the time series under examination? (c) Is the traffic of a gateway stationary in a short term period? (d) Is there a relationship between the number of connected devices and the traffic values? (e) Are home traffic time series sensitive to time aggregation? We use the following standard analysis techniques:

- 1) *correlation coefficients* – to measure similarity of RGWs;
- 2) *autocorrelation coefficients* – to evaluate how strong the connections between the values of a single time series are, and what their predictive power is;
- 3) *cross-correlation coefficients* – to measure how strong the connections between values of a pair of time series shifted in time are, and what their predictive power is;
- 4) *stationarity tests* (KPSS unit root test, Augmented Dickey-Fuller (ADF) test and others) – to check if time series are wide-sense stationary.

In all our experiments, when statistical tests are exploited, we use a significance level of $\alpha = 0.05$. For correlations tests, we use Pearson’s, Spearman’s, and Kendall’s correlations, and interpret the strength of the correlation as follows: $[0.0; 0.1) \rightarrow$ No Correlation, $[0.1; 0.3) \rightarrow$ Low Correlation, $[0.3; 0.5) \rightarrow$ Medium Correlation, $[0.5; 1] \rightarrow$ Strong Correlation. This interpretation is widely accepted [2], [6], [29], though the borders may slightly vary depending on the application domain, for example, in medicine higher borders for strong correlation are usually required [28].

The above methods revealed the following results:

- (a) There are gateways, for which we can make predictions about their future behavior due to low, but statistically significant autocorrelations of their traffic time series. The example with the highest autocorrelation is shown in Figure 2(left). In this figure, the y-axis defines the value of Autocorrelation Function (ACF) that depends on the time lag between the time series values (x-axis). We note that no gateway exhibits a seasonal behavior. There is also some predictive power of one gateway given another, as some cross correlations with lags across gateways are significant. An example of a high cross-correlations is depicted in Figure 2(right). Even-though these observations suggest some predictive power, due to the significant amount of silence or

Figure 2: Autocorrelation (on the left) and cross-correlation (on the right) of gateways.

background traffic, ARIMA modeling for this time granularity cannot yield useful results, as it is not able to predict the rare bursts of the active traffic.

(b) Wireless traffic data is not stationary in the traditional sense, as all stationarity tests were rejected. This means that the data distribution characteristics change over time. For example, the covariance function of the time series is not constant in sliding window. We have also noticed that the Zipfian distribution of time series also evolves over time, meaning that the time series are also not stationary in the general sense.

(c) For all the gateways we checked, the correlation between the overall traffic time series and the number of connected devices time series was statistically significant, but low (mean = 0.37, median = 0.38, stddev = 0.21). This is an interesting result, indicating that traffic at a gateway depends more on the user behavior, rather than on the number of connected devices.

(d) For the time-aggregated time series with larger time binning, patterns become more visible as traffic peaks become more similar. At the same time, when excluding many points of low traffic, the essential information about the high traffic periods persists. Correlation and distribution heavily depend on time aggregation:

— The smaller the aggregation period is, the more different the data distribution within the week is. Almost all Kolmogorov-Smirnov tests were rejected for the smallest aggregations. For higher aggregation periods distributions become more similar.

— The smaller the aggregation period is, the lower the correlations between time series are. At the same time, for larger aggregation periods correlations either significantly grow, or disappear completely.

Summary. Our preliminary analysis of gateway traffic reveals that traffic time series are not stationary, neither in the general, nor in the wide sense: both the probability density function and the main time series characteristics (e.g., mean and covariance) change over time. Consequently, time series with current one minute binning are highly irregular, there are no stationary gateways, and similarity between different gateways of our deployment is very low. Hence, extracting meaningful patterns of bandwidth usage both across time and gateways requires to adapt new analytical methodology.

5. TRAFFIC ANALYSIS FRAMEWORK

We now define and describe the key concepts, on which we base our proposed analysis framework.

Similarity. The core issue when comparing traffic time series of residential gateways is to define a suitable similarity measure. As discussed earlier, absolute values of traffic volume are not helpful to understand seasonal usage of home devices within or across homes. Instead, we consider similarity in terms of correlation, which takes into account the monotonicity of traffic volume changes, rather than their ab-

Figure 3: Hierarchical clustering of time series based on correlation similarity measure.

solute values, thus, providing invariance to scaling. We use three popular correlation coefficients as all kinds of dependencies between traffic time series described by these coefficients are important. *Linear* dependency is provided by Pearson's correlation, and *monotonicity* and *ranking-based* dependencies are provided by Spearman's and Kendall's coefficients. The correlation coefficients are not directly comparable but they have the same domain and semantic interpretation of strength, allowing us to use the highest possible value. More formally, the similarity measure is defined as follows:

DEFINITION 1. Correlation similarity measure $cor(X, Y)$ between two time series $X = \{x_i\}_{i=1}^n$ and $Y = \{y_i\}_{i=1}^n$ is a maximum correlation coefficient among statistically significant Person's $r(X, Y)$, Spearman's $\rho(X, Y)$ and Kendall's $\tau(X, Y)$ correlation coefficients:

$$cor(X, Y) = \max[r_{p_v < \alpha}(X, Y), \rho_{p_v < \alpha}(X, Y), \tau_{p_v < \alpha}(X, Y)].$$

If none of the three correlation coefficients are statistically significant $cor(X, Y) = 0$.

The significance of the corresponding correlation coefficient test is defined w.r.t. the zero-hypothesis H_0 is that there is no correlation, or the coefficient is equal to zero. The significance level α is (as before) set to 0.05.

A correlation-based similarity measure also leads to meaningful threshold values for time-series similarity. For example, in the hierarchical clustering of traffic time series illustrated in Figure 3, the distance measure is set to $1 - cor(\cdot, \cdot)$. As the correlation ≥ 0.6 is considered to be high, the corresponding threshold on a distance measure 0.4 is used to detect similarity clusters.

Spearman's and Kendall's correlation coefficients are insensitive to z-normalization of the data, while the Pearson correlation coefficient is normalization dependent. As we will see in Section 6.2, our correlation-based similarity measure allows to better grasp the actual device usage compared to similarity measures based on absolute values, such as the popular Euclidean distance. Euclidean and DTW distance also do not meet the needs of similarity measurement in the work [30]. This work extracts the patterns of human behavior but in terms of time series of item popularity over

online media and also proposes a distance measure invariant to scaling. But, unlike our case, they also consider the patterns to be similar if the peaks of activities are shifted in time. In case of behavioral patterns that are valuable to ISPs it is important that the traffic is active simultaneously or within the same aggregated time periods.

Stationarity. Since our goal is to extract time-evolving patterns and characterize these patterns across different dimensions of interest, we define a new notion of stationarity adapted to the peculiarities of our traffic time series. Our traffic data has very strong time semantics — traffic depends highly on the day of the week and on time of usage, so we cannot expect that the data distributions during the weekend and working days are the same. Thus, we are interested in time-framed patterns (from one day to another, or from week to another) and consider regularity of behavior in terms of non-overlapping time windows. In this respect, we measure the correlation similarity of the time series with itself, comparing each window of the chosen period with each other, in order to measure the entire stationarity of a period of interest. We also check whether the traffic data distribution changes significantly from one period to another using a non-parametric comparison test for arbitrary probability distributions (i.e. Kolmogorov-Smirnov test). More formally:

DEFINITION 2. *A time series of a gateway is **strongly stationary** for a particular window size if:*

- *it has a correlation similarity measure > 0.6 among all non-overlapping windows in consideration;*
- *the Kolmogorov-Smirnov test (that checks if the distributions of two time series is the same) is not rejected for all possible window pairs.*

The main difference between our 'strong stationarity' notion and the classical stationarity is that instead of using sliding windows, we use non-overlapping windows. Furthermore, apart from the similarity of the distributions, we also check the correlation similarity between the windows, which makes this a 'strong' notion of stationarity. Asserting that the time series of a gateway is strongly stationary, ensures that the underlying bandwidth usage is regular and can be described by a repetitive usage pattern.

Time aggregation. We use the notions of correlation similarity measure (Definition 1) and strong stationarity (Definition 2) in order to formulate optimization criteria for choosing the best time periods for aggregating traffic values, or the best binning of time series. More formally the problem is defined as follows:

DEFINITION 3. *Given a mapping function W of nonoverlapping time windows of length g defined over a set of times series U , the **best aggregation granularity** $g_{best} \in G$ is defined as*

$$g_{best} = \arg \max_{g \in G} E[cor(x(g), y(g))],$$

where $x(g), y(g) \in S$, a set of time series S defined from U through W : $S = W(U)$, $x(g)$ and $y(g)$ are aggregated traffic volume values according to the time binning g .

Mean is used as an unbiased estimate of $E[\cdot]$.

As we will see in Section 7.2, deciding which is the best traffic aggregation binning is crucial for extracting unknown meaningful recurring patterns of medium-term (week) and short-term (day) usage behaviors of a residential gateway. These patterns are called **motifs**.

Dominant devices. We also need to detect dominant devices per gateway, that is, the devices that have traffic time series very similar to the overall traffic of a gateway. We define a dominant device as follows.

DEFINITION 4. *Device d is ϕ -dominant per a gateway if the correlation similarity between its traffic and gateway traffic is larger than a threshold ϕ .*

Besides determining dominant devices of the traffic reported by the gateways of our deployment (Section 6.2), this definition will enable us to better characterize the motifs in terms of types of devices that contribute to the traffic of the motif the most (Section 7.2).

6. GATEWAY DEVICE ANALYSIS

In this section, we are interested in identifying the active usage traffic generated when residents actually run online applications, as well as in detecting the devices that contribute the most to the overall traffic.

6.1 Active Device Traffic

As we have seen in Section 4.1, the majority of the traffic volume values reported by the gateways are rather low. This background traffic is essentially attributed either to the control traffic generated by the operating systems of devices (e.g., during sleep mode or application software updates), or to low traffic generated by light applications running in the background (e.g., when a mail server checks for new emails, or when twitter updates the message list). Background traffic has its own patterns and fluctuations that influence our time-series analytics given that the majority of wireless devices in our data, such as tablets and smartphones, are frequently in the idle state and use their wireless radio rarely in order to increase the battery life.

In order to extract recurring patterns from active usage traffic generated when residents actually run online applications, we need to exclude the background traffic. Background traffic can be separated from active traffic by setting a threshold τ on the number of bytes in traffic time series. To obtain active traffic time series, all the values which are lower than τ are set to zero. Deciding on an appropriate threshold τ for background traffic is far from trivial, given the lack of a ground truth (both on the operating systems for particular sleep policies and the applications running on devices). Instead, we can exploit a general statistical technique based on the probability distribution of the traffic time series, as the boxplots described in Section 4.1. Given that the interval in which most of data values of time series belong falls between the whiskers of the plot, we use the upper whisker of a boxplot in order to define τ . This is supported by the fact that background traffic values are the most frequent in our data, while active traffic is sparse.

As this threshold is device specific, we estimate it for each device, per outgoing and incoming traffic separately. We study the background traffic for four weeks of data. For this period, we observed the traffic for 934 devices connected to user gateways. According to the histograms for outgoing and incoming traffic (refer to Figure 4), the background threshold for most of the devices is below 5000 bytes per minute (i.e., less than 1 Kbps), while for almost all the devices τ is lower than 40,000 bytes for both outgoing and incoming traffic, which corresponds to a rate of 5.3 Kbps. There are

Figure 4: Distribution of τ of outgoing (on the left) and incoming (on the right) traffic. 24 devices with $\tau > 40000$ bytes for incoming traffic, and 15 devices with $\tau > 40000$ bytes for outgoing traffic.

We checked if there is a dependency on the type of device and the distribution of traffic it produces. We grouped the devices by τ as follows. 'Small' group corresponds to $\tau \leq 5000$, 'medium' to $\tau \in (5000, 40000]$, and 'large' to $\tau > 40000$. We use the types of devices defined in Section 3. In the small and medium groups portable devices dominate, while in the last group fixed devices are the most popular as on PCs and laptops much more applications can run simultaneously in non-active mode. Thus, background traffic can be a significant feature for device type classification.

In summary, to exclude background traffic from consideration, we use a threshold per device of $\tau_{back} = \min(\tau, 5000)$. This value is an upper border of the background traffic for the majority of the devices, as illustrated in Figure 4. Our threshold of 5000 bytes per minute for background traffic is also consistent with the previous works [25], [23], which set it to 1 kbps, thus making our threshold more tight.

As we will see in Section 7, background traffic removal reveals more regularity in traffic time series. The ability to automatically detect the background traffic of a device will also help ISPs to improve the energy saving policies *without* using data aggregation from multiple homes as has been proposed in the literature [8].

6.2 Dominant Devices

A device is considered to be dominant if it characterizes the general behavior of a gateway over time with respect to the overall traffic. As before, we only consider wireless traffic and wireless devices.

Definitions 1 and 4 are used in order to detect ϕ -dominant devices. As we are interested in high time series similarity we have chosen ϕ threshold to be 0.6, as before only statistically significant correlations were reported. We perform the search of dominant devices for all the gateways that have at least one observation per week for each week of consideration, we have observed 153 such gateways. The data contains the time series of all devices that were connected to a gateway after March 17, 2014 together with its overall traffic. If there are several dominant devices detected, we rank them in descending order of their correlation similarity.

According to the results, 7 gateways had 3 dominant devices, 43 gateways had 2 dominant devices, 99 gateways had 1 dominant device, and only 4 gateways did not have any dominant device. In most of the cases, there is at least one dominant device per gateway, meaning that the bandwidth consumption of the gateway is determined by the usage of the device. There might be several dominant devices, which can indicate that the number of residents regularly using network is higher than one. There are at most 3 dominant devices per gateway, we ranked them in the descending order of correlation similarity value, hence, first dominant devices

has traffic time series that is the most similar to the overall traffic time series of a gateway.

We also checked what type of devices are dominant per gateway. Overall, among dominant devices we detected 74 fixed, 67 portable, 53 unlabeled, 9 network equipment devices, and 3 game_consoles. The distribution of the different device types, depending on the ranking of dominance, is shown in Figure 5. The plot shows that there are many gateways, for which the dominant devices for all the ranks are fixed devices. This is attributed to the fact that fixed devices produce in general more traffic and are usually connected for longer periods to the gateway. Still among dominant devices there is a significant number of portable devices, which are increasingly being used nowadays.

Figure 5: Distribution of types of dominant devices given their ranking.

The knowledge of dominant devices over long periods (one month in our case) is of great importance to ISPs, as it can provide a high level profiling of gateways.

Using Other Distance Metrics. For the sake of completeness we have compared the dominant devices obtained using our correlation-based similarity measure with those obtained when using the Euclidean distance or simply the absolute traffic volume used in work [23]. For the Euclidean distance computation, we consider the time series of a gateway $X = \{x_i\}_{i=1}^n$ and time series of a device $Y = \{y_i\}_{i=1}^n$, where n is the number of observations for four weeks of data. The Euclidean distance is computed using the formula: $dist_{Eucl} = \sqrt{\sum_{i=1}^n (x_i - y_i)^2}$. Alternatively, the devices which produce the highest volume of traffic are considered to be dominant traffic-wise.

As there are no clear thresholds for Euclidean and traffic-based dominances, we compare the results of our correlation-based dominant devices, where we used meaningful threshold, with the devices that are ranked using the Euclidean distance (ascending order) and the traffic volume (descending order). Using the correlation dominance we have detected 206 dominant devices. For some gateways there can be two or three dominant devices. For each gateway we detect its correlation-based dominant devices and obtain a ranking of dominant devices based on the other two measures. Then if the devices in the ranking are the same, meaning that the first device in one ranking is also the first in the second ranking and so on, we say that the devices are detected equally using the two measures.

Among the 206 dominant devices, 182 (88%) are ranked the same as Euclidean-based dominant devices, and 151 (73%) are ranked the same as traffic-based dominant devices. Nevertheless, there are many cases, where dominant devices have lower overall traffic (around 15%), even though they closely follow the traffic time series of the gateway, with an exception of a few bursts (3 or 4). Our similarity measure is able to detect these devices, which cannot be detected

using the Euclidean and traffic-based distances.

We have also tried more strict ϕ threshold for dominance, $\phi = 0.8$. Even with very tight constraint on dominance, there is still large amount of gateways (67%) that have at least one dominant device and the ratio of fixed devices among the dominant devices is even larger.

Dominant Devices and Number of Residents. Having the results of a recent user survey over a subset of 49 gateways in our deployment, which contained information on the number of users per gateway, we checked if the number of dominant devices is correlated with the number of residents. The result of this analysis showed that there is no evidence of significant correlation. This may be due to the fact that different users are active during different periods of time, and in case of multiple users (and therefore multiple devices) the number of overall dominant devices is lower.

On the other hand, in the gateways with one user, there is always one dominant device detected. In the case of two users (9 gateways), 2 dominant devices are detected in 5 gateways (56%) and 1 dominant device is detected in 4 gateways (44%) and there are no three dominant devices detected. We have calculated the correlation coefficient between the number of dominant devices and the number of users only for gateways with 1 and 2 users, and we obtained a statistically significant correlation value = 0.53. In the case where the number of users > 3 , the effect of multiple devices, discussed in the previous paragraph, is present again, and only 1 or 2 dominant devices are detected.

Summary. The most interesting findings of our analysis of dominant devices per home are:

- 1) Each gateway has at least one dominant device.
- 2) The majority of dominant devices are fixed devices.
- 3) Correlation based dominance is beneficial because it identifies dominant devices that are missed by Euclidean, or traffic-based distance notions.
- 4) The number of dominant devices provides a lower bound for the number of residents per gateway.

7. TIME AGGREGATIONS AND MOTIFS

In this section, we are interested in investigating which time aggregations of gateway traffic better reveal regular user behavior in houses. For example, whether the produced traffic is more significant in the morning rather than in the evening, during the weekdays rather than the weekends, etc. By checking various meaningful time aggregations ranging from 30 minutes to 12 hours, we have experimentally verified that the larger the aggregations are, the more correlations are observed within or across gateways. This is due to the fact that the periods of non-active traffic become smaller, while traffic peaks become more similar. If at the same time we exclude the points of background traffic, the actual usage patterns of home gateways become more visible.

Since there is no golden standard as to which aggregation should be used, the choice is usually application driven. In our work we rely on the notion of strong stationarity (see Definition 2) capturing repetitive usage patterns of gateways to systematically determine the right aggregation level. If a time series is strongly stationary, then the patterns found for this time series are stable and we can generalize the results of the analysis over this time series. This is not always truth if standard binning such as morning, working hours, late afternoon, evening, night is used, because usually the borders of this binning, number of bins and their length is

(a) Average correlation for stationary gateways starting at midnight

(b) Average correlation for stationary gateways starting at 2am

Figure 6: Aggregation curves for weekly patterns.

not experimentally verified but just arbitrary set.

We consider two kinds of windows: daily-windows starting from midnight to reveal short-term patterns of usage behavior and weekly windows starting from Mondays to reveal medium-term patterns. For four weeks of data and a weekly period with 3 hours aggregation 7% of gateways appeared as stationary. Thus, though there are strongly stationary gateways, still most of them change their behavior from week to week. Finally after removing the background traffic (see Section 6.1) 11% of gateways were detected as stationary. In the next section we choose the best aggregation period according to maximization of time series correlation.

7.1 Best Aggregation Period

In this section, we discuss how to choose the best aggregation period, according to the maximization of the time series correlations across time. The problem is formally stated in Definition 3. Background traffic is removed from all time series, as described in Section 6.1.

7.1.1 Weekly Patterns

First, we consider the best aggregation for medium-term patterns of weekly behavior. As traffic depends heavily on the time of the day from day to day we considered all time aggregations starting at midnight that are factors of 24 hours, namely 1, 2, 3, 4, 6, 8, 12, 24 hours and additionally we considered initial time series aggregation, which is 1 minute. We also try aggregation granularities which are larger than 2 hours, starting from 2am and 3am. For the analysis, we consider all the user gateways that have at least one traffic observation every week during the 4 weeks of interest. The total number of such gateways is 153.

An aggregation period is considered to be the best if it reveals the highest correlation of traffic time series of a gateway values from one week to another.

In order to compare aggregations, we calculate the average correlation among all the week-week pairs separately for each gateway, and for strongly stationary gateways (Definition 2). The plots of the average correlation values are shown in Figure 6.

The maximum points for strongly stationary gateways are reached at granularity periods of 6, 8 and 12 hours for aggregations from midnight (Figure 6a) and 8 hours for aggregations starting from 2am (Figure 6b). When considering all the gateways, large correlation points are reached for 3, 4 and 6 hours of aggregations starting at midnight, while 8 hour aggregations starting at 2am is still a maximum point. Since the 8 hours aggregation period starting at 2am is an absolute winner for weekly patterns, we use this aggregation for our further analysis. Note that this aggrega-

Figure 7: Stationary gateways per aggregation window.

gation has a meaningful semantic interpretation: each day is divided into 3 periods, namely, "morning" between 2am-10am, "working hours" between 10am-6pm, and "evening" between 6pm-2am. The traffic behavior of gateways for this aggregation is also of interest to ISPs.

7.1.2 Daily Patterns

As the initial observations are received at a rate equal to 1 minute, and for daily patterns we need to have a reasonable amount of points, we try the following aggregation periods: 1, 5, 10, 30, 60, 90, 120 and 180 minutes. We do not consider aggregations larger than 180 minutes as it is not desirable to have less than 8 data points per pattern. All the binning values are factors of 1440 minutes, which constitute a day.

As before we define the aggregation period to be the best if it reveals the highest correlation of traffic time series of a gateway values for daily patterns. Unlike weekly patterns, we do not require every day to be similar to each other, but we expect that Mondays should be highly correlated with Mondays, Tuesdays with Tuesdays, etc. For the analysis, we consider all the user gateways that have at least 1 traffic observation every day during the 4 weeks of interest. Their number is 100.

For daily patterns we also studied strongly stationary gateways, where the behavior of the same days of the week is stationary (in the sense of Definition 2). Note that for stationarity we require not only highly correlated observations among the corresponding days of the week (e.g., all Mondays should be correlated with each other), but we additionally require that the probability distributions of all instances of that weekday should be similar. The number of stationary gateways per aggregation granularity is shown in Figure 7. We also decompose the total number of stationary gateways to the number of gateways which have one stationary day of the week, two stationary days, and so on.

Figure 7 shows that the number of stationary gateways grows with the aggregation granularity. Additionally, more days are stationary within the same gateways if the granularity is larger.

In order to compare the aggregation granularities we calculate the average correlation among all the pairs of the same day of the week separately for all gateways and for gateways that appeared to be strongly stationary. The plots of average correlation are shown in Figure 8.

The results show that small aggregation periods correspond to low regularity in the data; moreover, there are no gateways with at least 1 stationary day of week for aggregation granularities of 1 and 5 minutes. The correlation value for all the gateways grows significantly up to 1 hour aggregation, then it becomes stable up to the level of 180 minutes or 3 hours. At the same time, the average correlation of the stationary gateways keeps growing with the larger aggregation granularity, and the highest value is reached for the 3 hours aggregation granularity, which is the aggregation pe-

Figure 8: Aggregation curves for daily patterns.

riod we use for daily patterns in the rest of this study.

7.2 Motif Discovery

As mentioned in Section 5, for motif extraction we only consider patterns that correspond to medium-term (week) and short-term (day) usage behaviors across time and across gateways. Patterns within a particular gateway only or of a longer period can also be identified following the proposed methodology.

The following definition of a motif is used in our work:

DEFINITION 5. Given a set of times series U , a mapping function W of non-overlapping windows, which extracts periods of interest S from U according to a window length and its starting point synchronizes with the corresponding timestamp of U (beginning of a day or a week), $S = W(U)$, **motif** is a set $M \subseteq S$, $M = (m_i)_{i=1}^k$, where k is a support of a motif. M has the following properties:

1. **individual similarity:** $\forall i \in \{1, 2, \dots, k\}, \exists j \in \{1, 2, \dots, k\} : \text{cor}(m_i, m_j) \geq \phi$,
2. **group similarity:** $\forall i, j \in \{1, 2, \dots, k\}, i \neq j : \text{cor}(m_i, m_j) \geq 3/4\phi$,

Thus, when a new subsequence is included in a motif it is very similar to at least one existing subsequence in S and it is reasonably similar to all the rest $s_i, i = 1, \dots, k$. In our case $\phi = 0.8$.

In other words, two time series are considered to constitute a motif if the correlation distance between them is very high. The threshold we have chosen is 0.8. Several motifs can be combined if all the time series that comprise the motifs have high correlations with each other. In this case, the correlations should be ≥ 0.6 .

Motif extraction enables us to enrich traditional analysis of the aggregated traffic reported by a gateway. As a matter of fact, we can detect detailed behaviors within the same house that can be attributed to different residents (e.g., adults or children), or to different habits (i.e., daily or weekly patterns). Identification of diverse behaviors inside a single house goes beyond the current state of the art. Furthermore, to provide additional information about the obtained motifs, we analyze them across the following dimensions:

1. How many dominant devices per gateway contributed to the motif? In this case we consider dominance for the corresponding time period of time series that formed the motif.
2. How do the dominant devices per motif and gateway relate to the overall dominant devices of a gateway detected for a period longer than 4 weeks?
3. What is the distribution of the dominant devices per motif? We consider portable, fixed devices, network equipment and others as discussed in Section 6.1.
4. Are there daily motifs, which are more common among weekends than working days and vice versa?

5. What gateways contribute the most to the motifs?

For the analysis we concentrate on significant motifs with high support values, so called motifs of interest.

7.2.1 Weekly Motifs

In order to find weekly motifs we use 8 hour aggregation period starting at 2am, as it is the best time aggregation according to the experimental results in Section 7.1.1. The motif search was done on user gateways that have at least one observation for each week, out of the six weeks starting from March 17th. The number of such gateways is 147.

Figure 9: Distributions of support values for weekly (left) and daily (right) motifs.

As a result, 101 motifs are discovered from 882 (147*6) weeks of observations. Out of those, 14 motifs have support ≥ 10 . The distribution of the support values is shown in Figure 9. For weekly motifs, the participation of gateways in motifs is rather low, but at least one week time series per gateway contributed to the motif construction. The top gateways among the gateways with the highest contribution provided at least 6 time series for weekly motifs while on average number of the distinct motifs per gateway is 2.76. The distribution of the number of distinct weekly motifs per gateway can be seen on Figure 10.

Figure 10: Distributions of the number of motifs, where a gateway participated in.

Some of the motifs of interest are shown in Figure 11.

In general, all the detected weekly motifs correspond either to the patterns of everyday evening usage, or to the patterns where certain days are the most influential.

We further elaborate on weekly motifs of interest, as shown in Figure 11. We label the motif in Figure 11a - motif1, Figure 11b - motif2, and Figure 11c - motif3. The distribution of the number of dominant devices for these motifs is shown in Figure 12a. We observe that these motifs have one or two dominant devices, and most of them correspond to the overall dominant devices of a gateway according to Figure 12b. Nevertheless, there are some devices, which are dominant per motif time slot, but not dominant for a gateway overall. The number of these devices is at least 2.5 times smaller than the number of common dominant devices.

We notice that motif1 and motif3 are mainly observed for portables (Figure 13), while motif2 is observed for fixed devices. This can be attributed to portable devices being used in the evenings. But, more regular users, like the ones contributing to motif2, tend to use fixed devices.

7.2.2 Daily Motifs

We have extracted daily motifs for the aggregation period that is considered to be the best in terms of the highest number of correlated patterns, as discussed in Section 7.1.2. This is the three hours aggregation which gives 8 points for each daily time series.

The daily motifs were extracted from time series of 100 user gateways (out of 196 gateways), which have at least one observation per day in raw time series for the observation period of four weeks. In total 112 motifs were extracted, with 48 motifs having support larger than 10. The distribution of the support values is shown in Figure 9. The most popular (with the highest support) daily motifs are connected to various evening usages, while there are still motifs with daily behaviors and mixed morning and evening behaviors. Surprisingly, for daily motifs each gateway contributed with at least 16 time series. The top gateways (among the gateways with the highest contribution) provided at least 28 time series for daily motifs. At the same time the average number of district motifs per gateway is 12.5.

The distribution of the number of distinct daily motifs per gateway is shown in Figure 10. The support of the daily motifs is more repetitive between the same homes than in the case of the weekly motifs. This can be attributed to the fact that more days per gateway were considered. 28 data windows are used for daily motifs, while 6 data windows are used for weekly motifs.

Analysis. We analyze in detail 4 representative daily motifs shown in Figure 14. The distribution of the number dominant devices is illustrated by Figure 15a.

We observe that motifs usually have one or two dominant devices. Unlike the weekly motifs, many of them do not correspond to the overall gateway's dominant devices (Figure 15b). However, the majority still coincides with the overall dominant. This higher ratio of new dominant devices is attributed to the small time intervals (i.e., a single day), while overall dominance is determined for 4 weeks of data.

The distribution of dominant device types is shown in Figure 16a. Motifs A, B and C which correspond to high usage behavior in the morning or/and in the evening are mainly created by portable devices, while motif D, with all day active usage (and similar daily motifs we detected), is more generated by fixed devices. In general, daily patterns have higher percentage of portable devices as dominant devices, especially in the cases of not continuous usage behaviors.

Most of the motifs correspond to both working days and weekends, but all day usage (motifD) contains more working days (Figure 16b). The relative support of working-day motifs is larger than that of weekends, as working days are more frequent in the training set.

Summary.

1) Portable devices are sources of short-term morning or evening activities, while fixed devices generate day and night long-term patterns.

2) Gateways participate in several motifs. This supports our hypothesis that a gateway involves multiple distinct behavioral patterns. Our approach is able to reveal those, thus leading to an accurate characterization of the gateways, which in turn provides valuable insights to ISPs.

We observe that the discovered motifs reveal fine-grained regular behaviors that can be exploited in order to better manage residential networks. For example, our analysis identifies groups of users, irrespective of their location and

(a) Heavy Weekend Users: Support = 26 time series (23 % occur during different weeks in the same gateways).

(b) Everyday Users: Support = 13 time series (15 % occur during different weeks in the same gateways).

(c) Workdays Users: Support = 21 time series (29 % occur during different weeks in the same gateways).

demographics, that share similar time periods of low activity (in different parts of the day, or night). These can be used by ISPs and CSPs to schedule maintenance processes in a way that minimally interferes with the user activities.

8. CONCLUSION

In this work, we analyze the wireless traffic time series of 196 home gateways. We describe a similarity measure suitable for capturing the characteristics of traffic *evolution* within and across gateways. We propose a notion of stationarity that, in addition to the similarity of data distributions, also imposes a correlation similarity across non-overlapping time windows. This work is a first step towards understanding fine-grained regularities on residential traffic consumption. ISPs and CSPs could leverage such analytics to enable remote maintenance services such as: (i) troubleshooting and firmware/software updates of RGWs, and (ii) hotspot resource management and collaborative networks, which require *fine time-scale identification* of gateways' and home devices' active and idle times. Existing methods rely heavily on wireless traffic stationarity for such predictions, which do not hold in home networks (cf. Section 2). Our analytics framework uncovers the best aggregation of home traffic values, in order to identify motifs and to detect gateways with similar/different traffic patterns. We are currently working

towards integrating our time series correlation and motif extraction, in a streaming big data analytics platform, such as Apache Storm or Amazon Kinesis.

Acknowledgments

We would like to thank Gevorg Poghosyan, Augustin Soule, Pascal Le Guyadec, Henrik Lundgren, Jaideep Chandrashekar and Christophe Diot for their precious help in making sense of wireless home traffic data. ABSTRACT

The World Health Organization (WHO) and drug regulators in many countries maintain databases for adverse drug reaction reports. Data duplication is a significant problem in such databases as reports often come from a variety of sources. Most duplicate detection techniques either have limitations on handling large amount of data or lack effective means to deal with data with imbalanced label distribution. In this paper, we propose a scalable duplicate detection method built on top of Spark to address these problems. Our method uses the k NN (k nearest neighbors) classifier to identify labelled report pairs that are most useful for classifying new report pairs. To deal with the high computational cost of k NN, we partition the labelled data into clusters for parallel computing. We give a method to minimize the cross-cluster k NN search. Our experimental results show that the proposed method is able to produce robust duplicate detection results and scalable performance.

1. INTRODUCTION

Adverse drug reactions, or ADRs, impose significant hazards to public health. They are one of the leading causes of hospitalization, disabilities, and death around the world. ADRs incur significant costs to health-care systems [10, 19]. Post-marketing drug safety surveillance plays an increasingly important role in ADR detection in comparison with pre-marketing drug clinical trials as clinical trials have limitations on the number of patients involved and the diversity of patient groups. Post-marketing drug safety surveillance mainly uses *Spontaneous Reporting Systems (SRS)* to detect signals of potential ADRs. These signals are then further assessed by experts to establish a causal relationship between a drug and an ADR. The World Health Organization (WHO) and drug regulators in many countries, such as the FDA in the US and the TGA in Australia maintain databases for adverse drug reaction reports. ADR reports are submitted from a variety of sources including general practitioners, pharmacists, hospitals, and consumers etc. The ADR report

database is the major part of the reporting system. Many drug safety assessment methods detect potential ADR signals through the comparison of the reported ADR ratio of a specific drug and that of other drugs in the database. Disproportionality often indicates a potential ADR signal [6, 7]. As these methods are sensitive to the number of ADR reports, data quality in these databases is essential to the performance of ADR detection. One significant problem faced by such a database is *report duplication*. Duplicates often result from two sources. First, reports from different data sources have overlaps as the same ADR may be reported by different organizations through different channels. Second, the follow-up reports of the same ADR are wrongly put as separate records in the databases. Duplicates may distort the report ratio of an ADR and affect the performance of these methods significantly. Nkanza and Walop [17] reported a 5% duplication rate in vaccine adverse event data, providing an indication of the spread of the problem.

Duplicated reports in an ADR database are often not exactly the same in each field. Table 1 shows two examples. In the first example, *report A* and *report B* are duplicate, but they differ in the *reaction outcome description* field and *report description* field. In the second example, *report C* and *report D* are duplicate, but they differ in *patient age*, *ADR name* and *report description* field. The different values in the *patient age* field are likely to be an error introduced when entering a handwritten report.

A database record consists of multiple fields. Duplicate detection techniques therefore have two levels: *field matching* and *record matching*. Field matching mainly concerns comparing numerical, categorical and string values in each field. Record matching concerns whether two or more feature vectors formed by common fields belonging to different records are duplicate.

There are many existing works on duplicate detection in relational databases. Early works are referred as *record linkage* with a focus on linking together two or more separately recorded pieces of information concerning an individual case [16]. Large amount of work deals with the comparison of fields that can identify a particular record, such as name, address, and age. The values of these fields are normally short strings. Many field matching techniques concern approximate comparison of strings based on various similarity metrics. Commonly used string similarity metrics include *edit distance* [13], *Hamming distance* [8], *cosine distance* and *Jaccard coefficient* [3] etc. Field matching alone is not able to detect many duplicates, e.g., two string values in the surname field can be totally different in the case that a woman

changes her maiden name to her husband's surname, but they belong to the same record.

Record matching considers each field as an element of a feature vector of a record. It combines the differences among common fields of two or more records to determine whether they are duplicate. The ways of combining field similarities of records differentiates record matching techniques. Some techniques calculate the probability of difference of values in each common field, converts these probabilities to log values and add them together [16, 11, 12]. Some techniques use supervised decision tree induction and unsupervised clustering to determine if a record is likely to match a set of other data records [5]. Active learning is also used for record matching to reduce the amount of training data [20].

However, the effectiveness of existing duplicate detection techniques on ADR databases is not well investigated mainly due to the slow progress of the industry's adopting information technologies. We collaborate with the Therapeutic Goods Administration (TGA) in Australia and use the ADR reports they collected during 6 month period to carry out this work. In this paper, we study the duplicate detection problem in ADR databases with a focus on detection performance and system scalability that is important for fast growing data in this area. Our contributions are as below:

1. To identify duplicates in ADR reports, pairwise distances between these reports often need to be calculated. The distribution of duplicate pairs and non-duplicate pairs is highly imbalance. This poses a significant challenge when selecting report pairs from a large dataset to train a classifier for exploiting useful information. The classification results are highly influenced by the overwhelming majority of non-duplicate report pairs. There is no generally applicable classification method to address this issue. We develop a

k NN based method to address this problem for ADR reports. k NN is helpful for the classifier to learn from individual reports and makes the classification results easy to understand. It also offers flexibility through assigning weights to the information carried in the neighbors in decision making. Our extensive experiments show that our method produces more robust detection results in comparison to SVM based classifiers.

2. A drug regulator database in a country with a relatively small population may already contain a large number of ADR reports that easily overwhelms the computing capacity for effective duplicate detection. In addition, k NN is both data- and compute-intensive when the dataset grows large. The MapReduce model is a convenient way to scale up the duplicate detection. However, its Google and open source implementation are mainly optimized for batch jobs so far [22]. Duplicate detection for ADR databases has a potential use-case for interactive and fast detection of duplicates for a specific report. Apache Spark [24] has the potential to support interactive data analytics. We implement a Spark based parallel system to support fast and scalable k NN classification for duplicates. Taking advantage of the distributed memory management and parallel data processing support offered by Spark, the system is able to handle large amount of ADR reports in a scalable manner.

The rest of this paper is organized as follows: Section 2 introduces the background technologies of our work; Section 3 defines the problem; Section 4 describes the system and our Fast k NN classification method; Section 5 gives the evaluation results of the performance of the system; Section 6 summarizes related works; and Section 7 concludes the paper.

2. BACKGROUND

2.1 k NN Classification

In a D -dimensional space \mathcal{D} , s and t are two vectors representing two data objects. We use $d(s, t)$ to denote the distance between s and t . Consider S and T are two sets of such vectors, for a vector $s \in S$, we denote its k nearest neighbors according to a given distance function in T as $knn(s, T, k)$. We assume that each $t \in T$ is associated with a label $L_t, L_t \in \{-1, +1\}$. The labels of vectors in S are unknown. We use $knn^+(s, T, k)$ to denote the vectors in $knn(s, T, k)$ with label “+1” and $knn^-(s, T, k)$ to denote vectors with label “-1”. k NN classifier assign a label to s according to the following equation (note that the number of vectors in $knn(s, T, k)$ is an odd number):

$$L_s = \begin{cases} +1, & \sum_{t \in knn^+(s, T, k)} L_t + \sum_{t \in knn^-(s, T, k)} L_t > 0 \\ -1, & \sum_{t \in knn^+(s, T, k)} L_t + \sum_{t \in knn^-(s, T, k)} L_t < 0 \end{cases} \quad (1)$$

Assigning labels to each $s \in S$ according to their nearest neighbors requires a k NN join operation between S and T to identify k nearest neighbors of set S in T , denoted as $S \bowtie_{knn} T$.

$$S \bowtie_{knn} T = \{(s, knn(s, T, k)) | \forall s \in S\} \quad (2)$$

2.2 Spark

Spark [24] is a cluster computing framework that supports iterative and interactive data processing. It provides a level of data abstraction called *resilient distributed datasets* (RDDs) [23] to represent a set of immutable data objects. These data objects can be partitioned among a number of cluster nodes. RDDs are fault-tolerant and can be reconstructed when their hosting nodes fail.

There are two types of operations that can be applied to a RDD in the Spark framework: *transformations* and *actions*. A transformation contains operations that produces a new RDD from an existing RDD while an action returns a value after operating on a RDD. Operations are often executed in parallel on a RDD. In addition to support *map*, *reduce* and *aggregate* operations on a RDD, Spark also offers operations such as *join*, *union* and *cartesian* to manipulate multiple RDDs. Different to MapReduce, RDDs where *map* and *reduce* operate on can be persistent in memory in nodes of the cluster, which greatly improves the efficiency of iterative and interactive applications. A duplicate detection system like the one discussed in this paper is an iterative process that contains data processing of multiple stages and it fits the Spark framework well.

3. THE PROBLEM

An adverse drug reaction report database \mathcal{A} stores reports continuously collected by a regulator. We consider that a set of new reports, denoted by R arrive in the database may contain duplicates among themselves as well as with existing reports in the database. The problem is to identify the following set of report pairs:

$$Dupe(R, \mathcal{A}) = \{(r, h) | sim(r, h) < \epsilon, \forall r \in R, \forall h \in \mathcal{A} \cup R - r\} \quad (3)$$

in which, *sim* is a scoring function that measures the similarity between two reports and ϵ is a threshold that determines whether two reports are duplicate.

Duplicate detection within database \mathcal{A} can be seen as a recursive process in which reports are sorted according to their arrival time to the database and reports with later arrival time are checked for duplication against those with earlier arrival time.

Note that even though an ADR database may contain 5% of reports that have at least one duplicate in the database, when it comes to the number of duplicated report pairs, the rate of duplicates is much lower. This is because the number of report pairs grows quadratically with the number of reports and non-duplicate report pairs grows much faster than duplicate report pairs. This results in highly imbalanced distribution of duplicate and non-duplicate report pairs in the dataset derived from \mathcal{A} .

4. THE SYSTEM

4.1 The Workflow

The workflow for duplicate detection in ADR database is shown in Figure 1. It contains the following major components:

- **Report database:** The report database stores reports collected by a regulator and new reports are continuously added to this database.
- **Text processing module:** Our system contains a text processing component to clean up text data in a report using common natural language processing techniques. Free text plays an increasingly important role in ADR reports as consumers increasingly participate in reporting drug side effects to regulators in recent years. Free text in a report not only is helpful for understanding drug side effects, but also contains useful information to identify duplicated reports. Compared to string fields such as name and address in existing duplicate detection systems, a free text field such as “report description” is significantly longer with majority of them being 250 and 300 characters long. This requires NLP techniques to extract useful information from the text for duplicate detection. On the other hand, regulators also increasingly monitor various data sources that contain large amount of text for ADR related information.
- **Pairwise distance computing module:** The module computes the pairwise distance among a set of reports including selected reports from the database and new reports arriving to the system.
- **Training datasets (labelled datasets):** The system maintains two temporary databases for duplicate detection: one contains report pairs that are known to be duplicate; the other contains samples of non-duplicate report pairs. The initial duplicate/non-duplicate labelling is done manually by domain experts from drug regulators, in our case, the TGA. Afterwards, the collection of report pairs in the two temporary databases are dynamically adjusted when new duplicates and non-duplicates are identified. Note that the duplicate report pair database stores all known duplicates while the non-duplicate report pair database only keeps a subset of known non-duplicates. The difference is due to the highly imbalanced distribution of duplicate and non-duplicate pairs.

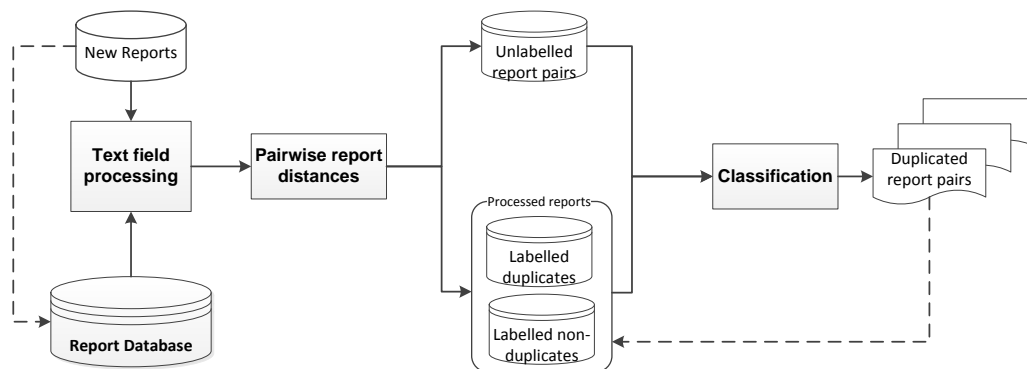

Figure 1: The workflow of the system – the dashed line represents that the source data becomes part of the target data when the processing finishes.

- Classification module: The report pairs are fed into the classification module that computes the scores for each pair and generates a list of duplicate pairs given a score threshold. Many classification algorithms fit into this system framework. We use k NN classifier as the default one for this application area. One advantage of k NN is that the classification results are easy to explain with human intuition and the basis of decision making can be justified clearly. This characteristics is particularly useful when the training dataset is highly imbalanced and global algorithms are difficult to separate them with general models.

4.2 Report Distance Calculation

A typical ADR report contains fields as shown in Table 2. Due to different missing data rates in different fields as well as schema inconsistency in data sources, common practices choose a subset of fields as input for duplicate detection. The fields used in our method are highlighted in bold fonts. The selection of fields is based on the WHO system as described in [18]. In the selected fields, *patient age* (“calculated age”) is numerical type. *Patient sex*, *residential state* and *onset date* are treated as categorical data type. *ADR name* (“MedDRA PT code”) and *drug name* (“generic name description”) have string type. Different methods deal with string type differently, e.g., they are treated as categorical type in probability based methods and programming level string type in SVM based methods. As mentioned, free text becomes increasingly important in ADR reporting systems, we therefore include the *report description* field in our duplicate detection system and treat it as string type.

For a numerical field, if the values of two reports in the field is the same, the distance is 0, otherwise 1. The same calculation applies to categorical field types. For fields of string type, we use *Jaccard similarity coefficient* to measure the distance between two values as below:

$$d(S_1, S_2) = 1 - \frac{|S_1 \cap S_2|}{|S_1 \cup S_2|} \quad (4)$$

in which, $|S|$ is the size of set S . The free text field is of string type, but as mentioned earlier, majority of values in the free text field are between 250 and 300 characters long. In order to eliminate the impact of typographical errors or

different ways of constructing sentences, we apply common techniques to *tokenize* the content in the *report description* field, *remove stop words*, and then *stem tokenized words* to their root forms before computing their distances.

The distances of values in these selected fields of any two reports form a distance vector between the report pair. The comparison between two distance vectors, i.e., measuring how similar a report pair is in comparison to another pair of reports, is based on the Euclidean distance between the two distance vectors of the two pairs.

Information	Fields
Case Details	case number, report date
Patient Details	calculated age , sex , weight code, ethnicity code, residential state
Reaction Information	onset date , date of outcome, reaction outcome code , reaction outcome description, severity code, severity description, report description , treatment text, hospitalisation code, hospitalisation description, MedDRA Low Level Term (LLT) code, LLT name, MedDRA Preferred Term (PT) code , PT name
Medicine Information	suspect code, suspect description, trade name code, trade name text, trade name description, generic name code, generic name description , dosage amount, unit proportion code, dosage form code, dosage form description, route of administration code, route of administration description, dosage start date, dosage halt date
Reporter Details	reporter type, report type description

Table 2: Data fields of an ADR report in TGA data. The bold font indicates fields used in our duplicate detection method.

4.3 Fast k NN Classification

With the pairwise distances calculated, a k NN join is applied to labelled report pairs, denoted by T , and report pairs containing new reports, denoted by S . The classification of a report pair $s \in S$ is based on the score computed from its nearest neighbors in T . Due to the imbalanced distribution of positive and negative labels, the negative report pairs easily overwhelm the positive ones. We therefore normalize the score using the distance between two pairs as below.

$$score_s = \sum_{t \in knn^+(s, T, k)} \frac{1}{sim(s, t)} - \sum_{t \in knn^-(s, T, k)} \frac{1}{sim(s, t)} \quad (5)$$

The label of s is therefore determined by the following equation, in which θ is a given threshold:

$$L_s = \begin{cases} +1, & score_s \geq \theta \\ -1, & score_s < \theta \end{cases} \quad (6)$$

4.3.1 Parallelization Strategy

Consider the number of report pairs in T is n and the number of report pairs in S is m , the computing complexity of k NN classification is $O(m \cdot n)$ for join and $O(m \cdot k)$ for score calculation. n exhibits quadratic growth with the number of reports. The amount of data to process easily overwhelms a single server. To make the classification scalable, we partition T and S into a set of clusters, denoted by $\{T_1, T_2, \dots, T_b\}$ and $\{S_1, S_2, \dots, S_c\}$ respectively. The cluster size in a partition is adjusted to fit into the memory capacity of a computing node. A naive parallelization strategy is to apply k NN join for each partition group $\{(T_i, S_j) | 1 \leq i \leq b, 1 \leq j \leq c\}$ and then merge the nearest neighbors from each partition group. This approach does not reduce the overall computing complexity and incurs high data transfer cost as each partition in S needs to compare with all partitions in T . The merge of intermediate nearest neighbors may potentially become another bottleneck that limits the scalability.

To address this problem, we exploit the locality of report pairs in T in partitioning. We first partition report pairs using k -means clustering to obtain c clusters. The center of each cluster is calculated and stored in memory. Note that clusters produced by k -means form a *Voronoi diagram* where each report pair in a cluster is closer to the center of the cluster it belongs to than to any other cluster centers. We then assign each report pair $s \in S$ to a cluster whose center is the closest to s comparing to other cluster centers. It is likely that most of the k nearest neighbors of s are within the cluster it is assigned, i.e., most of report pairs in $knn(s, T, k)$ can be found in $knn(s, T_i, k)$ where T_i is the cluster to which s is assigned. Certainly, there are chances that some of the k nearest neighbors of s are in clusters sharing borders with the cluster. The two scenarios are illustrated in Fig. 2.

Our method therefore consists of two stages to deal with the two scenarios. In the first stage, we compute the k nearest neighbors within a partition to which each $s \in S$ is assigned. In the second stage, the cross-cluster comparison is performed for those testing report pairs falling into the second scenario in Fig. 2. The key technical challenge is how to determine whether it is necessary to check neighbor partitions when identifying the k nearest neighbors of a testing report pair.

4.3.2 Observations

Figure 2: k NN under partitioned dataset: the circle represents the cluster center of a partition; the triangle represents a testing report pair s ; the dark square represents a positive report pair in $knn(s, T, k)$ and the light square represents a negative report pair in $knn(s, T, k)$. (a) $knn(s, T, k)$ are all in one partition; (b) $knn(s, T, k)$ are in different partitions.

To address this problem, we develop an optimization algorithm that intends to prune unnecessary cross-cluster comparisons. The algorithm is based on the following observations:

1. The number of positively labelled report pairs is small and it incurs low computational cost to calculate distances between these positive report pairs and report pairs in testing dataset.
2. When the k nearest neighbors of $s \in S$ are all labelled negative, there is no ground to classify s as a duplicate report pair.
3. When the distance between s and its nearest positive neighbor is greater than that between s and the k -th nearest negative neighbor in a subset of T , it is clear that there is no positive report pair in the $knn(s, T, k)$.
4. As mentioned above, k -means produces Voronoi partitions on the training report pairs, hence the hyperplane, denoted by h that separates two partitions is in the middle between the two cluster centers of the two partitions. If the distance between $s \in S$ and its k -th nearest neighbor, denoted by s_k in the partition to which it is assigned is less than its distance to the hyperplane, the distance between s and s_k , denoted by $d(s, s_k)$ is certainly less than distances from s to any report pairs in the other partition.

The scenario of observation 4 is shown in Fig. 3, where the distance between s and the partition hyperplane is $d(s, h)$, the distance between s and the closest report pair s_x in the other partition is $d(s, s_x)$. $d(s, h)$ can be derived according to [9] as below:

$$d(s, h) = \frac{d(s, p_j)^2 - d(s, p_i)^2}{2 \cdot d(p_i, p_j)} \quad (7)$$

in which, p_i and p_j denote the center of partition T_i and T_j respectively. As $d(s, b)$ is the shortest distance between s and the hyperplane b and connecting s and s_x needs to cross the hyperplane, we have $d(s, s_x) \geq d(s, b)$ according to

the triangle inequality. Therefore when $d(s, s_k) \leq d(s, b)$, it is not necessary to include the partition T_j with center C_j in the searching for $knn(s, T, k)$.

Algorithm 1 describes the steps for selecting additional partitions to be included kNN computing for a report pair s . Line 2 – 5 is based on observation 1 – 3 and line 6 – 12 is based on observation 4.

Figure 3: Additional partition selection for kNN under partitioned datasets: p_i and p_j represent two partition centers; the triangle represents a testing report pair s .

4.3.3 The Classification Algorithm

Algorithm 2 gives main steps of implementing the duplicate detection method described above with Spark primitives of transformations and actions. The stage 1 (intra-cluster comparison stage) is performed in line 6 – 8. The stage 2 (cross-cluster comparison stage) is performance in line 9 – 16. Stage 2 first computes the distances of the testing report pair to all positive training pairs. It skips

cross-cluster comparison if the top k most similar report pairs obtained so far are all negative, indicating there will not be any positive training report pairs closer than the k -th nearest negative report pairs. Otherwise, cross-cluster comparisons are performed in line 12 – 15. The output score of each report pair is used to assign a label to the pair according to Equation 6.

Algorithm 2 Fast kNN Classification.

Require: A training dataset T containing report pairs labelled as duplicate or non-duplicate
Require: A testing dataset S containing unlabelled report pairs
Require: b – the number of clusters for partitioning T ; c – the number of partitions for S

- 1: use k – means to partition T into b clusters: $\{T_1, T_2, \dots, T_b\}$ with cluster centers of these partitions denoted by $P = \{p_1, p_2, \dots, p_b\}$
- 2: run *map* operation to compute distances between P and $s \in S$
- 3: assign s the partition i where $dist(s, p_i), (1 \leq i \leq b)$ is minimal for vectors in P .
- 4: randomly split S into c partitions : $\{S_1, S_2, \dots, S_c\}$
- 5: **for** $i = 1$ to c **do**
- 6: run *join* operation on S_i and T^- based on cluster IDs (T^- denotes the negative report pairs in T)
- 7: run *map* operation to compute the similarity between joined report pairs
- 8: run *aggregate* operation to obtain the top k most similar report pairs for each $s \in S_i$ based on the output of the previous step
- 9: run *map* operation to compute distances between $s \in S_i$ and T^+ (T^+ denotes the subset of positive report pairs in T)
- 10: run *map* operation to combine the results from step 8 and step 9 to update the top k most similar reports pairs to s
- 11: **if** the output of step 10 contains at least one positive report pair **then**
- 12: run *map* operation on $\{(s, knn(s, T, k))\}$ for $s \in S_i$ to compute a set of additional partitions to compare using Algorithm 1
- 13: run *join* operation on S_i and additional partitions for $s \in S_i$ to compare
- 14: run *map* operation to compute the similarity between joined report pairs
- 15: run *union* and *reduce* operation to merge top k nearest neighbors in each partition for $s \in S_i$
- 16: **end if**
- 17: run *map* to calculate the score for $s \in S_i$ according to Equation 5
- 18: **end for**
- 19: **return** all $s \in S$ and corresponding scores

4.3.4 Further Pruning of the Testing Dataset

To further reducing the execution time of kNN classification, we can prune some report pairs from the testing dataset before applying the classifier. As shown in Equation 6, a pre-defined θ determines the label of a report pair. When the distance between a testing report pair and its positively labelled k -nearest neighbor is further than a threshold, the neighbor offers little hint to the label of the testing report

pair because of the low similarity between the two pairs. This observation can be used to prune the testing dataset.

When the testing dataset is large and the positive training pairs accumulate along time, it is necessary to speedup the computation of distances between each report pair in the testing dataset and each labelled positive report pair in the training dataset. We cluster the report pairs labelled as positive and use the cluster centers to determine whether a report pair in the testing dataset should be included in the classification. Assume the distance threshold between two report pairs is a function of θ , denoted as $f(\theta)$. The process is described as below:

- Step 1. Cluster the positive report pairs into l clusters using k -means. We denote the cluster centers as $cp_i (0 < i < l)$;
- Step 2. Compute the distance of the furthest report pair to its center in each cluster. We denote these distances as $dcp_i (0 < i < l)$;
- Step 3. For each report pair t in the testing report pair set, do the following:
 - (a) For each $0 < i < l$, calculate $dist(t, cp_i)$;
 - (b) if any $dist(t, cp_i) \leq dcp_i + f(\theta)$, include t into the testing set;

Fig. 4 shows an example of the process in 2-dimensional space. cp_i and cp_j are the centers of two clusters of positive report pairs. For simplicity, we assume the positive report pairs are partitioned into only two clusters. The inner circles are formed using the distance between the furthest report pair and the center in each cluster. The shortest distance between the dashed circle and its corresponding inner circle is $f(\theta)$. In Fig. 4, p and q are testing report pairs. p is outside of both dashed circles and those positive report pairs are considered not helpful to decide the label of p . p is therefore pruned from the testing dataset. On the other hand, q is close enough to cp_i (within its dashed circle) and the positive report pairs in the cp_i cluster may carry useful information for labelling q . q is therefore included in the testing dataset for classification.

Figure 4: Pruning the testing dataset: “+” represents a positive report pair and “-” represents a negative report pair. The triangle represents a testing report pair.

5. EVALUATIONS

We implement the duplicate detection system in Java with Spark 1.2.1 API. We evaluate the performance of our system in a cluster consisting of 14 physical nodes. Each node

has 2 x Intel Xeon E5-2660@2.20GHz CPU (8 cores) and 128GB physical RAM, in which 96GB is allocated to containers. The connection among nodes is via Infiniband networks. The OS in each node is Debian Wheezy. Cloudera CDH5 (5.0.0) with Hadoop 2.3.0 is installed with Yarn mode on. We run multiple *executors* on these nodes.

5.1 Datasets

We obtain ADR report data from TGA Australia. TGA maintains a database to store ADR reports submitted by various parties and collected by themselves. The sources that submit reports to the database include pharmaceutical companies, hospitals, general physicians, patients etc. TGA provides us 10,382 ADR reports they collected for a period of six months from July 2013 to December 2013. These reports consist 286 pairs of reports labelled as known duplicates. These duplicates were annotated by officers of TGA. Table 3 summarizes the dataset.

Report Period	1 Jul. 2013 - 31 Dec. 2013
Number of cases	10,382
Number of fields per report	37
Number of unique drugs	1,366
Number of unique ADRs	2,351
Known duplicate pairs	286

Table 3: Summary of TGA dataset.

The fields in each report in this dataset are listed in Table 2.

5.2 Fast k NN Performance

5.2.1 Baseline

Many classification methods are applicable to duplicate detection problem where distance vectors of report pairs are classified as similar or different. Support vector machine (SVM) is a popularly used one in duplicate detection [2, 20]. In our evaluation, we use a SVM classifier as the baseline for comparison.

SVM based methods take distance vectors between each pair of reports as input and map them into a high-dimensional space. These methods then use a hyperplane to separate distance vectors that represent duplicate report pairs and those representing non-duplicate report pairs. The hyperplane is obtained through learning from a training dataset containing labelled duplicates and non-duplicates. The hyperplane maximizes its margins to points belonging to the two different classes. With the hyperplane, new report pairs are considered duplicates if their distance vectors fall into the match side of the hyperplane with a large margin; otherwise, they are considered non-duplicates.

5.2.2 Precision and Recall

We measure the classification performance using the *area under precision and recall curve (AUPR)*. *Precision* and *recall* are defined as below in our case:

$$precision = \frac{\text{number of correctly identified duplicate pairs}}{\text{number of total identified duplicate pairs}}$$

$$recall = \frac{\text{number of correctly identified duplicate pairs}}{\text{number of total true duplicate pairs}}$$

AUPR shows how the precision values vary with different recall values. *AUPR* is able to visualize the difference of algorithms compared to other metrics and suitable for highly imbalanced datasets [4]. The goal to improve an algorithm with the precision-recall curve metric is to move the curve towards the upper-right corner.

Fig. 5 compare the performance of our Fast k NN algorithm and SVM. Fig. 5(a) and Fig. 5(b) show *AUPR* curves under different training dataset sizes. It is clear that in both cases, our algorithm significantly outperforms SVM based method. The main reason is that with highly imbalanced datasets, it is difficult to build a consistent model using SVM while large number of negative report pairs are surrounding few positive report pairs.

One way to improve the consistency of SVM classifier is to sample representative report pairs into the training dataset in hope that the model is applicable of a wide range of testing dataset. We implement an improved SVM classifier called *SVM clustering* by clustering training set and make sure report pairs in small clusters are included in the training dataset. Fig. 5(c) shows the actual area size varies with training dataset sizes under the three classification methods. It is easy to see that sampling a variety of report pairs into the training dataset does not have significant impact to SVM performance. Our method improves the classification performance by 19.1% in average in comparison to SVM classifier.

5.2.3 Effect of k

We also examine the impact of k on the classification performance and execution time. The results are shown in Fig. 6. We vary k from 5 to 21 and the variation of *AUPR* values is not significant, as shown in Fig. 6(a). This is due to that the score calculation takes the distance of a neighbor to the report pair being classified into account in Equation 5, which eliminates the impact of neighbors that are far away from the report pair to classify.

On the other hand, increasing k does increase the execution time of the Fast k NN classifier. As shown in Fig. 6(b), the execution time grows by 31% when k is increased from 5 to 21. This is mainly due to that a larger k potentially increases the number of partitions to compare.

5.2.4 Effect of cluster number b

The parallelism is affected by the number of clusters in the $k - means$ step in Algorithm 2, which determines the number of training dataset partitions as well as the number of partitions of joined testing and training datasets. Fig. 7 shows how the system performance is affected by the setting of the cluster number. Fig. 7(a) shows that as the number of clusters increases, the overall number of intra-cluster comparisons decreases in general, while the number of additional clusters to check in the next phase increases proportionally as shown in Fig. 7(b). The increase of cluster number results in smaller number of report reports in each cluster, which leads to the reduction of the total number of intra-cluster comparisons. However, the trend stops when the cluster number increases to 70 and the total number of intra-cluster comparisons slightly increases. This is due to the cluster sizes are uneven and the probability that a large portion of report pairs in the testing dataset is assigned to a large cluster increases. Therefore the overall comparison number increases.

Note, the total number of additional clusters to check increases in the second stage does not mean the total number of cross-cluster comparisons increases. The shrinking cluster size also reduces the number of comparisons in each cluster in stage 2. As shown in Fig. 7(c), the total number of cross-cluster report pair comparisons shows a decreasing trend as the number of cluster increases. Similar to intra-cluster comparison stage, the trend stops when the number of clusters increases to 70. It is also due to the uneven distribution of cluster sizes.

The computational complexity of the cross-cluster comparison stage is low compared to the intra-cluster comparison stage. As shown in Fig. 8(a), the total number of cross-cluster comparisons varies from 1.4% to 1.9% of the total number of intra-cluster comparisons. This also indicates that further reducing the number of cross-cluster comparisons is not able to have big impact on overall execution time.

The execution time change with different cluster numbers reflects the change of overall comparison number. Fig. 8(b) shows that the execution time has a decreasing trend when the number of clusters increases. When the cluster number is set to a number below 25, the memory of each executor can not accommodate joined partitions and frequent swapping triggers a few task failures due to timeout. The automatic retries significantly stretches the execution time. When the cluster number increases from 25 to 55, the execution time is reduced by 31%. When the cluster number becomes 70, the execution time slightly increases by 5.7% comparing to that when the cluster number is 55.

5.2.5 Scalability

We measure the scalability of Fast k NN from two aspects: firstly, we examine how it scales with the size of training dataset; secondly we investigate how it scales with the number of executors. As shown in Fig. 9, with different partition number of the testing dataset, the execution time increases proportionally with the increase of the training dataset size. The execution time increases 1.4 – 2.1 times when the size of training dataset increases 5 times.

Fig. 10(a) shows the execution time change with the number of executors. For different training dataset sizes, the increase of executor number leads to the decrease of execution time. The decrease trends become flatter as the executor number increases. This is due to that the overhead of data shuffle gradually increases while more nodes participate the computation. For comparison purpose, we show the pairwise distance computing time separately in Fig. 10(b). The input data for pairwise distance computing is relatively small and the data distribution cost is low in this step. As a result, its speedup is significant when the number of executors further increases. Fig. 10(a) and Fig. 10(b) also show that the time used in the pairwise distance computing step is only a small portion of the overall execution time.

5.2.6 Effect of Testing Set Pruning

In the following, we measure the effectiveness of the testing set pruning method. We use 204,736 randomly selected report pairs as testing dataset. The training data contains 1,000,000 report pairs, in which 266 pairs are duplicate. Fig. 11 shows the result. When the distance threshold is set to 0.9, nearly 100% of the testing pairs are included in the classification phase. When the threshold is set to 0.7,

Figure 5: Comparison of area under precision and recall curve: k NN vs. SVM. Total number of testing pairs – 20,000. (a) Total number of training pairs – 5 millions; (b) Total number of training pairs – 1 millions; (c) Change of area sizes under precision and recall curves: the number of clusters in *SVM clustering* is set to 8.

Figure 6: Effect of k : Total number of training pairs – 3 millions; Total number of testing pairs – 10,000. (a) Area under precision-recall curve (AUPR) comparison; (b) The execution time comparison.

about 75% of testing pairs are included in the classification phase. Setting the threshold to 0.5 does not produce significant pruning and 73% of testing pairs are included. When the threshold is set to 0.3, 65% of testing pairs remain. The pruning ratio is not exactly proportional to the threshold setting because of the non-uniform distribution of both positive training report pairs and testing report pairs. Note that all these threshold settings enable the duplicate report pairs in the testing dataset being included for classification.

On the execution time of classification aspect, the reduction is significant. The threshold setting of 0.3, 0.5 and 0.7 reduces the execution time to 35%, 65% and 61% of the classification time without pruning. This is mainly due to the reduced data transfer and memory use. Even though setting the threshold to 0.5 slightly prunes more testing pairs than setting it to 0.7, the classification time under threshold 0.5 is slightly longer than that under threshold 0.7. It is related to the report pair distribution and how balance the workload

of comparing these report pairs is among Spark data nodes that store them.

The setting of the threshold directly affects the performance improvement of testing set pruning. Potentially, the setting can be learned from the labelled data, which we leave as our future work.

6. RELATED WORK

We compare our method with closely related works on parallelizing k NN join as well as approaches for handling datasets with imbalanced label distribution.

C. Zhang et.al [25] describes a basic Block based data partitioning method for k NN join using Hadoop. It then proposes to build an index using R-tree for each local block in a dataset. The built-in k NN functionality of R-tree is able to speedup the k NN search in the local block. The method does not reduce the overall computing and communication complexity.

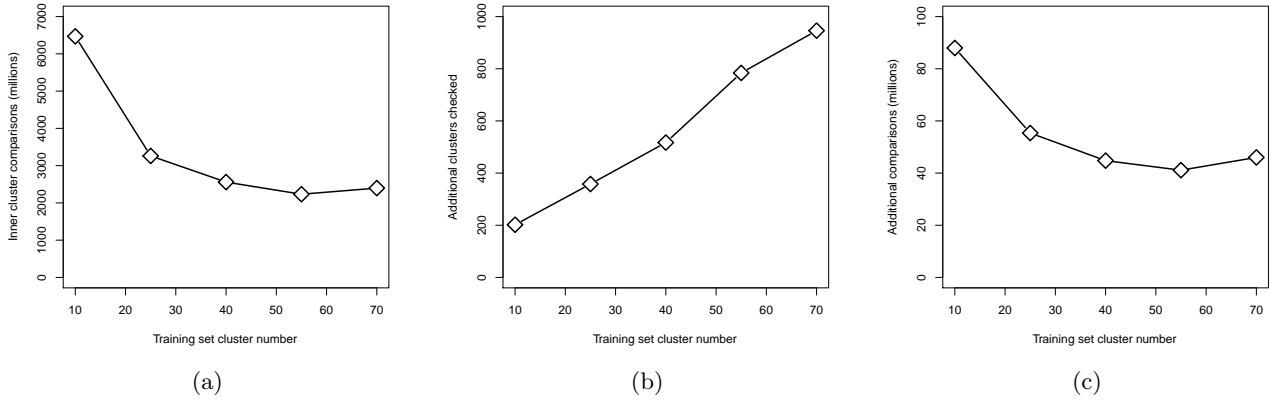

Figure 7: Impact of the cluster number: Total number of training pairs – 4 millions; Total number of testing pairs – 10,000. (a) The number of intra-cluster comparisons; (b) The number of additional clusters to check for each element in the testing set; (c) The number of cross-cluster comparisons.

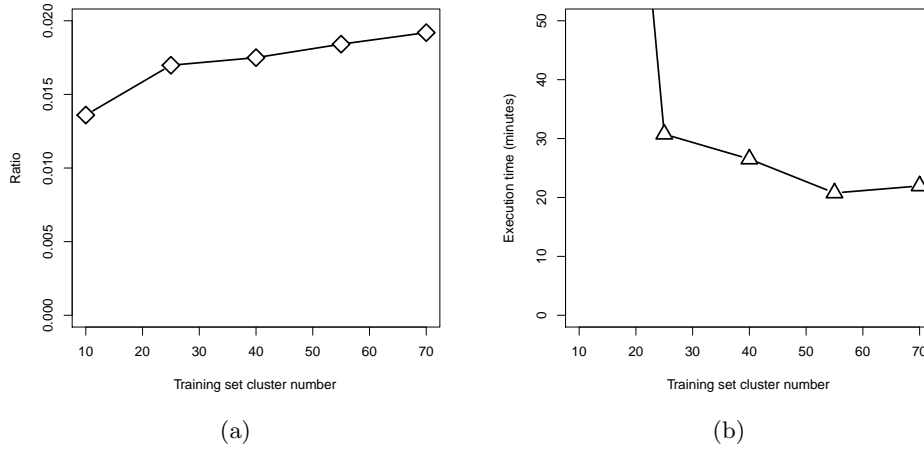

Figure 8: Impact of the cluster number of training set on cross-cluster comparison: Total number of training pairs – 4 millions; Total number of testing pairs – 10,000. (a) Ratios of cross-cluster/intra-cluster comparison number; (b) The execution time change with the cluster number: memory size of each executor is 32GB.

W. Lu et.al [15] gives an improved algorithm for parallelizing k NN join using MapReduce and aims to reduce the search space. It partitions datasets into a Voronoi diagram. The differences between our approach and [15] lie in the following aspects: firstly, our method uses k – means to partition the training dataset while [15] uses it as an option in data pre-processing to select pivots (partition centers). A *map* operation is then applied to use the selected pivots to partition datasets and collect partition statistics. As k – means produces Voronoi sets already, it is not necessary to run another data partitioning operation. Secondly, our approach uses the characteristics of imbalanced datasets to reduce the cross-cluster comparison rather than introducing another statistics collection step to achieve this goal. Our experimental results show that the cross-cluster comparison cost is low. Thirdly, our approach makes use of distributed memory management of Spark to cache data partitions in comparison to the ad-hoc caching mechanism in [15].

In addition, there are works on set-similarity join using MapReduce [21] and Voronoi partitioning for MapReduce [1]. These works focus on identifying the nearest neighbors. Our work differ from them in using k NN as a means for classifying highly imbalanced datasets, which gives us additional information for reducing the search space, e.g., when the distance between a report pair and its nearest positively labelled neighbor is further than a given distance threshold, the report pair is likely to be non-duplicate and therefore pruned from the search space.

W. Liu and S. Chawla [14] illustrates the problem of imbalanced label distribution in classification and proposes a weighted method for handling imbalanced data in k NN classifier. Our results show that k NN classifier is more robust and less affected by over-represented negative data than SVM on detecting highly imbalanced duplicate/non-duplicate report pairs. Further improving the classification performance of k NN require careful analysis of similarity of report

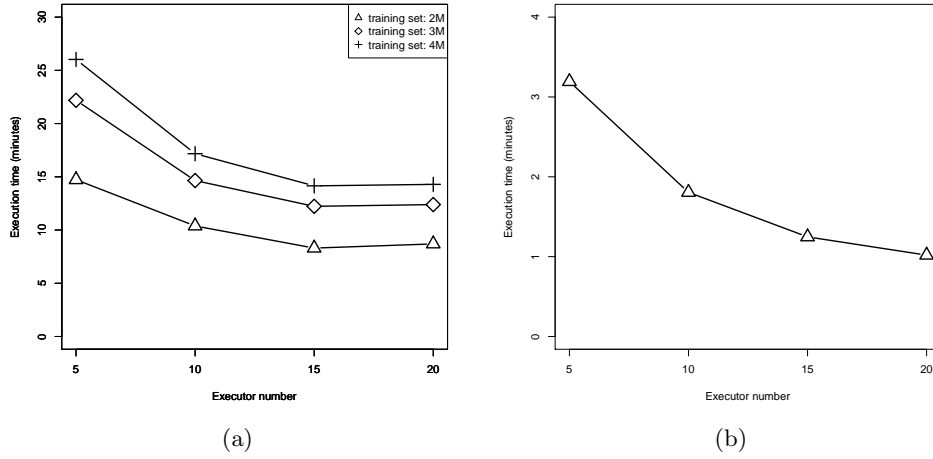

Figure 10: Execution time change with the number of executors: testing set size – 10,000; cluster number of the training set – 48; block number – 5; executor memory size – 32GB; executor core – 1. (a) Overall execution time; (b) Pairwise distance computing time (total number of reports – 10,382).

pairs by taking additional domain knowledge into account, which is our future work. Fortunately, the simplicity of k NN provides flexibility to accommodate new models.

7. CONCLUSIONS

In this paper, we studied duplicate detection in adverse drug reaction report databases. We proposed a Fast k NN classification method to deal with highly imbalanced label distribution in the dataset. Comparing to some datasets used for evaluating k NN join methods, there were relatively small number of fields chosen to calculate the pairwise distance vector between reports, however, the ADR report database contained a long text field with non-trivial distance calcula-

Figure 11: Effectiveness of pruning the testing dataset: training set size – 1,000,000; cluster number of the training set – 200; testing set size – 204,736; cluster number of the testing set – 30; $f(\theta)$ (threshold) is set to 0.3, 0.5, 0.7 and 0.9; executor number – 20; number of cores per execution – 4.

tion complexity. We showed that our method is effective in detecting duplicates in real ADR data and significantly outperforms SVM based classifier. The system we implemented using this method is capable of handling large amount of adverse drug reaction report data in a scalable way. We built the system using Spark. We effectively reduce the comput-

ing complexity by exploiting label imbalance and Voronoi partitioning of the training dataset. We also gave a method to prune the testing dataset to further improve the performance. We are not aware other parallel duplicate detection system in practical use in this domain with rapidly growing data and increasing importance. Our future work will focus on load balancing among executors for better scalability.

ABSTRACT

Microblogging platforms such as Twitter provide low cost access to an immense reserve of authoritative professionals, opinion leaders and hobbyists for a wide range of topics. Yet, as microposts are short and incredibly diverse, many of these experts are hidden. In this paper, we present *e#*, a system to retrieve experts automatically for a given set of keywords. Our design targets exhaustivity: *e#* can detect previously undetectable experts. The core idea is to enhance a state-of-the-art expert detection algorithm with a graph of expertise domains. Our system produces this graph from hundreds of Gigabytes of Web search query logs and behavioral data, processed in a distributed, parallel fashion. We provide a detailed description of our architecture, including an original SQL-based community detection algorithm. We then benchmark our system with 750 queries, using crowdsourcing. We observe that *e#* finds many more experts than a state-of-the-art baseline.

Keywords

Expert detection, query expansion, clustering

1. INTRODUCTION

Microblogging offers a mighty, low-cost means to disseminate and consume knowledge. Platforms such as Twitter let political analysts comment elections, sports journalists explain why their favorite team fell short, and technology fans criticize the weight of a new phone. In this paper, we investigate the problem of *expertise detection*: we want to retrieve experts from microblogs, given a topic expressed as a set of keywords. For example, suppose that we wish to learn more about American football from Twitter. Given a set of keywords such as *49ers* or *NFL* as input, can we return a list of all the authoritative Twitter accounts?

Expertise detection systems must achieve high *precision*

*Martin Hentschel was affiliated with Microsoft at the time of this work

and high *recall*. *Precision* measures the purity of the results. It is the proportion of experts returned by the system which are relevant to the topic. On Twitter, achieving high precision is challenging because the data contains an extravagantly large range of topics and vocabulary: it contains spam, fake accounts, but also many ambiguities. In our example, the simple term *football* designates a different sport in Europe and America. *Recall* measures the exhaustivity of the results. It is the proportion of relevant experts on the whole microblogging platform detected by our system. Recall is challenging because tweets are short. An expert in *49ers* is likely to be an expert in *West Coast football* too, because the 49ers is a popular football team from the US West Coast. Yet, as tweets cannot contain more than 140 characters, the chance to have both expressions in the same post is low. Therefore, a search for *49ers* may miss the experts for *West Coast football*.

Expertise detection has been studied for decades, but in a very different context: initially, it focused on finding experts from enterprise documents, in order to smoothen collaboration between employees. The corpora were small, heterogeneous and the queries were very specific (e.g., *FORTRAN developer*). With social media, the context is different: the topics of interest can be narrow (e.g., *49ers draft*) or broad (e.g., *sports*). The corpora are homogeneous (all messages have the same format), but their scale is massive. Also, the requirements in terms of precision and recall are different. In enterprise settings, the aim was to initiate professional collaborations, thus false positives were very costly. Most studies on expertise retrieval targeted precision, recall came as distant second [4]. In contrast, our users are looking for information sources, not collaborators. Hence, they value depth and variety, while false positives are relatively cheap. This shifts the balance towards recall. Unfortunately, achieving high recall is also much harder on social media, because microposts have a short length and an immense vocabulary.

How can we detect experts with both high recall and high precision? We present *e#*, a system to detect previously undetectable experts. Our strategy is based on *query expansion*, well known in the context of document search but seldom used for expert detection. We operate in two steps, offline and online. Offline, we build a collection of linked topics of expertise from Web data. Online, we exploit this collection to *augment* incoming queries, and feed the result to a precision-based expert detector. We obtain a variety of high quality experts.

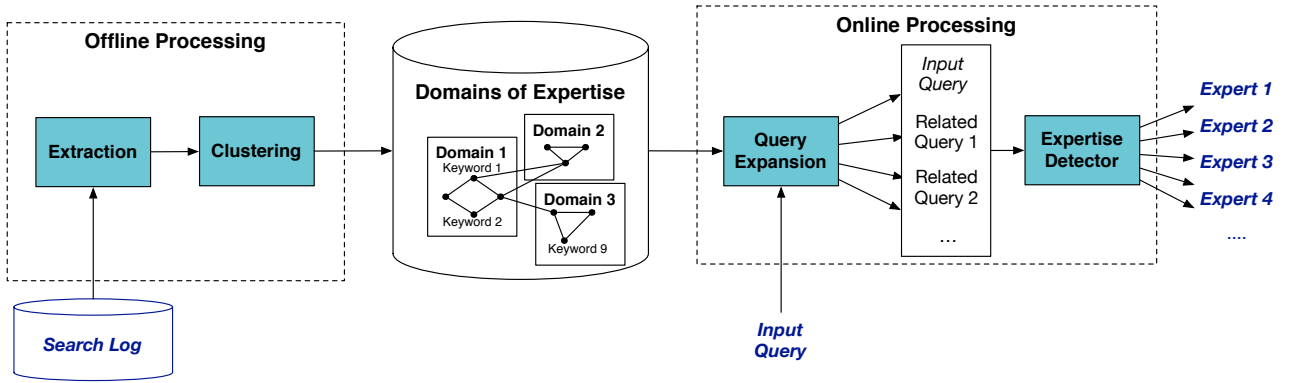

Figure 1: Overview of $e\#$ - our system augments an input query with related queries, inferred from the search log of a commercial search engine.

Two questions remain. First, how do we collect and link topics of expertise? We propose to exploit the search query log of a commercial search engine. This source gives us a massive, time-relevant collection of keywords. We infer the semantic associations between the terms with search and click behavior. Second, how do we exploit this collection? Our approach is to partition the search terms into *communities*, that is, groups of strongly related keywords. We then use these groups to enrich the queries. Because of the scale of the datasets involved, the engineering effort is non trivial. We present an original implementation of *modularity maximization*, a framework to detect communities in graphs. The advantage of our approach is that it can directly be implemented in (parallel) declarative languages such as Hive, Pig, Microsoft’s SCOPE or even SQL.

To summarize, here are our contributions:

- We present our pipeline $e\#$, which combines search query log analysis, community detection and query expansion at scale.
- We introduce a parallel, distributed algorithm to infer clusters of related keywords from large Web search logs.
- We describe a complete experimental evaluation, with real-life examples and a crowdsourcing study. We present our results on 750 queries from many different topics.

The rest of this paper is organized as follows. In the following section, we give an overview of $e\#$. We then present the base expertise detection algorithm on which we built $e\#$. In the fourth section, we detail how $e\#$ builds collections of related keywords to expand the queries. We expose how our system matches queries and expertise domains in the fifth section. We present our experiments in the sixth section. We then describe related works and conclude.

2. OVERVIEW

The main idea behind $e\#$ is to enhance an existing expert detection algorithm with a collection of expertise domains. Figure 1 gives an overview of our pipeline. It depicts two stages: an offline stage, during which we build the collection, and an online stage, during which we exploit it.

The offline stage can itself be decomposed in two steps. First, we process a search query log. Using search terms

and clicks, we build a weighted graph, in which each vertex represents a keyword and each edge represents a semantic association. Then, we detect *communities* in this graph, with a custom SQL-based algorithm. Each of the communities we obtain describes a topic of expertise, exploitable for query augmentation.

During the online stage, we run the actual query augmentation: we match the query with a topic of expertise from the database, and append the corresponding keywords. We then run a detection algorithm presented previously in the literature [14]. Section 3 presents the algorithm.

Thanks to the query log, our collection of domains is inherently current. For instance, at the time of writing, it contained keywords related to new technological products (smart watches or VR glasses) or upcoming media events (e.g., *Star Wars VII*). This is particularly useful when dealing with social media. Also, entries often come in many variants (e.g., *football*, *foftbal*, *foot*, etc...). This variety improves the robustness of our system at little CPU cost.

3. PRELIMINARIES - BASELINE

In this section, we present the algorithm on which we built $e\#$. Expertise detection involves two main challenges: *candidate selection* and *expertise ranking*. Candidate selection is the problem of finding candidate experts for a given topic. Expertise ranking is the problem of determining the strength of expertise given textual evidence. To solve both problems, we use a method proposed recently by Pal and Counts [14], shown to be competitive for Twitter data. The framework was simplified for production purposes, it currently runs in a commercial environment.

We implemented candidate selection on Twitter as follows. A candidate expert is either an author of a tweet, or a person mentioned in a tweet. In both cases, the tweet must match the query. By default, a tweet matches a query if it contains all of its terms after lower-casing [4, 14].

For expertise ranking, we first compute features of textual evidence, and then rank the candidates on these features. In their paper, Pal and Counts evaluate a dozen features. We kept those which they present as important: the topical signal (TS), the mention impact (MI), and the retweet impact (RI). These features are defined as follows:

$$TS = \frac{\#tweets\ by\ user\ on\ topic}{\#tweets\ by\ user}$$

$$MI = \frac{\#mentions\ of\ user\ on\ topic}{\#mentions\ of\ user}$$

$$RI = \frac{\#retweets\ of\ user's\ tweets\ on\ topic}{\#retweets\ of\ user's\ tweets}$$

The first two features, TS and MI , measure how much the user is specialized in the topic of interest. The third feature, RI , measures the influence of the user.

Before we perform the ranking, we normalize and aggregate the features. To normalize the features, we compute their z-score. For instance, if μ_{TS} is the average of TS and σ_{TS} its standard deviation, we compute $z_{TS} = \frac{x - \mu_{TS}}{\sigma_{TS}}$. In practice, the features appear to be log-normally distributed. Therefore, we take their logarithm to obtain Gaussian distributions. To aggregate the scores, we used a weighted sum, using the authors' guidelines.

In their paper, Pal and Counts propose an optional filtering step, based on cluster analysis. This step is computationally expensive, and it is contrary to our objective of improving recall. Therefore, we discarded it in our implementation.

4. COLLECTING TOPICS OF EXPERTISE

In this section, we describe how we build our collection of expertise domains. During the *extraction* phase, we derive a graph of semantic relationships from the search query log. During the *clustering* phase, we detail how to decompose this graph into communities, using a parallel, modularity-based approach.

4.1 Extracting Semantic Relationships

To build our collection of related topics, we exploit the search log of a commercial search engine. We chose this source because it is intrinsically current and exhaustive.

How can we infer semantic connections between terms from a search log? We propose to exploit the URLs clicked for each keyword. This approach lets us detect non-obvious semantic associations, and it is practical to implement [1]. Consider a vector space where each dimension represents a URL from the query log. In this space, we associate each query to a vector. Each component of the vector represents the number of clicks on the URL. To obtain the similarity between two terms, we can compute the cosine distance between the two vectors which represent them. If we compute the distance between every possible pair of terms, we obtain a term similarity graph. In this weighted, undirected graph, each vertex represents a query, and the edges describe their similarity. We illustrate this operation with Figure 2. This graph gives us the material for our next step: the community detection.

In practice, a few adjustments are necessary. For instance, we remove all the queries which appear less than 50 times per month, to reduce noise and save space. Even after this operation, the same term can appear with dozens, sometimes hundreds of variants (e.g., `san francisco`, `#sanfrancisco`, `sf`, ...). We leave these queries unchanged (no stemming, or correcting), in order to capture as many different cases as possible.

Figure 2: Extracting the similarity between terms from the search log.

4.2 Detecting High-Level Domains

Once the similarity graph is built, our next step is to create groups of related keywords. We solve this problem with *community detection*. The idea is to identify groups of queries which are densely connected to each other, but loosely connected to the rest of the graph. We assume that if a group of keywords obeys such a property, then we can use it to expand queries. The network analysis literature contains dozens of ways to formalize this notion [10]. We base our system on modularity maximization [13], which is simple and widely studied. We first present the original sequential algorithm, proposed by Newman et al., then we introduce our parallel variant.

4.2.1 Modularity Maximization

Overview. Consider an undirected graph $G = (V, E)$. For the sake of presentation, we consider that this graph is not weighted, but that more than one edge can connect two nodes¹. Consider a set of vertices $C \subset V$. The modularity measures how densely connected C is. To compute it, we count the number of edges within the set, and compare to what we would expect if the edges were drawn randomly between G 's vertices, preserving the vertex degrees. The modularity is the difference between these two terms. Let E describe the expected value:

$$Modularity = \#edges - E[\#edges] \quad (1)$$

Partition G 's vertices into p partitions C_1, \dots, C_p . If we sum the modularities of each of these partitions, we obtain the *total modularity*:

$$TMod(\{C_1, \dots, C_p\}) = \sum_{i \in 1..p} Mod(C_i) \quad (2)$$

¹We can convert the similarity graph described in the previous section into this representation. To do so, we rescale and discretize the weights to obtain integers. Then, we create one edge for each unit.

This is our objective function. A high value indicates that we found many dense communities. A low value means that either the graph does not contain any community, or that the partitioning is sub-optimal.

Computing the Modularity. We defined the modularity as the difference between the number of edges within a set of vertices and the expected number of edge within this set. To obtain the first quantity, we can simply count. Now, how do we obtain the second one?

For a set of vertices C , the variable m_C describes the number of edges and $E[m_C]$ the expected number of edges. We have:

$$Mod(C) = m_C - E[m_C] \quad (3)$$

We want to compute $E[m_C]$. Draw an edge at random between two vertices of G . Let P_C describe the probability that the edge connects two vertices of C , and let m_G denote the number of edges in the graph. We obtain:

$$E[m_C] = m_G * P_C \quad (4)$$

Let's compute the probability P_C . Let $D_G = 2 * m_G$ represent the sum of all the degrees of all the vertices of the graph, and let D_C represent the sum of all the degrees of the vertices in C . For a given edge, the probability that one of the endpoints ends up in the set C is D_C/D_G . Therefore, the probability of having both endpoints in the community is:

$$P_C = (D_C/D_G)^2 \quad (5)$$

Putting everything together, we obtain:

$$Mod(C) = m_C - m_G * (D_C/D_G)^2 \quad (6)$$

Note that the modularity is often normalized: many authors use $Mod(C)/m_G$ instead of $Mod(C)$. As m_G is a constant, this approach is equivalent to ours.

Greedy Heuristic. Maximizing modularity is a NP-hard problem [13]. The seminal single-machine heuristic, presented by Newman et al., operates in a greedy, bottom-up manner. We initialize the algorithm by assigning each vertex to its own community. Then, at each iteration, we find the two closest communities, and merge them. We stop when we cannot improve the score anymore, or when we have reached a satisfying number of communities.

The critical part of the algorithm is to define "closest". According to Newman, two communities are close if merging them leads to an improvement in the global modularity. Formally, if C_1 and C_2 describe these communities, we have:

$$\Delta Mod = Mod(C_1 \cup C_2) - Mod(C_1) - Mod(C_2) > 0 \quad (7)$$

Instead of computing the three terms of this equation separately, we can use a computational shortcut [13]. If $m_{1 \leftrightarrow 2}$ represents the number of edges between C_1 and C_2 , we have:

$$\Delta Mod = m_{1 \leftrightarrow 2} - E[m_{1 \leftrightarrow 2}] \quad (8)$$

Let D_1 and D_2 represent the sum of degrees of C_1 and C_2 's vertices. We obtain the second term as follows:

$$E[m_{1 \leftrightarrow 2}] = \frac{D_1 * D_2}{2 * m_G} \quad (9)$$

4.2.2 SQL-based Modularity Maximization

To deal with the scale of commercial search engine query logs, we developed a custom variant of Newman's procedure.

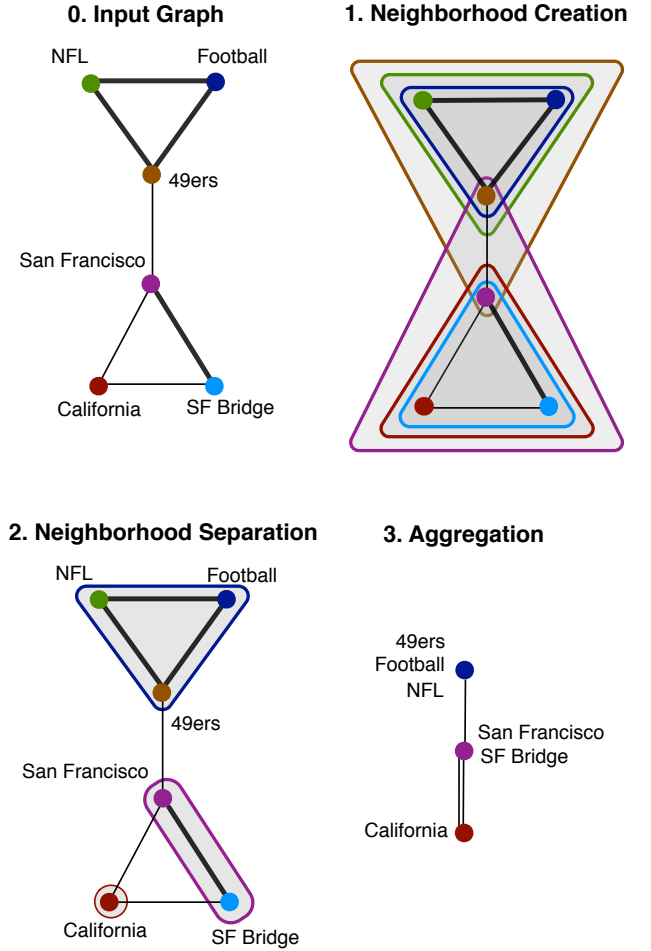

Figure 3: First iteration of our modularity optimization algorithm on a fictive example. The shaded triangles represent neighborhoods.

Compared to previously published frameworks such as [17], our approach can be directly implemented in a SQL-like language such as Hive, Microsoft's SCOPE or Pig. Therefore, we can parallelize it with standard map-reduce relational operators [5].

As previously, we initialize the algorithm by assigning each vertex to a community. Then, we repeat the following three steps:

1. For each community, list all the *neighbor* communities. Two communities are neighbors if (a) they are connected and (b) if we union them, the total modularity increases ($\Delta Mod > 0$). We obtain several *neighborhoods*, one for each community.
2. The neighborhoods found in Step 1 are overlapping: one community may belong to several neighborhoods. To remediate this, take each community, list all the neighborhoods to which it belongs and keep the closest one (ΔMod is as large as possible).
3. For each neighborhood, aggregate all the communities into one large, new community

```

neighbors = select c1.query as query1,
                  c2.query as query2,
                  distance
from graph
inner join communities c1 on query2
inner join communities c2 on query1
where ModulGain(query1,query2) > 0;

partitions = select query2,
                   argmax(distance, query1)
from neighbors
group by query2;

communities = select query1 as comm_name,
                    query2 as query;

```

Figure 4: Body of the community detection algorithm in pseudo-SQL. The table **Graph**(query1, query2, distance) represents the graph, and **Communities**(comm_name, query) represent the communities (the foreign key relationships are underlined).

We illustrate these steps in Figure 3, and present the pseudo-code in Figure 4.

4.2.3 Parallelization and Optimization

We presented our algorithm in pseudo-SQL. This approach is *declarative*: we rely on the data management system to effectively parallelize the code. We now discuss a few query processing methods to achieve good performance.

The most time consuming operation is the join between the communities and the graph, necessary to list the neighborhoods (the first query in Figure 4). If the nodes have enough main memory, we can speed it up with a replicated join: we replicate and index the **communities** table at each node. Then, we split the **graph** table, broadcast the partitions, and execute the join at each node. If this is not possible, we must chain two map-side joins. We cluster the tables **communities** and **graph** on the join keys (first query1, then query2), send each partition to a node, then perform the join at each node.

The following two operations (grouping and renaming) are much simpler, and can be executed in one map-reduce pass. The mappers emit the tuples with the key query2, then the reducers perform the aggregation and the renaming.

5. QUERY MATCHING

We now describe how to retrieve a community for a given query. Our approach is based on exact match: we find the community which contains the query terms exactly and in order, after lower-casing. Once we identified the relevant community, we run the expert search for all the related terms separately. We then union the results and rank the experts. This approach is purposely conservative, and it is straightforward to implement.

An advantage of production query logs is that terms often come in hundreds of variants, with alternative spellings and mistakes. This improves the flexibility of the matching at little computational cost.

Figure 5: Convergence of the community detection algorithm.

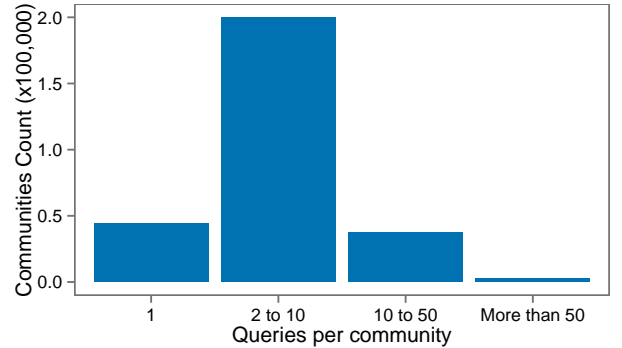

Figure 6: Distribution of the community sizes.

6. EXPERIMENTS AND EVALUATION

We now describe our experiments with *e#*. We first present the topics we extracted from a month of search queries. We then demonstrate *e#*'s effectiveness with a crowdsourcing study.

6.1 Topics of Expertise

We described how to extract topics of expertise with community detection. In this section, we illustrate our methodology with real world data. We use a full month of web search query logs (May 2014, US only, 998 GB). The graph we obtain contains approximately 60 million edges (1.45 GB). We describe our hardware setup in Section 6.3.

Figure 5 shows how many topics our algorithm finds after each iteration. We see that it starts with lots of tiny communities, then the count decreases very fast. Roughly, the procedure converges after 6 iterations. Figure 6 shows the distribution of the topic sizes. We observe that a large majority of communities contains between 2 and 10 queries (around 60%). We also found around 20% of orphans. We have very few communities with more than 50 items.

Figure 7 shows three groups of related keywords. To obtain this figure, we plotted the community which contains the term **49ers** (in dark blue), along with its three closest communities - in light blue, light green and dark green. The **49ers** community contains many non-trivial keywords: alternative spellings (**niners**), related activities

Set Name	Count	Examples
Sports	100	49ers, hernandez, buffalo bills, nascar, baltimore ravens
Electronics	100	bluetooth, ipad mini, garmin, xbox, vacuum cleaners
Finance	100	nasdaq, dow futures, msft, quotes, bloomberg
Health	100	scoliosis, asthma, diabetes, bmi, bulimia
Wikipedia	100	world war II, aashiqui 2, lycos, beyonce, albert einstein
Top 250	250	sarah palin, mapquest, honda, antonov225, saudi arabia

Table 1: Queries used for our crowdsourcing study.

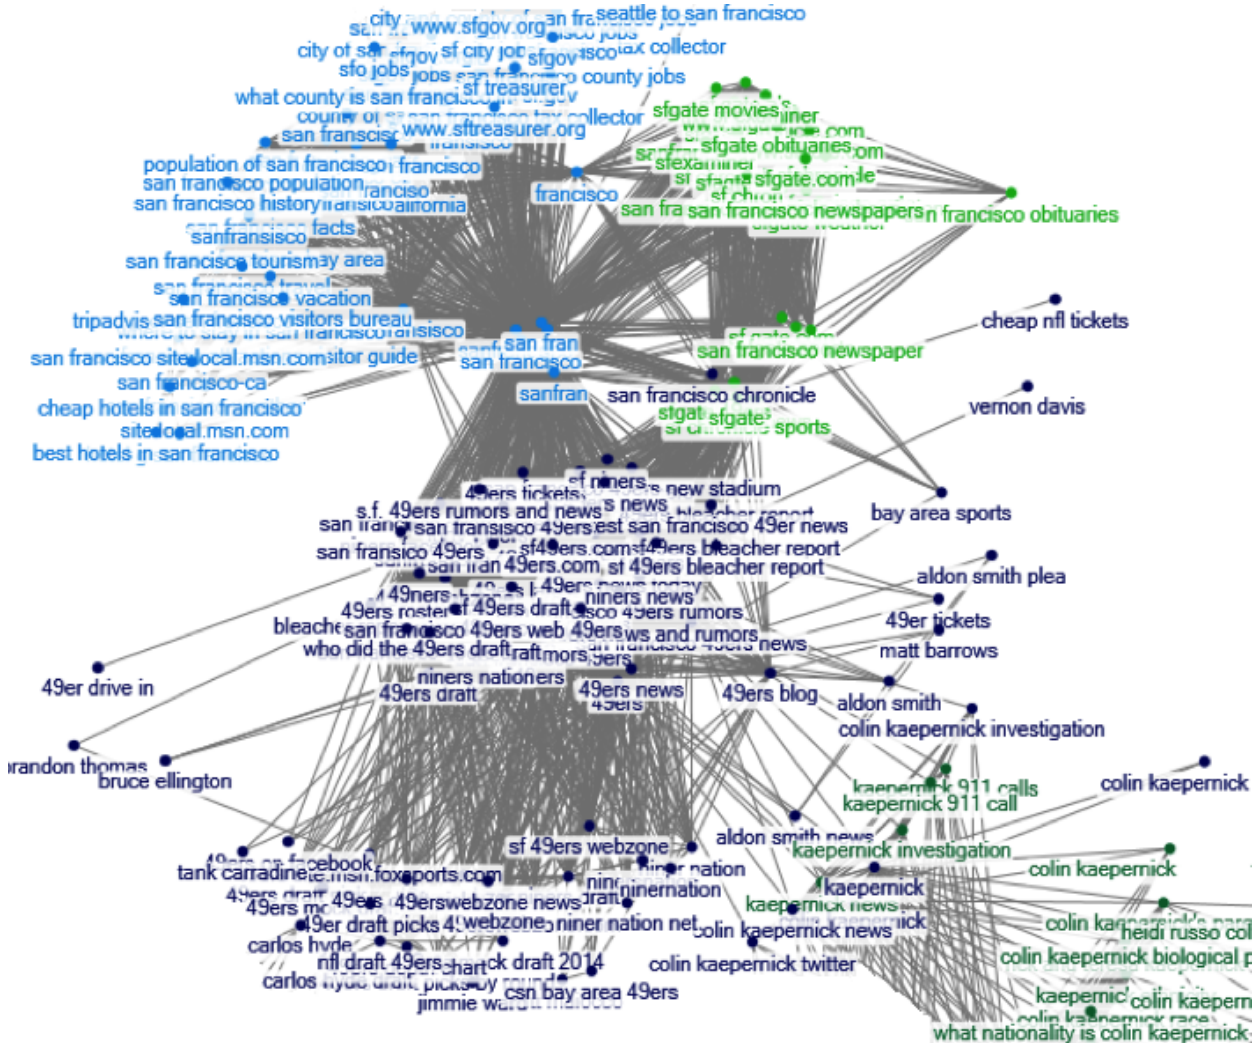

Figure 7: Graph and communities around the term “49ers”.

(49ers draft), or players (bruce ellington, vernon davis). We see that the query-log distance lets us detect semantic associations - we could not have detected these relations with a string-based distance. The three other groups contain topics which are somehow related to the 49ers, but not closely enough to be used in query expansion. The light blue community contains topics related to San Francisco tourism. This is not surprising, because the 49ers is the official team of the city. The light green one mentions “SF Gate”, which is a popular San Francisco newspaper (with a thick sports section). The dark green set focuses on Colin Kaepernick, a star player in the 49ers.

6.2 Impact on Expertise Retrieval

In this section, we demonstrate e $\#$'s effectiveness on Web data with a crowdsourcing study.

6.2.1 Experimental Setting

We compare two algorithms: Pal and Counts’ algorithm, detailed in the second section of this paper, and e#. To test the algorithms, we used queries which reflect popular interest in many different domains. Our assumption is that if a topic is popular on the Web in general, then it is likely to be popular on social media too. We used six sets, described in Table 1. The sets **Sports**, **Electronics**, **Finance**

Table 8: Proportion of queries for which at least one candidate expert was found, before and after query expansion.

and **Health** contain the 100 most popular search terms from a commercial search engine, for each category. The set **Wikipedia** contains the title of the top 100 Wikipedia pages visited in 2014. It gives us an alternative view of popular interests. To increase diversity, we added the set **Top 250**, which contains the top 250 queries of a commercial search engine for July 2014. In total, we used 750 different queries.

We provide some examples of experts for the queries **49ers**, **bluetooth**, **dow futures**, **diabetes**, **World War I**, and **Sarah Palin** in Tables 2, 3, 4, 5, 6 and 7 respectively. We observe that the experts are diverse: among others, we notice journalists (CNBC Newsroom), individuals (Arthur Hogan), support groups (Diabetes 101) and local associations (Wales Remember).

To assess the quality of the results, we were assisted by 64 crowdworkers, provided by a commercial third party. Evaluating expertise is a challenge for two reasons. First, the workers themselves must have some knowledge of the topic to recognize other experts. Second, the task is somehow subjective. We strived to incorporate these considerations in our experimental design. For each query, we generated up to 15 experts per algorithm and interleaved the results. To avoid worker fatigue, we chunked the resulting sets into smaller sets of at most 6 experts. We also randomized the order to prevent the position bias. We asked the workers to spot “non-experts”, that is, accounts from which they could *not* get any objective information about the topic of interest. We chose to exclude “non-experts”, rather than validate experts, because we assumed that the former task requires less background knowledge than the latter. We gave examples, encouraged high response times, presented links to the Twitter pages, and gave crowdworkers the option to ignore questions for which they were not confident. We filtered spammers with trivial preliminary questions. We set up the experiments such that each expert was reviewed by 3 different workers, and aggregated the results with majority voting.

6.2.2 Impact on Recall

In Table 8, we present the impact of query expansion on the size of the result sets. We show the number of queries for which at least one expert was found, before and after expansion. We note that in all six cases, we obtain a neat improvement. We notice the smallest performance gain with the **Finance** set: the baseline results are already very high, and e# only brings a 3% improvement. We observe the most dramatic effects with **Top 250**: e# answers 35% more queries. This result is not surprising: we trained e# on the search log from which the queries come from, therefore we expected it to perform well.

Figure 8: Effect of the query expansion on the number of experts per query.

Figure 9: Impact of the z-score on the number of experts for the set Top 250.

Figure 8 present a finer view of e#’s impact on the number of experts retrieved for each query set. It presents the number of queries for which the algorithms return n experts or more, with n varying between 0 and 14. For instance, the leftmost bars show that 100% of queries have 0 hits or more. The rightmost bars show the number of queries for which our algorithms found 14 experts or more. In almost

(a) Sets electronics, finance, and health.

(b) Sets commerce, top 250, and Wikipedia.

Figure 10: Size vs. quality trade-off. The impurity is the proportion of results marked as non relevant by the judges.

every cases, we observe that query expansion improves the number of experts found (in average of about 10%, up to 30%). We conclude that our expansion strategy works: it does improve recall.

6.2.3 Impact on Precision

The major challenge in query expansion is to enhance recall without hurting precision. Indeed, query expansion may weaken the quality of the retrieved experts. This degradation has multiple sources: it comes from noise in the corpora, noise in the clustering, or errors in the expansion (e.g., disambiguation problems). In this section, we study the extent of this penalty.

Before we present our results, recall that our algorithm needs to be tuned. The users must choose a minimum z-score, under which the experts are rejected. This threshold defines a trade-off between precision and recall: a low value will lead to many low quality experts, a high value will lead to a few excellent experts. We illustrate this effect for **Top 250** in Figure 9.

Figure 10 compares the quality of the experts found for different levels of recall. For a given number of experts per query, it returns the *impurity*, that is, the proportion of ex-

Step	VMs	Runtime	Read	Write
Extraction	65	38 min.	998 GB	2.6 GB
Clustering	65	2 hours	2.6 GB	94 MB
Expansion	1	< 100 ms.		
Detection	1	< 1 sec.		

Table 9: Resource consumption for one iteration (September 2015)

perts marked as non relevant by the crowdworkers. We observe that the difference between the algorithms is very subtle. It is maximal for the first few results of the set **Sports**, it is almost imperceptible for **Finance** and **Health**. In the dataset **Electronics**, *e#* performs slightly better than its competitor. In conclusion, the accuracy penalty incurred by *e#* is minimal, if not negligible. We can improve expert detection recall with minimal losses in precision.

6.3 Resource Consumption

We now provide hints about the resource consumption of *e#*. The offline part of our system runs weekly on a production cluster. Table 9 reports statistics for one iteration (September 2015). It must be noted that our environment is completely virtualized, and thus performance depends heavily on availability: a relational operator can use between one and hundreds of virtual machines, depending on its nature and the cluster’s workload. Besides, we have no control over the underlying hardware. The data center comprises servers with 12 x86-64 cores, between 32 and 64 GB main memory and SSD drives with 1 to 3 TB. But each of these servers can handle dozens of virtual machines. The collection of expertise topics produced by *e#* weighs about 100 MB. We store and index it in SQL Server 2014, which allows us to query it in a few milliseconds. We refer the reader to Pal and Counts [14] for more details about the final query detection.

7. RELATED WORK

Our work bridges two fields of study: expertise retrieval and query expansion. It is, to our knowledge, the first attempt to augment expert search with an external thesaurus.

7.1 Expertise Retrieval.

Researchers have been interested in detecting experts for several years now, in particular since the problem was introduced at TREC in 2005 [2]. An extensive review was written by Balog et al. in 2012 [4]. The two oldest approaches are the *candidate model* and the *document model*. In the candidate model, a textual profile is created offline for each candidate (for instance, by aggregating all the documents authored by the candidate). Then, these profiles are ranked with traditional IR model [7]. The document model operates the other way around. First, a set of relevant documents is identified for the query. Then, the algorithms find the associated people and rank them according to the relevance of the documents and their degree of association [15]. More recently, authors have proposed alternative models. Discriminative models such as the Arithmetic Mean Discriminative model are robust and they can integrate heterogeneous, arbitrary features [9]. Graphs models have also gained popularity. For instance, Serdyukov et al. have shown the effectiveness of random walks on “expertise graphs” [18].

Jianshu et al. is, to our knowledge, the first team to have published work about expert detection on Twitter [20]. Their system is based on a graph describing the topical similarity between the users. To detect authorities, they run a variant of PageRank on this graph for each topic. An alternative was proposed by Pal et al. [14]. We introduce a production version of their framework. Recent work has studied how to incorporate location data into expertise retrieval, focusing on “local” experts rather than “general” experts [6].

As our framework is based on query expansion, we do not compete with any of these approaches. Our system can work with any Expertise Retrieval system.

7.2 Query Expansion.

Authors have proposed query expansion methods for decades in document search. Researchers were already building “classes of similar terms” to improve search before 1960 [16]. To measure the proximity between terms, they used co-occurrence in the training documents. Qiu et al. proposed a notable improvement with “concept-based” query expansion [16]. The main idea was to represent the terms by points in a vector space, where each dimension represents a document. From this representation, it was possible to build a so-called similarity thesaurus. Recent publications have shown that external source of knowledge can also improve search, such as WordNet [19] or ontologies [12].

Our work differs from all of the above because we use a query log. This source of data is relevant for two reasons. First, it is relatively easy to manipulate: we do not have to process the whole collection of documents (in our case, this would mean the whole Web). Second, it is constantly renewed; thus, we believe that the microblogging vocabulary is better captured by this source than by existing ontologies. Other authors have used query logs for query expansion, such as Cui et al. [8]. They observe that if a set of documents is frequently selected for a certain keyword, then their terms are probably strongly correlated to this keyword. However, they still use the underlying documents.

It seems that little work was presented on query expansion in the context of expertise retrieval. Macdonald et al. have mostly focused on local query expansion, i.e., using top ranked documents for pseudo-relevance feedback [11]. Balog et al. have presented ways to incorporate external evidence of expertise into language models [3]. These lines of work are complementary to ours, but they are not overlapping.

8. CONCLUSION

We introduced an approach for expertise detection on social media that emphasizes recall. We showed that finding related domains of interests can be expressed as a graph community detection problem. We presented a parallelized implementation and showed the evaluation results on a large Twitter data set. Our findings demonstrated that $e\#$ can increase the number of experts without losing quality. Future work includes expanding into other social networks such as Quora and Facebook, and exploring different community detection paradigms.

ABSTRACT

Internet user behavior models characterize user browsing dynamics or the transitions among web pages. The models help Internet companies improve their services by accurately targeting customers and providing them the information they want. For instance, specific web pages can be customized and prefetched for individuals based on sequences of web pages they have visited. Existing user behavior models abstracted as time-homogeneous Markov models do not provide efficient support for modeling user behavior variation through time. This paper presents DECT, a scalable time-variant variable-order Markov model. DECT digests terabytes of user session data and yields user behavior patterns through time. We realize DECT using Apache Spark. Our implementation is being open-sourced and we deploy DECT on top of Yahoo! infrastructure. We demonstrate the benefits of DECT with anomaly detection and ad click rate prediction applications. DECT enables the detection of higher-order path anomalies that are masked out by existing models. DECT also provides insights into ad click rates with respect to user visiting paths.

Keywords

Markov Model; Context Tree; Distributed Computing; Time Series; Anomaly Detection; Link Prediction

1. INTRODUCTION

Understanding Internet user behavior is a key to the optimization of Internet services and software. A web browser or server can prefetch or prepare webpages for a user, if the system knows the user will visit the page in the short future [23]. A service provider can customize clickable ads for

a user, if the provider knows which ads the user is likely to click [17]. Service providers can also design search engines to fit human browsing dynamics [13].

Markov model (first-order, time-homogeneous) is commonly adopted for Internet user behavior modeling [5]. It is, however, amnesiac; the probability of the next user visit is purely based on the current status of the user. Higher-order Markov models cure the amnesia issue by digesting historical visiting sites of users [15]. Variable-order Markov models improve higher-order Markov models by pruning away unnecessarily higher-order paths for space saving purposes [3].

While the community has developed a string of advanced Markov models to describe Internet user behavior patterns, one strong assumption is constantly kept in all existing models: user behavior patterns do not change over time.

The above assumption, however, does not hold in the real world. New products are releasing; UI of existing websites are changing; cyber attacks occur; breaking news happen. *The Internet is evolving, and the observed Internet user behavior patterns should reflect the changes.*

This paper presents DECT (distributed evolving context tree), a time-variant model for efficiently describing Internet user behavior patterns and their changes through time. DECT is a time-variant variable-order Markov model. It improves the state of the art variable-order Markov models by releasing its assumption of static time-invariant user behavior patterns. DECT is designed to handle large volumes of user session data and can be efficiently constructed via distributed computing.

Time-variant variable analysis, e.g., visit counts of services, has been widely used in industry to detect anomalies like attacks, failures, and bugs. However, these commonly used variables are stateless or only first-order with respect to Markov models.

In contrast, DECT enables higher-order time-variant visiting path analysis. DECT yields both regular time series of individual path visiting probabilities and high-dimensional time series for a set of related paths, e.g., paths that share the same prefix. We demonstrate in Section 4.1 that DECT can produce deep signals for anomaly detection. It helps reveal stealthy attacks, e.g., application layer DDoS attack [21] and browsing mimicry attack [22]. First-order Markov models, in contrast, could mix these signals into noises. We demonstrate in Section 4.2 that DECT distinguishes ad click probability variations based on historical web pages a user visits, while existing first-order prediction is blind to differ-

^{*}The work was mostly done while the first author was an intern at Yahoo! Labs.

Table 1: Symbols, Terms and Definitions

Term	Definition
s	site the primitive unit to record user behavior (e.g., a URL, a web service, a website)
E	session a sequence of sites that a user visits (every session has a beginning and an end)
\bar{p}	path a substring of a session
τ	target the next site a user is going to transit to
\bar{c}	context a sequence of visited sites prior to τ

ent types of users who come from diverse paths.

The contributions of our work are summarized as follows.

- We design DECT to digest large volumes of user session data and construct time-variant user behavior models in a distributed manner.
- We explain the benefits of a time-variant user behavior model and showcase application examples of DECT in anomaly detection and ad click prediction.
- We realize DECT using Apache Spark and demonstrate its performance processing terabytes of real-world user session datasets.

2. DECT

We discuss two major features of DECT in this section: *variable-order* and *time-variant*. These features are realized through a *flattened context tree*, which embeds time series information in its leaf nodes.

2.1 Definitions and Overview

We study user behavior in terms of their visiting paths on the Internet. A (desktop or mobile) user session is recorded as a sequence of visits to a set of Internet *sites* – resources that users are visiting. Sites vary from specific URLs to domains¹. We define related variables that are used to express user visiting paths in Table 1.

Higher-order Markov models have been proved effective in modeling static user behavior [5]. Given a path \bar{p} , a higher-order Markov model can be trained to predict the last transition of \bar{p} based on previously visited sites in \bar{p} . In this setup, we refer to the last transition in \bar{p} as the target τ , and the sites prior to τ as the context \bar{c} .

The key question we aim to answer is how target transition probabilities change over time. When considering the higher-order Markov model as a weighted directed graph $G_M = (V_M, E_M)$, we construct our model to keep track of:

- change of V_M : new and obsoleted nodes
- change of E_M : transition matrix variation

DECT enables the tracking of both changes, and it provides two features to handle large amounts of data and mitigate exponential space explosion caused by regular higher-order Markov model:

- variable-order context-target probability
- fine-grained parallel path computing and pruning

We realize the two features through *flattened context tree* – a new parallel and concise data structure for building distributed time-variant variable-order Markov model.

¹The granularity of sites is a data collection parameter.

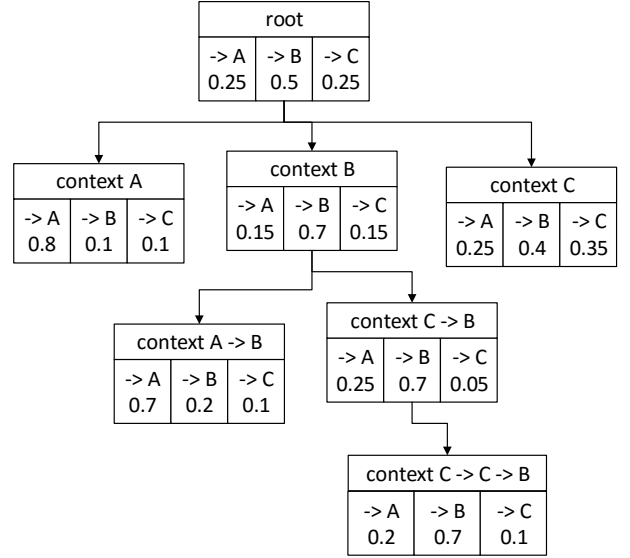

Figure 1: Example of regular context tree (pruned to represent a variable-order Markov model).

2.2 A New Context Tree Structure

Context tree is a common data structure for constructing variable-order Markov model [2,5,6]. We first give a brief description of regular context tree and its operations. Then we present our flattened context tree structure for distributed tree construction and fine-grained parallel pruning.

2.2.1 Regular Context Tree

A regular context tree T_C is a k -ary tree where k is the number of all possible sites. T_C records static transition probabilities of any target given a limited length context. The limited context length is the depth of the tree.

We give an example of a regular context tree in Figure 1. A site $s \in \{A, B, C\}$. Each node maps to one context that is recorded. A node $n_{\bar{c}}$, which corresponds to context $\bar{c} = (s_{-y}, \dots, s_{-2}, s_{-1}, s_0)$, positions at depth y in T_C . Its parent is the node with context $\bar{c}' = (s_{-(y-1)}, \dots, s_{-2}, s_{-1}, s_0)$ at depth $y - 1$. Its children are nodes with context $\bar{c}_{c_i} = (s_{-(y+1)_i}, \dots, s_{-2}, s_{-1}, s_0)$ at depth $y + 1$ where $0 \leq i \leq \xi_{\bar{c}} \leq k$. $\xi_{\bar{c}}$ is the total number of children of \bar{c} .

$n_{\bar{c}}$ stores the target probability distribution with respect to the context $\bar{c} = (s_{-y}, \dots, s_{-2}, s_{-1}, s_0)$, i.e., $P(\tau_j | \bar{c})$ where $0 \leq j \leq \kappa_{\bar{c}} \leq k$. $\kappa_{\bar{c}}$ is the total number of reachable targets given the context \bar{c} .

Pruning Pruning a regular context tree of a higher-order Markov model results in a variable-order Markov model. The standard T_C pruning strategy is a bottom-up process: pruning away $n_{\bar{c}}$ if both criteria are satisfied:

1. $n_{\bar{c}}$ is a leaf node.
2. The distance, e.g., KL divergence, between the target probability distribution of $n_{\bar{c}}$ and that of its parent node $n_{\bar{c}'}$ is less than a predefined threshold \mathcal{T}_{pv} .

Time-variant capability Unfortunately, regular context tree is designed to accommodate static transition probabilities. The transition matrix of the corresponding Markov model is fixed when the model is built. Updating the tree to reflect a time-variant model is expensive. It requires to

Figure 2: Example of flattened context tree with change of transition probabilities in time series.

Table 2: Flattened Context Tree vs. Regular Context Tree

	FCT*	RCT*
Node semantics	(context, target)	context
Tree depth	1	highest order
Probability time series	embedded	none

*FCT/RCT: flattened/regular context tree

recalculate node probabilities and reevaluate previous pruning procedures for pruned nodes.

2.2.2 Flattened Context Tree

We present a *flattened context tree*. We define the pruning strategy to facilitate distributed tree operations for our time-variant Markov model. We prove that our parallel pruning strategy preserves the tree structure: one branch can be pruned only if all its children are pruned.

A flattened context tree T_F only has a depth of two: depth 0: root, and depth 1: all data nodes. Each depth-1 node $n_{\bar{p}}$ corresponds to a path $\bar{p} = (\bar{c}, t) = (s_{-y}, \dots, s_{-2}, s_{-1}, s_0, t)$ and it records a time series of transition probability $\Psi(\tau|\bar{c}) = \{P_t(\tau|\bar{c}) : t \in T\}$. In comparison, a node $n_{\bar{c}}$ in T_C stores the distribution of transition probabilities according to context \bar{c} . Table 2 shows the most significant differences between our flattened context tree and regular context tree. We illustrate the structure of flattened context tree in Figure 2.

The advantage of the flattened tree structure is that each node can be processed independently of other nodes, which enables fine-grained parallel probability computing and pruning for each (\bar{c}, τ) pair. Furthermore, different nodes in T_F can be processed on a different processing unit in a distributed manner to scale out the process.

Pruning The purpose of pruning is to transform a higher-order Markov model to a variable-order one. Pruning of T_F is performed for individual nodes in parallel. A node $n_{\bar{p}}$ is pruned away if \bar{p} is rarely visited through a large segment of the monitored time period. The criteria can be measured as the total number of *path visits* or the total number of *path appearances* during the overall monitored time period. The latter yields *True* or *False* in each inspection window and

sums the total number of *True* for the overall time period.

THEOREM 1. In a flattened context tree T_F , a node $n_{\bar{p}}$ records the target transition probability time series of path \bar{p} . \bar{p}' denotes a suffix string of \bar{p} . $n_{\bar{p}}$ in T_F can be pruned if $n_{\bar{p}'}$ (node corresponding to \bar{p}') can be pruned.

PROOF. If a path \bar{p} is visited, its suffix path \bar{p}' is visited. And two different paths \bar{p}_1 and \bar{p}_2 can share the same suffix path \bar{p}' . So $V(\bar{p}') \geq V(\bar{p})$ where $V(\bar{p})$ is the number of path \bar{p} visits. Given \mathcal{T}_{pv} as the pruning threshold for path visits, $V(\bar{p}) < \mathcal{T}_{pv}$ holds if $V(\bar{p}') < \mathcal{T}_{pv}$. \square

If one restructures a flattened context tree T_F back to a regular context tree T_C , Theorem 1 guarantees that all children of a branch node are pruned away before the branch node is pruned. It is consistent with the standard pruning strategy presented in Section 2.2.1.

Time-variant capability Time series information is embedded into each node $n_{\bar{p}}$ in T_F , so T_F reflects the change of the corresponding Markov model through time. Change of E_M (discussed in Section 2.1) is distributed across $\Psi(\tau|\bar{c})$ in each node. Changes of V_M (discussed in Section 2.1) are also stored in new or obsolete nodes if not pruned.

2.3 Growing the Flattened Context Tree

A flattened context tree T_F grows through time. We use a sliding window w to aggregate sessions through time and yield transition matrices of our time-variant Markov model at different times. Time series yielded from nodes in the flattened context tree are extended when new sessions are consumed and the tree has grown.

2.3.1 Session Batch

Session batch is a set of sessions. It is the smallest sliding unit for w . Sessions are batched according to the timestamp of its first visited site. A session may last across several batch time periods, but the *entire* session is recorded only once in the first batch it appears². The timestamp of the session batch is the start of the session batch.

Session batches do not interference with each other, and they can be preprocessed in parallel to facilitate the tree construction. In each session batch:

- All paths at different lengths are identified (through n -gram with variable- n) and parsed into tuples (\bar{c}, τ) .
- The counts of each tuple are accumulated.
- A set of 4-tuples $(\bar{c}, \tau, t_b, \eta_{(\bar{c}, \tau)})$ is yielded as the session batch digest where t_b is the session batch timestamp and $\eta_{(\bar{c}, \tau)}$ is the count of tuple (\bar{c}, τ) in the batch.

2.3.2 Sliding Window

The sliding window w covers a fixed number of session batches and each slide takes in a new session batch and abandons the earliest batch in the previous w .

In each sliding position, three operations are performed:

- 4-tuples $(\bar{c}, \tau, t_w, \eta_{(\bar{c}, \tau)})$ are accumulated from session batch digests where t_w is the timestamp of the earliest session batch in the window.
- 3-tuples $(\bar{c}, t_w, \eta_{\bar{c}})$ are accumulated from the 4-tuples where $\eta_{\bar{c}}$ is the count of context \bar{c} in the window.

²Our current design does not support streaming because it requires the entire user session to finish before it can be sessionized and batched.

Table 3: Description of Spark Runtime Stages of our DECT Prototype

Functionality	#(SS)	Description
Input handling	1	reading user session data from HDFS
Modeling	19	n -gram generation, batching, in-window aggregation, probability calculation, pruning
Time series generation	9	assembling time series and storing them onto HDFS
Statistics generation	3	generating and yielding statistics throughout the entire processing procedure

#(SS): number of Spark runtime stages

- iii) A set of 4-tuples $(\bar{c}, \tau, t_w, P(\tau|\bar{c}))$ is yielded as the window digest where $P(\tau|\bar{c}) = \frac{\eta(\bar{c}, \tau)}{\eta_{\bar{c}}}$.

2.3.3 Flattened Context Tree Update

Digests of w at different positions are aggregated according to tuple (\bar{c}, τ) in the window digest. Each tuple forms a depth-1 node $n_{\bar{p}}$ in the flattened context tree T_F . The time series at each node $(\Psi(\tau|\bar{c}))$ at node $n_{\bar{p}}$ where $\bar{p} = (\bar{c}, \tau)$ is extended when a new window position is processed. w at different positions of a single node can be computed in parallel if all session batches are known.

Pruning of T_F can be performed at any time based on the generated time series at nodes. As discussed in Section 2.2.2, pruning is performed at nodes that are rarely visited. If $n_{\bar{p}}$ is pruned, $\Psi(\tau|\bar{c})$ prior to the pruning action is lost. $n_{\bar{p}}$ can be added back to T_F if it becomes popular in the future, but without the segment of $\Psi(\tau|\bar{c})$ when it is pruned away.

2.3.4 Time Series Production and its Applications

T_F records the user behavior pattern evolvement and it can be consumed by a variety of time series analysis tools (e.g., anomaly detection, path prediction).

User behavior evolvement data generation. The user behavior evolvement data are yielded in three major forms for post-processing and analytics:

- $\Psi(\tau|\bar{c})$: individual time series for each (\bar{c}, τ) pair
- $\{\Psi(\tau_i|\bar{c}) \mid 0 \leq i \leq \kappa_{\bar{c}}\}$: high-dimensional time series for all targets of a context \bar{c} where $\kappa_{\bar{c}}$ is the total number of reachable targets of context \bar{c} .
- $\{\Psi(\tau|\bar{c}_i) \mid 0 \leq i \leq \varrho_{\tau}\}$: a collection of time series for a target τ where ϱ_{τ} is the total number of contexts which can reach the target τ .

$\{\Psi(\tau_i|\bar{c}) \mid 0 \leq i \leq \kappa_{\bar{c}}\}$ forms a high-dimensional time series where each dimension is $\Psi(\tau_i|\bar{c})$. We write $\{\Psi(\tau|\bar{c}_i) \mid 0 \leq i \leq \varrho_{\tau}\}$ as a collection because each $\Psi(\tau|\bar{c}')$ is not independent of $\Psi(\tau|\bar{c})$ where \bar{c}' is a suffix of \bar{c} , yet it is quite useful to compare $\Psi(\tau|\bar{c})$ with $\Psi(\tau|\bar{c}')$.

User behavior evolvement data analysis. Three most important components of an aggregated user behavior time series are *trend*, *seasonality*, and *irregular component*.

Trend $\Psi_T(\tau|\bar{c})$ describes long-term movement without calendar related and irregular effects.

Seasonality $\Psi_S(\tau|\bar{c})$ characterizes regular cyclic movements influenced by seasonal factors.

Irregular component $\Psi_I(\tau|\bar{c})$ records non-systematic and unpredictable component(s) after trend and seasonal components are removed from the signal.

Many user behavior time series $\Psi(\tau|\bar{c})$ can be very well

decomposed into the three components as described in (1).

$$\Psi(\tau|\bar{c}) = \Psi_T(\tau|\bar{c}) + \Psi_S(\tau|\bar{c}) + \Psi_I(\tau|\bar{c}) \quad (1)$$

$\Psi_S(\tau|\bar{c})$ can be further divided into daily and weekly seasonal components as found in our experiments.

Two major applications of our model are described next.

Anomaly Detection aims to discover anomalous user behavior with respect to specific visiting paths. A *spike* or a *ravine* in a time series could indicate breaking news, flash crowds, Denial-of-Service attacks, service failures, etc. A plateau appearing in the *trend* component of a time series may indicate a persistent attack or a test for a new feature. User behavior evolvement data $\Psi(\tau|\bar{c})$ and $\{\Psi(\tau_i|\bar{c}) \mid 0 \leq i \leq \kappa_{\bar{c}}\}$ are yielded for anomaly detection.

Ad Click Prediction is an application to predict how likely a user will click an ad on her current visiting site given her visiting path of the current session. Different visiting paths leading to the same site may give different ad click rates, and the probability trends of different paths may be different. User behavior evolvement data $\Psi(\tau|\bar{c})$ and $\{\Psi(\tau|\bar{c}_i) \mid 0 \leq i \leq \varrho_{\tau}\}$ are yielded for ad click prediction.

3. IMPLEMENTATION

We implement DECT via Apache Spark using Scala. We deploy DECT on top of Yahoo! infrastructure to support anomaly detection and other services on Yahoo! network.

Our DECT implementation is open-sourced on github [19]. The implementation takes advantage of scalable and robust transformations on resilient distributed dataset (RDD) in Spark, e.g., `mapValues` and `join`. DECT compiles to 32 Spark stages at JVM runtime (shown in Table 3).

Our implementation consumes plaintext session data stored on HDFS where each line records a user session³. A user session consists of a timestamp t_s and a sequence of visited sites $E = \{s_0, s_1, \dots\}$. DECT digests the plaintext session data and yields two types of information: *i*) time series harvested from the flattened context tree, stored on HDFS, and *ii*) statistics on processed data, e.g., total number of i th-order time series, printed to Spark log.

Our realization is optimized from the following aspects:

1. Session and path (n -gram) data are aggregated at early stages to minimize unnecessary duplicate data processing. For example, before generating and counting n -grams in each session E , same E with the same session batch timestamp t_b are counted and deduplicated.
2. Compact data structures are used to reduce storage and transmitting overhead, e.g., a context as a single JVM string, instead of an array of sites (JVM strings).

³We employ a **Pig** script to retrieve, sessionize and store raw user event data from HCatalog onto HDFS prior to DECT.

Figure 3: Higher-order path time series anomaly detection⁵.

3. Job parameters are broadcasted, e.g., string splitter.
4. Partitioning strategies are manually specified to reduce data movement among worker nodes.

4. EVALUATION

We conduct experiments on two Yahoo! daily user session datasets to answer the following key questions:

1. What do we benefit from our time-variant user behavior model over existing static stochastic models?
2. Is our design scalable to handle enterprise-wide tasks consisting of billions of sessions?

We evaluate DECT with all data collected through Yahoo! data highway. We analyze Yahoo! user activities within the first half of 2015. In the evaluation, we focus on user sessions within a single product, e.g., Yahoo! mail. Visits to alien sites during sessions are ignored⁴.

We process user session data of Yahoo! US websites (English version) within two products separately: Yahoo! mail and Yahoo! finance⁵. Each site in a session is roughly a view in the model-view-controller (MVC) web architecture, and it has a unique URL.

4.1 Case Study: Anomaly Detection

Time series of site visits are commonly used as anomaly detection signals. However, if no context information is specified, anomaly signals of specific visiting paths are masked out by other signals. Therefore, it causes false negatives.

We pick a typical Yahoo! mail site W (i.e., τ in Section 2)⁵ and show that anomalies in higher-order path signals are significant and can be revealed by DECT. We use DECT to compute visiting probabilities of W for all contexts $\{\bar{c}\}$ that exist. We then fed time series $\{\Psi(\tau_i|\bar{c}) \mid 0 \leq$

⁴DECT can be deployed at the client/browser side to model and analyze Internet-wide user behavior.

⁵According to Yahoo! data privacy requirements, *i*) detailed data statistics are not provided; *ii*) probabilities in figures are disguised while their relative positions are preserved.

Figure 4: Ad click probabilities given different paths. The bold dotted line denotes the overall ad click rate of users on a site. Each thin line denotes ad click rates of users on this site coming from one specific visiting path⁵.

Figure 5: Ad click probability of a wanderlust⁵.

$i \leq \kappa_{\bar{c}}\}$ yielded by DECT into EGADS for anomaly detection. EGADS is a generic and scalable framework for automated anomaly detection on large scale time-series data [10]. The entire anomaly detection application consists of DECT (time-variant user behavior modeling) and EGADS (time series anomaly detection).

Fig. 3 shows two higher-order anomalous time series identified by EGADS. The upper subfigure, a common seasonal time series across a month, is the visiting probability of W across all Yahoo! mail sites. One anomalous time series (site X to W) is detected during that month (several spikes in the middle subfigure). Another anomaly is found on the 8th day of visiting path “Y to X to W” in the lower subfigure. Any anomaly (spike) with respect to a higher-order path may be hidden in the time series of its suffix path.

4.2 Case Study: Ad Click Prediction

Existing ad click prediction techniques do not take historically visited paths into account. We run DECT on the Yahoo! finance dataset to show that such information is useful in distinguishing probabilities of ad clicks.

We draw the overall ad click rate on a Yahoo! finance site⁵ in Fig. 4 with the bold dotted line. We then use DECT to

Figure 6: Performance pivot discovery of DECT.

Figure 7: Order impact on computation complexity.

investigate three ad click rate time series, each of which has a site previously visited (one-time context) before the target site. Fig. 4 shows that the click rate of users coming from one site can be 5 times higher than that of another.

Besides the finding that *ad click rates are related to user visiting paths*, another interesting conclusion we reached is that *the more a user views articles on a site, the less likely she will click an ad on that site*. We illustrate the decrease of ad click rates on a Yahoo! finance site⁵ in Fig. 5. We explain the phenomenon that frequent readers tend to continuously consume target information, e.g., stock values, and ignore ads. Ads could be less effective and more annoying to frequent readers than normal visitors. This work is being deployed at Yahoo! for better ad-targeting.

4.3 Performance analysis

We demonstrate the performance of our implementation by processing a subset of Yahoo! mail data (around 0.1 billion user sessions, 10GB storage size on HDFS)⁵.

Scalability and Performance Pivot. Our realization of DECT is based on the scalable Apache Spark framework. A distributed system results in an increasing amount of communicating/scheduling overhead when scaling out. We are interested in discovering performance pivots and parameter tuning on real-world datasets.

We conduct several groups of experiments with DECT

running on different numbers of worker nodes. We measure the degree of parallelism via the maximum number of processing units (vCore)⁶ concurrently allocated at any execution stage. Fig. 6 shows that our implementation scales out well before reaching a performance pivot. Performance pivots are reached for DECT with order limit 4 at 9010 vCores and order limit 2 at 4210 vCores. Increasing the number of processing units after the pivots wastes more in overhead than gaining better performance. The more complex the computation is, e.g., higher order limit, the larger amount of processing units are required to reach the pivot.

Magnitude of frequently visited higher-order paths. DECT is a variable-order Markov model. It employs a pruning procedure to remove time series of rarely visited higher-order paths. We are interested in the order impact on the overall computational complexity.

We execute DECT with various order limits. Because the total number of possible paths is exponential in path order, the results in Fig. 7 show that: *i)* the processing time increases exponentially with the increase of the order limit, and *ii)* the pruning procedure reduces the number of time series by a constant factor on Yahoo! mail dataset.

5. RELATED WORK

Our work is motivated by time-homogeneous Markov user behavior modeling, time series analysis, and evolutionary network analysis.

Time-homogeneous Markov modeling. Web user behavior has been studied for various purposes, such as PageRank [13], link prediction [17], document prefetching [23]. A variety of time-homogeneous Markov models have been tested to describe Internet user behavior [5]. The time-homogeneous indicates that the transition matrix of the Markov model does not change through time. We list some existing models classified by their Markov orders below.

- First-order Markov model: [12, 13]
- Second-order Markov model: [23]
- Higher-order Markov model: [15]
- Variable-order Markov model: [2, 5, 6]

Variable-order Markov models compute different orders for different paths to reduce storage expenses. The idea was proposed by Bühlmann and Wyner [3]. There exist two generic approaches to construct variable-order models.

Pruning-based approach: starting with a complete higher-order model and iteratively pruning low-entropy branches to get a incomplete tree, e.g., [6].

Growing-based approach: starting with a first-order Markov model and expanding leaves with inconsistent distribution into branches, e.g., [2].

Our design follows the former approach for straightforward parallel design. The operations of growing higher-order paths, i.e., slicing and clustering, are computational heavy and the results cannot be efficiently reused over time.

Time series analysis. A time series denotes the change of a variable over time [8]. Time series analysis has been applied to many fields including signal forecasting [9], data feature extraction [7] and anomaly detection [4, 10, 11, 20].

Time series analysis is widely used to detect anomalous

⁶The number of workers is linear to the number of vCores.

user events in the industry. However, studied variables in existing systems are mostly primitive, e.g., counts of site visits. They only represent zeroth-order or first-order (one-hop) paths [10]. The prediction is fast but loses rich context information. DECT, in contrast, utilizes historical site visiting information to provide more detailed signals for anomaly detection and ad click rate prediction as shown in Section 4.

Evolutionary network analysis. Dynamic networks appear in social networks, wireless sensor networks, Internet of Things, and the Web. The analysis of evolving networks provides a comprehensive understanding of such networks [1] and enables applications such as link prediction [18] and anomaly detection [16].

Graphs are generic models for dynamic network representation [1]. More specifically, dynamic networks usually generate complex cyclic graphs, and evolutionary network analysis heavily relies on unique properties of such graphs, e.g., community discovery [14]. Compared to cyclic graphs, variable-order Markov models are tree-equivalent structures. In our model, we bring some concepts from evolutionary network analysis, e.g., *change of V_M* and *change of E_M* . But, in general, it is currently unclear how evolutionary network analysis methods can be applied to dynamic web user behavior modeling.

6. CONCLUSIONS AND FUTURE WORK

This paper presents DECT, a scalable time-variant web user behavior model. It characterizes the changing nature of Internet user behavior with a time-variant variable-order Markov model. DECT can be efficiently realized on scalable distributed frameworks, e.g., Apache Spark, to process large volumes of user behavior data. DECT enables time series analysis on individual or related sets of long (higher-order) user paths. We open-sourced DECT and deployed it at Yahoo! to support path time series analysis such as anomaly detection, click probability prediction and path trend discovery. In the future work, we plan to work on streaming pruning strategies to enable streaming user behavior processing using DECT.

ABSTRACT

The paper introduces Strudel, a development and execution framework for transactional workloads both on SQL and NoSQL systems. Whereas a rich set of benchmarks and performance analysis platforms have been developed for SQL-based systems (RDBMSs), it is challenging for application developers to evaluate both SQL and NoSQL systems for their specific needs. The Strudel framework, which we have released as open-source software, helps such developers (as well as providers of NoSQL stores) to build, customize, and share benchmarks that can run on various SQL/NoSQL systems. We describe Strudel's architecture and APIs, its components for supporting various NoSQL stores (e.g., HBase, MongoDB), example benchmarks included in the release, and performance experiments to demonstrate usefulness of the framework.

1. INTRODUCTION

As a large number of web applications adopt cloud computing platforms, various types of “NoSQL” systems have emerged and been employed as scalable and elastic data stores. They are expected to serve transactional workloads¹ of an application that interacts with a large and varying number of users on top of commodity server resources (typically in the cloud).

Now that application developers have many choices of NoSQL systems as well as SQL systems (i.e., RDBMSs), they face various questions (which we would call “SQL-or-NoSQL questions”): When should we use a NoSQL store instead of a traditional RDBMS? How can we choose a NoSQL system that suits for our purpose? With a particular NoSQL system, what kind of trade-off do we face between scalability/elasticity gain and the cost of reduced consistency/integrity support? What about other alternatives such as

¹We focus on user-facing transactional application workloads instead of analytic ones.

purchasing a parallel RDBMS product or sharding (partitioning) open-source RDBMSs?

Standard benchmarks (such as TPC-C) have been very helpful for evaluating and choosing RDBMS products. On the other hand, the effort on benchmarking for NoSQL does not seem catching up with the evolution of NoSQL systems. Currently, YCSB [16, 12] is the most commonly used benchmark for NoSQL, but it mainly focuses on micro-benchmarking of key-value read/write operations. As NoSQL supports various features such as transaction and more complicated queries, more benchmarks are needed to capture the requirements behind such features.

It is challenging to develop benchmarks, especially to compare SQL-based systems and NoSQL systems together, given many different query APIs. It is also challenging to cover the wide range of the application needs. A transactional data store is just part of a larger application system, and its role and requirements are significantly different among applications.

Thus, we can hardly expect that a limited number of standard benchmarks are enough for transactional workloads over SQL/NoSQL systems. Given the variety of data stores and the variety of application needs, we need a way to efficiently develop a large and evolving suite of benchmarks, from micro-benchmark level to application-level, with minimum engineering effort in terms of (1) developing a new benchmark on existing SQL/NoSQL systems and (2) supporting a new SQL/NoSQL system for existing benchmarks.

In this paper we introduce our development and execution framework, called Strudel, for transactional benchmark workloads with expectation to contribute to the benchmarking effort in the community.

The design philosophy of the Strudel framework is to provide composability and reusability with (1) decomposing benchmark implementations into small components with multiple abstraction layers and (2) employing a configuration description language to combine these components into a specific workload in a reproducible and shareable manner. In order to bridge the gaps among various data stores, the framework provides multiple abstraction layers: most notably Entity DB API and Session Workload framework. A configuration description language is adopted in the framework to enable developers to compose a system and workload with custom properties in XML.

We have used and kept extending the framework for years through our research and product development of elastic relational stores (SQL engines on top of KVS [25]). As it

has matured as a generic and extensible framework, we recently released it (including benchmarks and SQL/NoSQL supports as described later) as open source software[9] for wider development purposes.

In this paper, we describe the design and architecture of the Strudel framework, its support on various NoSQL systems, benchmark examples we have developed, and performance experiments to demonstrate usefulness of the framework.

2. RELATED WORK

YCSB The Yahoo! Cloud Serving Benchmark (YCSB) [16, 12] is the most commonly used benchmark for NoSQL systems. However, from our objective to conduct performance studies on transactional aspects of SQL and NoSQL systems, the original YCSB has very limited support of transactional workloads. Researchers have extended YCSB to experiment transactions over multiple key-value objects (e.g., [17]). With an appropriate framework, we should be able to share such custom efforts to serve for more general application performance analyses.

As NoSQL systems evolve from a simple Key-Value store, there are increasing needs of performance studies with higher-level (i.e., application-level) workloads, which are especially important to compare SQL systems and NoSQL system from the application developers' viewpoints. YCSB++ [23] extends the original YCSB to evaluate advanced features of NoSQL systems (HBase and Accumulo). The features that are relevant to transactional workload evaluation include (1) pushing filtering to the data store, (2) measurement of data staleness due to weak consistency. One possible idea is to integrate such features with the Strudel framework to evaluate advanced NoSQL features not only for micro-benchmarks but also for application-level benchmarks.

OLTP-Bench OLTP-Bench [18, 6] is an extensible testbed for benchmarking RDBMSs for (primarily) transactional workloads. Our framework and OLTP-Bench are not mutually exclusive but complimentary. We focus on a special class of OLTP problems where developers have "SQL or NoSQL" questions. OLTP-Bench, aiming for more general OLTP use cases, provides a lot of useful features that our framework misses, such as sophisticated (e.g., more realistically skewed) data and workload generation and a rich set of SQL workloads (including traditional ones that we do not focus on). A skilled developer may reuse these features combined with the Strudel framework.

Performance studies There have been various performance studies reported on NoSQL systems, including the the original work of YCSB [16]. For an example of performance studies from the application's viewpoint, Klein et al.[22] report their performance evaluation of NoSQL systems for a healthcare application. Their customer (a healthcare provider) requests them to evaluate NoSQL technologies for a new electronic healthcare record system to replace the current version that uses an RDBMS. They developed evaluation tests by modifying the code of YCSB to fit the application's data model. With an appropriate development framework provided, their development could have been easier. In addition, whereas their study excludes RDBMSs (according to the customer requirements), it would need more engineering effort, in general, to compare NoSQL with RDBMSs.

Floratos et al. [20] report comparative performance stud-

ies between SQL and NoSQL systems, including comparison between SQL Server and MongoDB for YCSB workloads. We hope Strudel is useful to extend such studies to cover more NoSQL systems and various benchmarks that capture application-level requirements.

3. ARCHITECTURE

Figure 1 illustrates the layered architecture of the Strudel framework that provides composability and reusability in benchmark application development. The abstraction layers are visualized as orange boxes with underscored italic words (representing the names of APIs). Among them, Java Persistence API (JPA) is a Java standard for object-relational mapping (that converts Java object manipulation to SQL queries). The Strudel framework provides the other APIs.

Entity DB is a simplified data access API that covers transactional data access features that are common in various NoSQL systems as well as relational databases (Section 4). Basic implementation of Entity DB on a NoSQL system would not be very difficult (we also provide another API, Transactional KVS, to make it easier). If a benchmark is implemented on Entity DB API, it can run on various NoSQL systems as well as RDBMSs that support the JPA standard.

The Session Workload is a framework that helps developers to implement benchmark application on different data access APIs (Entity DB, JPA, and native NoSQL APIs) by reusing the code as much as possible (Section 5).

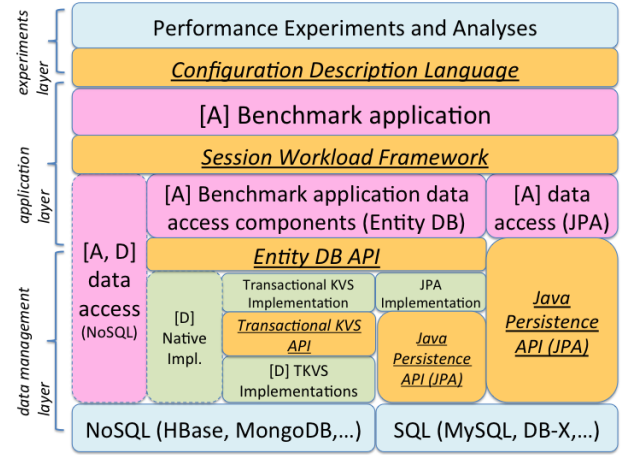

Figure 1: Layered Architecture of Strudel

In Figure 1, red boxes labeled with [A] are components a developer needs to implement for each benchmark application, and green boxes with [D] are implemented for each NoSQL system. The label [A,D] indicates a component to be implemented for each pair of a benchmark and a NoSQL system, and our goal is to minimize such components.

A developer can conduct a specific experiment by combining these components with a particular set of configuration parameters. We employ a configuration description language for such experiments to make experiments reproducible and individual components reusable across different experiments (Section 6).

Strudel also provides workload management and execution engines for experiments in a cluster environment in an

automated manner (Section 7).

4. ENTITY DB API

Entity DB API is one of the abstraction layers that are useful to develop workloads that can run on various data stores. It employs a subset of JPA (Java Persistence API) to fill the gap between SQL and NoSQL systems. JPA is a standard Java API for Object-Relational Mapping, providing a way to map Java objects (entities) and relational tables and a way to access data in a relational database through such Java objects.

JPA provides a basis for us to abstract out the details of underlying data stores so that application developers can focus on data handling in an object-oriented manner. However, to most NoSQL systems, JPA is not applicable directly since the concept of object-relational mapping relies on expressive power and declarativeness of SQL and the relational model.

Thus, we have designed a simplified version of APIs that consists of standard Java annotations (e.g., `@Entity`, `@Id`) of JPA and extended annotations as well as simplified data access methods. Whereas this API is not meant for application production use (missing various features required in production)², it would support simplified application prototypes to quickly compare data store alternatives before the real application version is developed.

4.1 Entity Group Annotations

One of the key difference of NoSQL systems from the traditional RDBMS is that not all the data items are equal in terms of transactional data access. Distributed transactions are often expensive in a commodity cluster (especially cloud) environment in order to handle a large number of concurrent read/write accesses with high availability under a short response time requirement of interactive applications. Thus, most NoSQL systems provide a way to compromise transactional consistency for scalability to avoid distributed transaction as much as possible. In a typical case, a NoSQL system allows ACID data access only on a data set associated with a single key. HBase [2] (open source implementation of Bigtable [15]) provides an atomic check-and-update operation on a single row of a (big)table. For transactions over multiple rows, we need to use an external transaction manager (e.g., Omid [19]) to implement concurrency control and recovery.

In order to provide a common API to incorporate such transaction support, we adopt the concept of *entity groups*. Helland [21] argued that, in order for an application to be truly scalable, it must forgo expensive distributed transactions; instead, each transaction must operate on a uniquely identifiable collection of data (i.e., *entity groups*) that lives on a single machine. Google Megastore [14] supports entity group as a way to associate multiple entities to a group key and guarantee efficient ACID transactions within a single group.

We introduce a set of annotations to specify entity groups in a similar way to Megastore. In addition to standard annotations (`@Entity`, `@Id`, `@IdClass`), we introduce the following annotations: `@Group`, `@GroupId`, `@GroupIdClass`.

²For production use, there is an open source product, for example, DataNucleus that supports common APIs for Java data persistence on some of NoSQL systems: <http://www.datanucleus.org/>

We illustrate how these annotations are used in an example benchmark (which emulates an auction application) in Figure 2. The code uses the JPA standards to define Bid Java class as an entity (`@Entity`) with a compound key (`sellerId`, `itemNo`, `bidNo`) (as annotated with `@Id`), which is packaged as one object of a class `BidId` (`@IdClass`).

```
@Group(parent = AuctionItem.class)
@Entity
@Indexes({
    @On(property = "auctionItemId"),
    @On(property = "userId")
})
@GroupIdClass(ItemId.class)
@IdClass(BidId.class)
public class Bid {
    @GroupId @Id private int sellerId;
    @GroupId @Id private int itemNo;
    @Id @GeneratedValue
    private int bidNo;
    private double bidAmount;
    private long bidDate;
    private int userId;
```

Figure 2: Example code with annotations

With extended annotations, a benchmark developer can associate two entity classes together (as a parent-child relationship) in one group by specifying `@Group` annotation at a child class to indicate its parent. In this example, `Bid` is associated with `AuctionItem` (so that we can consistently access all the bids on one particular auction item and update the item when the maximum bid price changes). A group id (`@GroupId`) is a member of a compound key (a group key) that specifies a group instance. A set of group ids on an entity class must be a subset of the set of ids (i.e., a (compound) primary key) that are annotated with `@Id`.

4.2 Data Access Operations

CRUD Operations Entity DB API supports basic CRUD (Create-Read-Update-Delete) operations: (1) create (2) get, (3) update, and (4) delete operations (Figure 3). They (roughly) correspond to persist, find, merge, and remove operations of `EntityManager`, a data access interface of JPA³.

Secondary Key Access Unlike JPA, the current Entity DB API does not support a SQL-like query language or automatic retrieval of related entities with a join column (i.e., annotations such as `@OneToMany`, `@ManyToOne`). Instead, it provides a way to read multiple instances of the same entity class by specifying one of the entity's property as a *secondary key* (`getEntitiesByIndex` in Figure 3).

Group Transactions The current version of the framework only supports a transaction within an entity group (designing API to indicate a "global" transaction is a plan for a future version). A transaction starts with a given group key and commits after multiple CRUD operations. Figure 4 shows an example of transaction execution. The application code gives an instance of `EntityTask` interface to the EntityDB API (`"edb.run()"`), then the underlying Entity

³A subtle difference from JPA is that there is no concept of attachment/detachment in the current version: an application always needs to use an update operation to apply changes in an entity Java object to the database.

```

<T> T get(Class<T> entityClass, Object key);
void create(Object entity);
void update(Object entity);
void delete(Object entity);
<T> List<T> getEntitiesByIndex(
    Class<T> entityClass, String property,
    Object key);

```

Figure 3: EntityDB Interface (partial)

DB implementation runs the instance of EntityTask by giving an EntityTransaction object (`run(EntityTransaction tx)`). The entity task (i.e., the application code) uses this transaction handler (`tx`) to issue multiple CRUD operations.

The reason behind this rather convoluted API design (instead of providing usual begin/commit operations) is to abstract out transaction retry handling, especially for optimistic concurrency control. A transaction of applications for NoSQL systems is often simple and lightweight. It is easy to retry the entire transaction when a commit request fails under optimistic concurrency control. In order to analyze the impact of transaction conflict in different NoSQL systems, we want experiment different retry policies without changing the application code.

```

BidResult r = edb.run(Bid.class, itemId,
    new EntityTask<BidResult>() {
        public BidResult run(EntityTransaction tx) {
            AuctionItem item =
                tx.get(AuctionItem.class, itemId);
            if (item == null) {
                return BidResult.NONE;
            }
            if (bid.amount() <= item.getMaxBid()) {
                return BidResult.LOST;
            }
            tx.create(bid);
            item.setMaxBid(bid.amount());
            tx.update(item);
            return BidResult.SUCCESS;
        }
    });

```

Figure 4: Example of group transaction

4.3 Auxiliary Data Maintenance

Entity DB API supports two features that involve maintenance of auxiliary data in the underlying data store: (1) values for automatic unique key generation and (2) indices.

Auto Key Generation Entity DB API lets the developers specify the standard `@GeneratedValue` annotation to use a generated unique value for an id. Just as the standard JPA, an underlying implementation can choose a way to generate unique values based on the data store’s capability.

The major difference from the standard specification is the uniqueness requirement: In JPA, `@GeneratedValue` is used to generate a unique value within a table. In Entity DB, it can only be *locally* unique: it is required that the compound group/primary keys that include this id as a member are unique. For example, in Figure 2, the id `bidNo` is automatically generated when a Bid entity instance is created. In fact, `itemNo` is also a generated value specified in the AuctionItem class definition. The value of `itemNo` must be unique

within a particular user (identified with `sellerId`), and the value of `bidNo` must be unique within a particular auction item.

This local uniqueness requirement gives the underlying data store more freedom to use a scalable and efficient way to generate values.

Indices To use secondary-key data access, the developers need to explicitly specify an index on a property of an entity. Notice that the role of an index at logical design level is different from the case with relational databases where selection of an index is logically transparent from queries. Thus, we introduce a special annotation (`@Indexes`) separated from JPA’s index annotation (`@Table.indexes`).

One non-trivial semantics of this index-based entity access is its consistency under a specific entity group design. In terms of transaction isolation, an index entry can be seen another (system-defined) entity, and question is whether it is grouped together with the entities it refers to.

An index can be included (and is included by default) in the group if the compound index key (i.e., a set of ids) includes the compound group key. We call such an index an *in-group index* and otherwise we call it an *out-of-group index*. For example, in Figure 2, there are two indices on AuctionItem (which is in fact a compound key with `sellerId` and `itemNo`) and `userId`. The former index is in-group (the index key equals to the group key) and the latter index is out-of-group.

If the index is not included in the group, we cannot prevent a *phantom read*: a transaction cannot read the all the bids on the same item (which is done through the index) in an isolated manner (e.g. it cannot be isolated from insertion of a new bid).

In the current Entity DB, we only allow an index on immutable columns: the value is specified only at creation of an entity instance and does not change until the instance is deleted.

4.4 Implementations

4.4.1 Generic Transactional KVS

Whereas Entity DB API is simplified for minimum support for entity data access, it still needs engineering efforts to develop an implementation for a particular NoSQL system. We provide yet another API for transactional key-value data access so that a provider of a NoSQL system can quickly implement this further simplified API instead of directly implementing Entity DB.

In Transactional KVS, a data record is just a pair of byte-array key and value, and records are grouped by a group key (another byte array). Data access is done by a group transaction (started with a group key) and simple put/get operations.

The framework provides an Entity DB implementation for Transactional KVS, which automates (1) mapping from entities to byte array key-value objects, (2) index management, and (3) auto key generation.

Index and Key generation As a baseline implementation of Entity DB API, we implemented an index and a key-generation counter as sets of key-value objects on top of the Transactional KVS data model. For each index key, we create an object with the index key and a value that encodes the pointers to the indexed entities. A counter object is created for each parent key (i.e., the compound primary

key except an ID to be generated) of an entity, and its value is a counter number.

Consider the example in Figure 2 when an application workload creates a new instance of Bid entity. Bid has two indices (`auctionItemId` and `userId`) and a generated key (`bidNo`). There are three auxiliary key-value objects updated when we create a new Bid (which is a new key-value object by itself): (a) an index object of type `auctionItemId` with key (`sellerId`, `itemNo`), (b) an index object of type `userId` with key `userId`, and (c) a counter object of type Bid with key (`sellerId`, `itemNo`). Among them only the object *a* is included in the group with the Bid entity, and creation of Bid involves a following sequence of three transactions:

1. updates a counter object *c* and acquires a new value for `bidNo`.
2. updates an index *b* to insert a key of Bid (`sellerId`, `itemNo`, `bidNo`) using the result of transaction 1.
3. updates an index *a* and creates a new key-value object for a Bid entity.

The order of these transactions is important to keep an index *b* consistent. Even if another transaction accesses the index *b* between transaction 2 and 3 (or even if transaction 3 fails), it will just read a dangling pointer in the index to a non-existent entity, which does not cause inconsistency. On the other hand, if these transactions create a Bid entity but fail to update the index *b*, it results in inconsistency (i.e., the existing entity cannot be accessed by the index). When the entity is deleted, the order of transactions will become opposite. When the entity is updated, we do not update the index (i.e., the current Entity DB assumes keys are immutable).

Notice also that the counter object *c* could have been updated in the transaction 3 if there were no out-of-group index such as *b* (that needs a new committed value of `bidNo` from *c*). In this case, creation of an entity is done by a single transaction and the counter *c* and index *a* is implemented with a single key-value object since they have the same key.

We have developed the following implementations of Transactional KVS.

HBase [2] To implement transactions, we employ HBase's check-and-put operation, which is in general called a *compare-and-swap* (CAS) operation and operates value comparison (read) and update (write) in an atomic manner.

Since check-and-put is applicable only to a single row, all the records (entities) that belong to the same group must be packed into one row. To do this, we implement each key-value record as a column name-value pair (HBase/Bigtable's columns are created in an ad-hoc manner).

In addition to these columns, each row has a special column that holds a transaction version. When the Entity DB starts a transaction, it will read the current value of this transaction version on a row that corresponds to an instance of entity group. All the updates are buffered at the client side during the transaction. At a commit request, the Entity DB issues a check-and-put operation that applies the buffered updates to the corresponding row if the current transaction version equals to the one at the beginning of the transaction.

Omid [5] Omid is a transaction server on top of HBase in order to realize ACID transactions over multiple rows [19]. It

employs optimistic multi-version concurrency control using multi-versioning of HBase (each row can have multiple versions associated with (logical or physical) timestamps). For each transaction, Omid server issues a new timestamp value, with which a transaction client puts updates to HBase rows. A commit request is sent to the Omid server and ensured after conflict check and writing a log entry for recovery. Although it is a centralized server, the required computation at the transaction server is lightweight and it will not become a bottleneck for scalability easily. For our Entity DB implementation, we also implemented *sharded* Omid servers, by applying hash partitioning over the group key and routing a transaction request to one of multiple Omid servers. In our small-scale experiments up to 10 HBase region servers, however, we did not need more than one Omid server to achieve scalability (Section 8.2).

MongoDB [3] MongoDB's update operation is atomic for a single document and consists of query part and update part (i.e., a more general form of the CAS operation). Similar to the HBase implementation, we pack entities of the same group into one document. In the query part of the update, we include the document id (that corresponds to a group key) and a value of a transaction version (stored as a field in a document).

TokuMX [10] TokuMX is an enhanced version of MongoDB. One of the enhancements is to support a multi-statement transaction over multiple documents whereas the original MongoDB only supports a single statement transaction (i.e., an update operation) over a single document. A client can begin and commit or rollback a transaction. During a transaction, a client can read and update multiple documents. Isolation is achieved by locking documents (i.e., it takes pessimistic concurrency control).

One big limitation in the current TokuMX version is it does not support a multi-statement transaction for sharded document collections (i.e., partitioned data).

Our Entity DB implementation uses a cluster of independent TokuMX servers and partition data based on the group key. It emulates sharded MongoDB with application-level request routing. Since a transaction for one group key is always executable with a single server, we can employ TokuMX's multi-statement transaction.

This implementation has a limitation when it is used in practice: it does not support rebalancing of partitions (or "chunks" in MongoDB's terminology), which is one of the most important feature of NoSQL to provide elasticity.

4.4.2 Java Persistence API

The Strudel framework includes an implementation of Entity DB API using JPA so that a benchmark on Entity DB can run on any RDBMSs as long as it supports JPA. It is straightforward to implement Entity DB API using JPA since most of the features of Entity DB have the direct counterpart in JPA.

The implementation automatically translates a secondary key access to a query in JP QL, JPA's standard query language (which is then translated to SQL of a specific RDBMS).

In order to optimize physical design of the database, the developer can use any other JPA annotations. For example, selection of indices is an independent decision from the secondary key access specification (`@Indexes`) of Entity DB API: the developer specifies indices using the standard JPA (i.e., `indexes` attribute of `@Table` annotation).

4.4.3 Native Implementations

Our framework lets the developer implement a custom way to map entity access to a specific NoSQL system. We expect a future version of Strudel include such custom implementations for popular NoSQL systems.

For example, by mapping parent-child relationship to a specific data model supported by a NoSQL system, we can eliminate some of the indices specified in `@Indexes` as follows:

Nested data structure Various NoSQL systems, such as HBase and MongoDB, support a nested data structure: HBase’s column family can be used to represent a set of child records (e.g., a set of bid records on a particular auction item). MongoDB’s data model is a document, allowing to group entities in a flexible manner. If the secondary key to access is the parent key (e.g., `auctionItemId` index in Figure 2), we can retrieve these nested entities in one operation.

Range key access. HBase employs range partition to distribute a table and supports a range query on the row ID. By encoding parent-child relationship as a prefix of a row ID, we can efficiently implement a secondary key access (if the secondary key to use is a parent key).

5. SESSION WORKLOAD FRAMEWORK

Although Entity DB provides a common API which is reasonably implementable for many NoSQL systems, it is often too restrictive for a specific NoSQL system or an RDBMS, which have more advanced features that can contribute to higher application workload performance.

We provide another abstraction layer, *Session Workload*, at an application level for session-oriented workloads so that developers can create benchmarks that can run various data access APIs besides Entity DB API.

The Session Workload framework enables developers to build workloads that emulate interactive applications in a similar way to TPC-W [11] (emulating e-commerce) and RUBiS [8] (emulating auction) benchmarks.

Emulated user interaction for each user is called a *session*, which consists of a sequence of actions (called *interactions*). An interaction is a unit of the application’s work, which is a predefined data accessing procedure without user intervention (one interaction may execute multiple transactions to perform a unit of work). A user issues a request for an interaction one by one (with optional intervals called “think time”). A user behavior is modeled as a state transition and the next interaction request is chosen based on the predefined probability and the results of the previous interactions.

The Session Workload framework makes the benchmark code reusable and customizable through the following features: (1) Interaction interface that separates data access logic and other part of benchmark code, and (2) highly configurable parameters including state transition definitions.

5.1 Interaction Interface

Figure 5 shows the interface for interactions. An interaction must implement three parts: **prepare**, **execute**, and **complete**. When an execution engine runs one interaction, it calls these three methods in this order.

The **prepare** operation is to generate a parameter that indicates a specific action that the interaction will take in the next **execute** operation. Typically, this operation emulates a thinking process of a human for this interaction (i.e. not

the application side procedure). For example, an auction benchmark emulates how a bid price is decided given the current session state (e.g., information on the auction item retrieved in the past interactions).

The **execute** operation implements the actual action that accesses the data. Given the parameter (**param**) generated by **prepare** and the data access API (**db**), the method performs transactions with the data store.

The **complete** operation defines how the session state is modified based on the result of **execute** operation. For example, to emulate a human’s browsing activities on a web application, the result of a browsing interaction includes a list of retrieved items. The **complete** operation may choose one of such items as “current item of interest” (i.e. part of the *state*). The modified state is used in the following interaction, which may take an action on the chosen item (e.g., placing a bid).

```
public interface Interaction<T> {
    void prepare(ParamBuilder paramBuilder);
    Result execute(Param param, T db,
                  ResultBuilder res);
    void complete(StateModifier modifier);
}
```

Figure 5: Interface for Interaction

We designed to split these methods so that we can implement a benchmark in a reusable manner for multiple data access APIs, as we describe in the following.

Generic Interaction Interface The Interaction interface employs Java’s Generics to parameterize a data access API and reuse the benchmark code as much as possible. In Figure 5, the type variable *T* corresponds to a class of data access API (e.g., EntityDB and JPA’s EntityManager). The application code can be written agnostic to a specific data access API as long as it does not need to know what *T* actually is. For example, the prepare method does not have to know if an interaction is used with EntityDB or any other API.

Abstract Interaction Classes To make a benchmark reusable for many data access methods, a developer is encouraged to create an *abstract interaction class* for each interaction in the benchmark. An abstract interaction class implements two methods of the interface, **prepare** and **complete**, and lets its sub-class implement the remaining **execute** method.

In the benchmarks we have developed, we implement both EntityDB and EntityManager (JPA) versions of interactions. These two implementations share majority of the benchmark code (e.g., entity definitions, data generation, workload parameter generation, state transition) (see Section 8.6 for details).

5.2 Session State Transition

A benchmark workload based on the Session Workload framework can be easily customized for a specific experiment. A state transition model that emulates a user behavior is given at run-time as an XML data. Figure 6 shows an example of an XML element (**session**) that contains state transitions (**transitions**). The **session** element typically contains various other parameters that take part of the session state in order to customize behavior of the interactions.

```

<session>
  <packageName .../>
  <Transitions>
    <transition name="START">
      <next name="HOME" />
    </transition>
    <transition name="HOME">
      <next name="SELL_AUCTION_ITEM" prob="0.2" />
      <next name="SELL_SALE_ITEM" prob="0.1" />
      <next name="VIEW_AUCTION_ITEMS_BY_SELLER" prob="0.1" />
      <next name="VIEW_SALE_ITEMS_BY_SELLER" prob="0.1" />
      <next name="VIEW_AUCTION_ITEMS_BY_BUYER" prob="0.1" />
      <next name="VIEW_SALE_ITEMS_BY_BUYER" prob="0.1" />
      <next name="VIEW_BIDS_BY_BIDDER" prob="0.1" />
      <next name="VIEW_WINNING_BIDS_BY_BIDDER" prob="0.1" />
      <next name="END" prob="0.1" />
    </transition>
    <transition name="SELL_AUCTION_ITEM">
      <next name="HOME" />
    </transition>
  </Transitions>
</session>

```

Figure 6: State transition in XML

5.3 Benchmarks

The current Strudel also includes example implementations of benchmarks for micro-level and application-level experiments on top of the Session Workload framework.

Micro Benchmark The Micro benchmark emulates a simplified user content management application in order to serve as a microbenchmark. The data and workload scale in terms of user IDs. To represent different patterns of user data access, the user content consists of the following four types of entities:

- *personal items* represent content privately owned by individual users. Each user has a set of items as one entity group (i.e., the number of groups scales as the number of users). An item is only read and written by its owner.
- *shared items* represent shared content written and read by the users. Items are grouped into multiple entity groups associated with set IDs (which give another scaling factor besides the user IDs).
- *public items* represent individual users' content that are open to the public for reading. An item is only written by its owner but can be read by other users.
- *message items* represent content exchanged from one user to another, having a sender ID and a receiver ID.

The benchmark defines various read-write and read-only interactions for each type of entities. A developer can compose a workload by creating a state transition that includes any subset of these interactions. By mixing interactions on these four types of entities, a developer can emulate the need of a specific application to some degree without coding a new benchmark.

In Section 8, we use *personal* items and *shared* items to demonstrate various scenarios of transaction performance analyses.

Auction Benchmark For application-level benchmarks, we have implemented an auction benchmark, which is similar to AuctionMark in OLTP-Bench [6] and RUBiS benchmark [8] but customized to use entity groups. The Bid entity in Figure 2 is part of this benchmark (shown after omitting some detailed code).

6. CONFIGURATION DESCRIPTION LANGUAGE

The Strudel framework provides abstraction layers to separate a benchmark application into various customizable pieces from a data access API implementation of a specific data store to a parameter generation of a benchmark workload. In order to combine these pieces together as one specific benchmark experiment, we employ a configuration description language that is similar to ones used for system component deployment in Grid and cloud infrastructures [13, 24, 7]. We have separately released this language as open source software called Congenio [1].

Our XML-based language supports the following features: (1) inheritance (@extends attribute), (2) document unfolding (foreach element), (3) reference resolution (@ref attribute), and (4) value expression (See the web site [1] for more details of the language).

With @extends, an experiment document can refer to existing templates (that define various components such as benchmarks and data stores) and customize the default values of these templates. With foreach elements, an experiment document can generate a set of documents, each of which corresponds to one workload execution with a specific set of parameters. Figure 7 illustrates such an experiment document to run an auction benchmark on HBase with different number of data servers (5, 10) and different workload scales (i.e. the number of users and worker servers).

```

<jobSuite>
  <foreach name="scale">
    <s><w>1</w><u>10000</u></s>
    <s><w>2</w><u>20000</u></s>
    <s><w>4</w><u>40000</u></s>
  </foreach>
  <foreach name="server" sep=" " >5 10</foreach>
  <job extends="auction-hbase">
    <workerNum ref="scale/w"/>
    <serverNum ref="server"/>
    <userNum ref="scale/u"/>
  </job>
</jobSuite>

```

Figure 7: Job definition in XML

The definition of an experiment in Figure 7 refers to a specific job template as illustrated in Figure 8. A job template combines various components including a workload (benchmark), database (access to data stores), and cluster (worker servers that run workloads).

```

<job>
  <workerNum>1</workerNum>
  <serverNum>1</serverNum>
  <userNum>10000</userNum>
  <threadsPerWorker>200</threadsPerWorker>
  <cluster extends="cluster">...</cluster>
  <database extends="tkvs-hbase">
    <name>auction</name>
  </database>
  <workload>
    <session extends="session-auction">
      <numOfThreads ref="threadsPerWorker"/>
    </session>
    <measure>...</measure>
  </workload>
  <report>...</report>
</job>

```

Figure 8: Example of job composition

When the execution platform (Section 7) runs an experiment with a given job definition, it records a document after inheritance resolution along with other information

(measured results, etc.). After inheritance resolution, the document includes all the information imported from other documents (referred to by `@extends`). This is very useful to reproduce the same experiments. In our lab, we use a version control system (git) to commit this document and experiment results together in the same version.

7. EXECUTION PLATFORM

Strudel’s execution platform consists of the workload manager and a cluster of workers.

The workload manager starts with a given job definition XML file (in the configuration description language) and interacts with worker servers as well as servers of SQL/NoSQL systems. The workload manager has the following features:

- server configuration and start-up (invoking external scripts for NoSQL/SQL systems).
- data generation and population
- workload control and workflow management
- performance monitoring (JMX) and aggregation of the reports from workloads.
- performance reporting as JSON files.

The Strudel framework does not include the individual scripts to configure and start/stop servers since it depends on the infrastructure (e.g., whether the system is deployed on the cloud platform, a Hadoop cluster, or a simple cluster servers mounting a shared file system).

The actual workload is run by a cluster of worker nodes that receive a workload definition from the workload manager. A worker is a workload execution engine that is deployed on a cluster of server machines. The workload manager coordinates a cluster of workers to run a benchmark workload in a scalable manner (a large number of threads) to put enough load on a scalable data store.

The Session Workload is one type of workloads the workers can run. It can run any custom workloads if they implement a workload interface defined in the Strudel framework. For example, it should be easy to develop a special workload that runs the YCSB benchmark.

8. DEMONSTRATION

In this section, we demonstrate some use cases of Strudel to conduct performance experiments. Notice that the objective of the following experiments is not a formal performance study to state any conclusive claims on a particular data store but a demonstration of the features of our framework.

8.1 System Settings

In our experiments, we use the following settings.

HBase [2] We use HBase version 1.1.1 on top of Hadoop version 2.7.1. HBase servers consist of a single master server (which manages the entire system and metadata) and a set of region servers (which manages data partitions (i.e., regions)). In the experiments, we mean the number of region servers by the number of data servers. A region server is collocated with Hadoop HDFS data node (to maximize locality of I/O). The name node of HDFS is located separately in a dedicated server. HBase also requires ZooKeeper processes to achieve coordination across servers. We use 3 ZooKeeper

processes collocated with the master server and two of the region servers.

Omid [5] We use version 0.8.0. Omid works with HBase and we use the same setting for HBase as the HBase-only data store. Omid supports multiple ways to persist transaction status for recovery. We use the default of the current version: storing the states on HBase. We use the same HBase cluster with the application (benchmark) workloads. In the experiment, we use only one Omid server and the number of data server refers to the number of region servers as in the case of the HBase-only setting.

MongoDB [3] MongoDB’s version is 3.0.5. To employ sharding (horizontal data partitioning), we need to deploy 3 config servers (just like ZooKeeper for HBase) and a set of shard servers (which we refer to by “data servers” in the experiments). We also need “mongos” servers that route applications’ requests to appropriate shard servers. We deploy one mongos server for each worker server as it is a common use case to collocate a mongos server with an application server.

TokuMX [10] For TokuMX we use version 2.0.1. As mentioned in Section 4.4, when we use multi-statement transaction with TokuMX, we cannot use sharding (automated partitioning). So we deploy a set of independent single-node TokuMX servers (which we call “data servers”), and let our EntityDB implementation route data access to these servers (emulating the application-level sharding).

MySQL [4] For experimenting JPA-based implementation of benchmarks, we use MySQL (Ver 14.14 Distrib 5.1.73) with default settings. We only use a single server MySQL in this demo.

Server machines. We use cluster machines in our lab with the following features: CentOS 6.6 (Linux 2.6.52), Intel Xeon E5620 2.40 GHz 16 core CPU, 16GB 1333 MHz RAM, Intel Pro2500 SATA SSD 240GB. Some OS parameters (e.g., the maximum number of open files) are set as data store providers recommend.

8.2 Data Store Scalability

First, we demonstrate a simple workload running on various data stores and show how these stores scale with an increasing number of data servers.

Based on the Micro benchmark, we composed a workload executing a single interaction that updates 4 *personal* items in the same group (which is randomly chosen from 1 M groups). We configure the workload so that transactions never conflict with each other: Each execution thread randomly chooses one user ID from an individual pool that is disjoint from the pools of other threads and uses the ID to choose a group (that belongs to this user).

We measure the throughput of the workloads using 1600 session concurrency (16 workers each of which runs 100 threads that keep running the update interaction without think time) for different data stores (except Omid) with changing the number of data servers (3, 5, 10). We made sure that the throughput is saturated (i.e., increasing session concurrency does not increase the throughput).

For Omid, we needed a larger number, 10800 (36 workers and 300 threads per worker), of concurrency to saturate the same number of data stores: Because one interaction takes longer time, a larger concurrency is needed to generate a sufficient number of read/write operations on the data stores. Using the Omid transaction server with HBase adds some

overhead (longer response time for each interaction and a larger number of data servers to achieve a throughput number) but it does not limit scalability at least for 10 region servers.

For MySQL we show the result of the JPA-based implementation (the figure has only one bar for a single server MySQL execution). We also ran the same workload on the Entity DB-based implementation but it did not show any significant performance difference for this simple workload (hence, it is omitted). In fact, these two implementations would generate the same SQL queries. Notice that the throughput of MySQL is good as a single data server: A 3-node NoSQL system does not achieve the same throughput *per data server*. This observation is consistent with [20], which reports the superior efficiency of an RDBMS compared to NoSQL stores. If the application workload can fit with a single data server, an RDBMS might be the most cost effective approach. If elasticity (dynamic re-balancing of partitions) is not required, purchasing a parallel RDBMS product may pay off for its efficiency.

In this demonstration, we did not cover parallel RDBMS products but it would be easy to run the same workload as long as the product is given with JPA support.

Figure 9: Throughput of item update interactions (4 items per interaction, 1600 concurrent sessions) on different number of data servers.

8.3 Transaction Concurrency

The result of the previous experiment demonstrates efficiency of a lightweight implementation of entity-group transaction with a simple check-and-update (HBase) compared to an approach with an additional transaction server (Omid). One drawback of this approach is that there is no concurrency allowed within a group (i.e., concurrent updates on the same group will fail). In many applications, this may not be a problem: when a group is associated with an individual user, a single user would not issue a large number of concurrent transactions. However it would not be always the case (e.g., auction bidding).

The next experiment we demonstrate is to see the trade-off between HBase (single-row transaction) and Omid (multi-row transaction) in terms of transaction concurrency. We use a workload that updates one *shared* item randomly chosen from a randomly chosen group. We fix the total number of items (80K) and change the size of group (400, 40, 4 items per group). From the viewpoint of the Omid transaction manager, these cases are identical (no difference be-

tween intra-group and inter-group). But for HBase, the total number of groups will decide the concurrency limit of the workloads (if two transaction updates different items in the same group, they will conflict with each other and only one can be successful). The result with 3200 concurrent sessions on 5 data servers (region servers) is shown in Figure 10. As the number of groups becomes smaller, HBase's throughput degrades and becomes worse than Omid.

Figure 10: Throughput under different transaction concurrency: 3200 concurrent sessions, 5 data servers, 1 update/interaction, 80K items in G shared groups (K items/group)

It is beneficial to use a transaction server when the concurrency within a group needs to be high, even if it adds significant extra overhead (additional commit processing) compared to the main part of transaction (amount of read/write),

In a real application development setting, developers will need to manage the trade-off by building workloads to emulate the application's needs and conducting similar experiments.

8.4 Transaction Conflict

Recall that TokuMX is an enhanced version of MongoDB and supports a multi-statement transaction based on locking of documents (data items). An application developer would wonder how and when this feature should be used. One interesting experiments using our framework would be comparison between optimistic concurrency control with MongoDB (single-document transactions) and pessimistic concurrency control with TokuMX (multi-document transactions).

At high-level, we know a rule of thumb, which is to take a pessimistic approach when conflict will likely happen in order to avoid unnecessary re-computation. But it always depends on a specific case.

In this example, a workload consists of a single interaction that updates 4 items in a randomly chosen group. The difference from the experiments in Figure 9 is that there are (varying degrees of) conflicts. We use 3200 concurrent sessions that update items in 3200 groups under the following three conditions: (1) 400 *personal* items per group: each thread will keep updating its own group (i.e., no conflict), (2) 400 *shared* items per group: each thread will randomly choose one of 3200 groups and choose 4 from 400 items (i.e., mild conflict), (3) 40 *shared* items per group: each thread

will randomly choose one of 3200 groups and choose 4 from 40 items (i.e., heavy conflict). The results are shown in Figure 11.

We notice the difference besides the concurrency control in the two versions: they are also different in allowed transaction concurrency (just like HBase and Omid). The MongoDB version of entity group transaction cannot have concurrency within a group. Hence, we do not see the difference between the case 2 and 3 for MongoDB. Their throughput values are almost equal to each other and are much lower than the throughput in the case 1.

On the other hand, the TokuMX version employ a lock for each item (i.e., document) and it looks very effective in the case 2 showing only slight degradation from the case 1.

However, the behavior of the TokuMX version is quite different in the case 3, showing a very low performance. In fact most of the transactions fail due to either deadlock or failure to acquire a lock, and these transaction will keep retrying until they finish successfully.

To compare optimistic and pessimistic concurrency control under heavy conflict, there is a fundamental difference in the cost of retrying transactions. In this particular case of optimistic concurrency control using CAS operations, the conflict relationship among transactions is very simple and there will be no deadlock: i.e., at least one of the conflicting transactions will “win.” Although retrying involves inefficiency, there is always progress in the computation. On the other hand, the pessimistic concurrency control may suffer from deadlock, in which case nobody wins. Thus, to ensure progress of the computation, the execution threads need to *back off* and wait longer time before retrying. In fact, the above result is after tuning the back-off policy using configuration options provided by the Strudel framework.

Figure 11: Throughput under different degree of conflict: 3200 concurrent sessions, 5 data servers, 4 updates/interaction over 3200 shared/personal groups

When it is very cheap to retry a transaction, the optimistic concurrency control can be an easier approach. In a practical setting, employing pessimistic concurrency control might be tricky in a cluster environment (especially when the system is built with open-source components and deployed on the cloud platform). Careful performance analysis is necessary to validate if it is really worth employing. The best approach would depend on the requirement of a specific application, and our tool can help the developer to explore

various options.

8.5 Application-level Performance

To demonstrate a scenario of an application-level performance analysis, we compare HBase and MySQL using the auction benchmark. For MySQL we use two benchmark implementations based on Entity DB API and JPA, respectively.

The JPA version of auction benchmark uses join queries when they are applicable. For example, in an interaction that shows the information on all the bidding by a particular bidder, the tables of items and bids are joined together. In the auction workload, all the interactions that use join are read-only, and the number of tables joined is always 2.

Figure 12: Throughput of auction benchmark with different session concurrency on different data stores

In this experiment, we increase the session concurrency from 200 to 3200 (200 threads per worker server) without think time on the same number of data servers (10 for HBase and 1 for MySQL). The number of users (and the size of the data set) is made proportional to the session concurrency (50 users per thread). The throughput of the workload is visualized in Figure 12.

As expected, HBase is scalable for an increasing number of concurrent user sessions. One observation, however, is that its throughput values are lower than the values of a single MySQL server when the number of concurrent sessions is small. This implies that MySQL’s execution of interactions with SQL is more efficient than executing the same interactions with put/get operations of HBase.

Another observation is that the JPA-based version performs better than Entity DB-based version on MySQL when the session concurrency is small, whereas the upper limit of throughput does not seem much different between these two implementations.

To see more detail of the efficiency of interaction execution, Figure 13 visualizes the average response time of individual interactions when the session concurrency is small (200). For the purpose of presentation, we only visualize 5 interactions picked up from 15 interactions used in the workload.

First, we observe the response time of two read-write interactions: sell-auction-item and store-bid. One noticeable point is that the store-bid interaction takes much longer time than the sell-auction-item on HBase (whereas the sell-auction-item performs similarly among three data stores).

Figure 13: Response time of different interaction types in auction benchmark on different data stores (session concurrency = 200)

The store-bid interaction creates one Bid entity and updates one AuctionItem entity in one transaction (i.e. updating one row). In fact, however, creating one Bid involves two additional row updates for out-of-group auxiliary data items: a key-generation counter and an index on the bidder id. On the other hand, key-generation and index maintenance are internal operations for MySQL, adding only negligible overhead.

We see much larger difference between HBase and MySQL for read-only interactions. We picked up three read-only interactions to represent three types of queries: (1) *view-auction-items-by-seller* gets auction items with a secondary key (the user ID of a seller). It illustrates different use of an index in Entity DB and JPA, (2) *view-bids-by-bidder* gets bids by a particular bidder as well as the corresponding auction items. The JPA-version uses a two-table join query with Bid and AuctionItem, (3) *view-winning-bids-by-bidder* gets bids by a particular bidder that *won* the auction items. The JPA-version uses a two-table join query with additional filtering conditions.

The view-auction-items-by-seller interaction reveals the difference in HBase and MySQL Entity DB: MySQL uses its internal index mechanism to implement Entity DB’s secondary key access, which is more efficient than an index object implemented on top of HBase. For this interaction, MySQL uses the same SQL for Entity DB version and JPA version (hence similar performance).

The view-bids-by-bidder interaction takes much longer time in Entity DB versions (MySQL and HBase) compared to the JPA-based implementation that uses a join query. However, the JPA-based implementation did not gain further benefit by adding filtering conditions for the view-winning-bids-by-bidder.

In a real development case, we need to take response time requirements for individual interactions to choose an implementation strategy. For example, 200 milliseconds for the view-bids-by-bidder interaction of HBase in the figure might not be acceptable for an interactive web application. The current implementation of this interaction executes a nested loop of get operations to emulate a join of Bid and AuctionItem. A possible improvement is to issue get operations asynchronously to hide latency of individual get responses.

8.6 Code Reusability

In addition to the above experiment scenarios, we also demonstrate the reusability of the code enabled by the Strudel framework.

Table 1 shows the size of components to implement the Entity DB interface for each NoSQL store. Each cell contains the lines of code and the number of classes (in a parenthesis). In the table, TKVS refers to the code of Transactional KVS (Section 4.4) that is commonly used by every implementation.

Table 1: The size of store components: lines of code (number of classes)

TKVS	HBase	Omid	MongoDB	TokuMX
3130 (36)	796 (6)	454 (4)	680 (4)	507 (4)

Table 2 shows the size of components to implement Auction and Micro benchmarks. The labels entity, param, and base correspond to definition of entity objects, parameters used in session interactions, and abstract interaction classes (Section 5), respectively. The remaining two columns, Entity DB and JPA, are components specific to data access APIs. The table does not include XML files that define session state transitions, which are part of configuration the developer can customize for specific experiments. The session state transition is agnostic to data access APIs.

Table 2: The size of benchmark components: lines of code (number of classes)

	entity	param	base	Entity DB	JPA
Auction	943 (9)	202 (3)	1346 (17)	1090 (18)	1043 (17)
Micro	681 (8)	212 (4)	1004 (19)	931 (19)	985 (19)

Notice that a more important point than the number of lines is *separation of concerns* achieved by the framework. For example, the benchmark components that are specific to data access APIs only need to implement individual data reads and writes that appear in the interactions.

8.7 Other Scenarios

Besides the scenarios the above demonstration covers, we have also used the Strudel framework for our research and development in a more customized manner. We developed custom components for our proprietary systems to run various experiments, including: (1) elasticity analysis to evaluate dynamic server scaling out (using a custom workflow that invokes various scripts to control data migration while a workload is running), (2) evaluation of bulk-loading APIs of NoSQL systems (using a custom workload that is not based on the session workload framework).

Especially, the elasticity analysis is essential to evaluate NoSQL systems. In a future version, we plan to include a generalized version of our custom components in the framework.

9. FUTURE WORK

We consider the following items in the future version of Strudel:

- Extended Entity DB API as a larger subset of JPA to incorporate more powerful query functionality of NoSQL (e.g. MongoDB) such as mapping parent-child entity relationship to a nested document (which enables retrieving parent and children together in one operation).
- Supporting multi-entity-group transactions on Entity DB API in a generic way to cover various solutions of multi-key transactions on NoSQL systems.
- Native EntityDB support of representative NoSQL systems such as HBase and MongoDB (Section 4.4.3).
- Better support of online analyses (e.g., an additional framework for scale-out analysis)
- Various data/workload generation (e.g. integration with such features from YCSB, OLTP-Bench).
- Better and easier integration with underlying infrastructure (e.g., software containers (e.g., Docker), resource managers (Hadoop YARN), and cloud platforms as well as software configuration and deployment tools (e.g., Puppet [7]).

In actual applications, scalable transaction support is only part of the data management support. There are other data management features that must be considered: (1) entity search, (2) integration with analytic workloads. In either case, the developer has to choose if these functionality should be achieved by the same data store that serves transactions or done by external systems (search engines or analytic stores). Choice of SQL and NoSQL systems must take such features into account, which are beyond the scope of the current framework.

10. CONCLUSION

We introduce Strudel, a development and execution framework for transactional workloads both on SQL and NoSQL systems. Entity DB API provides a way to develop a benchmark using a common access API that is reasonably implementable on various NoSQL systems as well as RDBMS (through JPA). Session Workload framework provides another abstraction layer to decouple logic on data access (with a particular access API) from other logic in the benchmark (such as session state transition and parameter generation). We have implemented Entity DB API for various NoSQL systems by introducing a lower level API for transactional key-value access. A future version of the framework will explore custom EntityDB implementation on individual NoSQL systems to exploit advanced features of these systems (such as a query on a nested data structure).

GROM: a General Rewriter of Semantic Mappings

Giansalvatore Mecca¹ Guillem Rull² Donatello Santoro¹ Ernest Teniente³

¹ Università della Basilicata – Potenza, Italy

² Universitat de Barcelona — Barcelona, Spain

³ Universitat Politècnica de Catalunya — Barcelona, Spain

ABSTRACT

We present **GROM**, a tool conceived to handle high-level schema mappings between semantic descriptions of a source and a target database. **GROM** rewrites mappings between the virtual, view-based semantic schemas, in terms of mappings between the two physical databases, and then executes them. The system serves the purpose of teaching two main lessons. First, designing mappings among higher-level descriptions is often simpler than working with the original schemas. Second, as soon as the view-definition language becomes more expressive, to handle, for example, negation, the mapping problem becomes extremely challenging from the technical viewpoint, so that one needs to find a proper trade-off between expressiveness and scalability.

1. INTRODUCTION

Many applications benefit from the availability of a *semantic schema* over a database, i.e., a set of views over the base tables that provide a richer description of the semantic relationships among the underlying data and a more accurate definition of the constraints. The use of such semantic views has been thoroughly studied for the purpose of query languages [6], data integration [1], and data access [2], but there are little studies of how the presence of these views impacts *data exchange* [4] applications.

Data exchange consists of moving data from a source database to a target database. This task is usually performed by developing *schema mappings*, i.e. executable transformations that specify how an instance of the source repository can be translated into an instance of the target.

In this paper, we present **GROM** [9, 8], a system conceived to support the management of mappings among view schemas. **GROM** was designed to handle mapping scenarios in which a semantic description is available over the target database, and possibly over the source database. It allows data architects to develop mappings among the two semantic schemas, rather than the underlying database schemas. Studying this variant of the problem is important for several

reasons:

(i) The semantic web has increased the number of data sources on top of which such descriptions are developed.

(ii) Views play a key role in information integration since they are used to give clients a global conceptual view of the underlying data, which may come from external, independent and heterogeneous information systems [7].

(iii) Many of the base transactional repositories used in complex organizations often undergo modifications during the years, and may lose their original design. It is important to be able to run the existing mappings against a view over the new schema that does not change, thus keeping these modifications of the sources transparent to the users.

More generally, semantic schemas help to improve the overall design of the original schemas, and emphasize important semantic relationships and constraints that would not be apparent otherwise. Therefore, designing rich, high-level mappings between these schemas has often significant advantages. However, semantic schemas are virtual and mappings between them are not directly executable.

GROM solves the important problem of making these high-level mappings executable over the original database instances. It rewrites mappings between the two virtual semantic schemas under the form of standard mappings over the underlying concrete databases, in order to execute them and generate an instance of the target database from an instance of the source database. Under appropriate hypothesis, discussed in the next sections, the whole process happens in a completely transparent way, thus greatly simplifying the overall data-translation task.

Essential to this problem is the trade-off between expressiveness and complexity. In fact, the rewriting is fairly straightforward if views are conjunctive queries – it reduces to the standard view unfolding algorithm. However, conjunctive queries have a limited expressive power, unable to capture many semantic relationships between the data. Negation, for instance, is crucial to capture disjointness constraints and many classification rules.

The main concern behind the design of **GROM** was to provide an expressive view language that can truly benefit data architects in defining rich semantic abstractions. To this end, we adopt the language of non-recursive Datalog with negation. This makes the rewriting significantly more complex, as we discuss in Section 3.

In the following we describe how we plan to organize the demonstration of **GROM**. We outline the kind of mapping scenarios that will be considered with the help of a running example introducing the main features of the system. Given

the focus of this proposal, we have chosen to omit many of the technical details that are in published papers [9]. We concentrate on a description of the system from the user perspective and illustrate the main technical challenges and what an attendee may learn by playing with it.

The system is available under an open-source license at the following URL: <http://db.unibas.it/projects/grom/>.

2. MAPPING REWRITING

Assume we have the two relational schemas below and we need to translate data from the source to the target.

Source schema: $S\text{-Product}(id, name, store, rating)$
 $S\text{-Store}(name, location)$

Target schema: $T\text{-Product}(id, name, store)$
 $T\text{-Store}(id, name, address, phone)$
 $T\text{-Rating}(id, product, thumbsUp)$

Both schemas refer to the same domain, which includes data about products, stores, and ratings. Due to the different organization of the two databases, it is not evident how to define the source-to-target mapping. In particular, it is difficult to relate tuples in the $T\text{-Rating}$ target table to those in the source. Suppose now that a richer semantic schema has been defined over the target, as shown in Figure 1. To simplify things, in this example we consider that only the target database comes with an associated semantic schema; we discuss the more general case in the next section.

Figure 1: A Simple Target Semantic Schema.

The semantic schema distinguishes among popular, unpopular, and average products. Each concept and association is defined in terms of the database tables by means of a set of views, as follows (we use different fonts for **semantic concepts** and *relational tables*; in addition, source tables have a S -prefix in their name, and target tables a T -prefix; we use values 0 and 1 for the *thumbsUp* attribute):

$v_1 : \text{Product}(id, name) \Leftarrow T\text{-Product}(id, name, store)$
 $v_2 : \text{PopularProduct}(pid, name) \Leftarrow T\text{-Product}(pid, name, store), \neg T\text{-Rating}(rid, pid, 0)$
 $v_3 : \text{AvgProduct}(pid, name) \Leftarrow T\text{-Product}(pid, name, store), T\text{-Rating}(rid, pid, 1), \neg \text{PopularProduct}(pid, name)$
 $v_4 : \text{UnpopularProduct}(pid, name) \Leftarrow T\text{-Product}(pid, name, store), \neg \text{AvgProduct}(pid, name), \neg \text{PopularProduct}(pid, name)$
 $v_5 : \text{SoldAt}(pid, stid) \Leftarrow T\text{-Product}(pid, pname, stid)$
 $v_6 : \text{Store}(id, name, addr) \Leftarrow T\text{-Store}(id, name, addr, phone)$

We adopt the expressive language of non-recursive Datalog with negation. Notice how negation is crucial to capture the semantics of this example and it may either correspond to negated base tables (view v_2 , table $T\text{-Rating}$) or even to negated views (v_3 , PopularProduct). Views can also be defined as unions of queries (not shown in the example).

The important observation here is that in many cases semantic concepts are closer to source data than physical target tables, and therefore the task of defining mappings is considerably simplified. In our example, notice how the views hide table $T\text{-Rating}$. As a consequence, the classification of a product in the target semantic schema is easily derived from ratings in the source database as follows: products with ratings consistently above 4 stars (out of 5) are the popular ones, those always graded less than 2 are considered to be unpopular, and the rest are average.

As is common [4], we use *tuple generating dependencies* (tgds) and *equality-generating dependencies* (egds) to express the mapping. In our case, the *source-to-semantic* translation can be expressed by using the following tgds with comparison atoms:

$m_0 : \forall pid, name, store, rating : S\text{-Product}(pid, name, store, rating), rating < 2 \rightarrow \text{UnpopularProduct}(pid, name)$
 $m_1 : \forall pid, name, store, rating : S\text{-Product}(pid, name, store, rating), rating \geq 2, rating < 4 \rightarrow \text{AvgProduct}(pid, name)$
 $m_2 : \forall pid, name, store, rating : S\text{-Product}(pid, name, store, rating), rating \geq 4 \rightarrow \text{PopularProduct}(pid, name)$
 $m_3 : \forall pid, name, store, rating, location : S\text{-Product}(pid, name, store, rating), S\text{-Store}(store, location) \rightarrow \text{SoldAt}(pid, sid), \text{Store}(sid, store, location)$

Intuitively, tgd m_0 specifies that, for each tuple in $S\text{-Product}$ such that the value of *rating* is lower than 2, there should be an UnpopularProduct in the semantic schema. Similarly for m_1 and m_2 . Mapping m_3 relates products and stores in the source to instances of SoldAt association in the semantic schema.

The mapping designer can also express a number of constraints about the target semantic schema under the form of egds.¹ The egd below corresponds to a key constraint on PopularProducts : it states that whenever two popular products have the same *name*, their *id* must also be the same:

$e_0 : \forall id_1, id_2, n : \text{PopularProduct}(id_1, n), \text{PopularProduct}(id_2, n) \rightarrow id_1 = id_2$

In addition to being more natural, designing mappings over semantic schemas has another important benefit to the data architect. By taking advantage of the semantics of the views, the mapping designer does not need to care about the physical structure of the data in the target schema. As an example, s/he does not need to explicitly state in m_0, m_1, m_2 that popular, average, and unpopular products are also products. The class-subclass relationships are encoded within the view definitions, and we expect their semantics to carry on into the mappings.

This, however, is true provided that we are able to translate such a *source-to-semantic* virtual mapping into a classical, executable source-to-target mapping among the two physical databases. This is the main task performed by GROM, as discussed in the following section.

3. OVERVIEW OF THE SYSTEM

The main technical problem addressed by GROM, depicted in Figure 2, can be stated as follows. Assume we are given:

¹Previous papers [9] discuss how to handle foreign-key constraints as well.

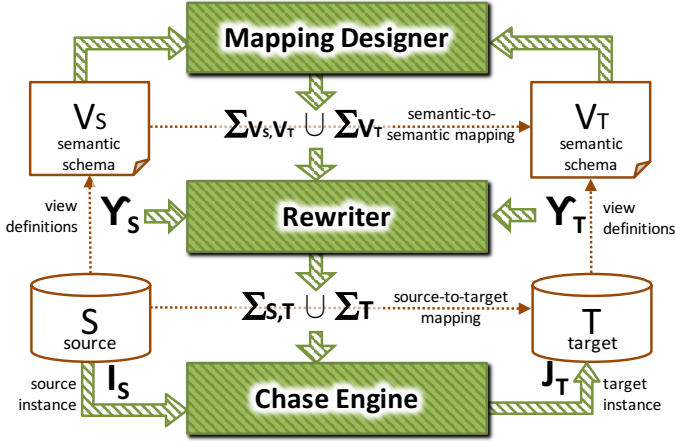

Figure 2: Architecture of the System.

- (i) a source relational schema, \mathbf{S} , and a target relational schema \mathbf{T} ;
- (ii) a source semantic schema, \mathbf{V}_S , and a target semantic schema, \mathbf{V}_T , defined by means of sets of view definitions, Υ_S and Υ_T , over \mathbf{S} , \mathbf{T} respectively. View definitions may involve negations over base and derived atoms, as discussed in Section 2;
- (iii) a set of target constraints, Σ_{V_T} , i.e. target egds to encode key constraints and functional dependencies over the semantic schema;
- (iv) finally, a semantic-to-semantic mapping, Σ_{V_S, V_T} , defined as a set of s-t tgds over \mathbf{V}_S and \mathbf{V}_T .

As it can be seen from Figures 2 and 3, the system is composed of various modules. Users develop the semantic mappings using a graphical mapping-designer and view browser. The GROM rewriter takes as input \mathbf{S} , \mathbf{T} , \mathbf{V}_S , \mathbf{V}_T , Υ_S , Υ_T , and the semantic-based mappings, $\Sigma_{V_S, V_T} \cup \Sigma_{V_T}$. It rewrites these as a new set of source-to-target dependencies $\Sigma_{ST} \cup \Sigma_T$, from the source to the target database. These, in turn, are fed to the chase-engine module, along with an instance I_S of the source database, to be executed and generate an instance J_T of the target. A few observations are in place.

Variants of the Problem. First, this general version of the rewriting problem easily reduces to a simplified variant in which only a target semantic schema is available, and no source one, as in our running example in Section 2. In fact, assume we know how to rewrite source-to-semantic mappings Σ_{SV_T} , i.e., mappings designed from the source schema \mathbf{S} to the target semantic schema \mathbf{V}_T . Assume now we are given view definitions for the source schema, Υ_{V_S} , in addition to the target ones, and a mapping Σ_{V_S, V_T} between the two semantic schemas. It can be seen that this case can be reduced to the simpler case by using the composition of two steps [9]: (i) first, we apply the source view definitions in Υ_{V_S} to the source instance, I_S , to materialize the extent of the source views, $\Upsilon_{V_S}(I_S)$; (b) then, we consider this materialized instance as a new source database, and solve the source-to-semantic mapping problem.

The Mapping Language. A second, important observation is concerned with the output of the rewriting engine. It is known [1] that the language of embedded dependencies (tgds and egds) is closed wrt unfolding conjunctive views, i.e. the result of unfolding a set of conjunctive view defini-

tions within a set of tgds and egds is still a set of tgds and egds. Unfortunately, as we have shown in [9], this is not true when views allow for negated atoms, as in our setting. This justifies two important choices wrt the algorithm:

To start, the rewriting algorithm is sound but not complete. Informally speaking, given mappings $\Sigma_{SV_T} \cup \Sigma_{V_T}$, GROM generates a rewritten set of source-to-target mappings $\Sigma_{ST} \cup \Sigma_T$ such that, whenever these admit a universal solution [4] J_T over I_S , then also the original source-to-semantic mappings admit solutions on I_S , and it is the case that $\Upsilon_T(J_T)$ is a solution for $\Sigma_{SV_T} \cup \Sigma_{V_T}$ and I_S . However, we say nothing about the cases in which $\Sigma_{ST} \cup \Sigma_T$ fail.

Then, as we mentioned, to better handle the effects of negation in view definitions, we choose as a mapping-definition language for $\Sigma_{ST} \cup \Sigma_T$ the one of *disjunctive embedded dependencies* (deds). Deds generalize tgds and egds since they may have disjunctions in the conclusion. Following is a ded generated by GROM for the running example in Section 2:

$$d_0 : TProduct(pid_1, name, store_1), \\ TProduct(pid_2, name, store_2) \rightarrow (pid_1 = pid_2) \mid \\ TRating(rid, pid_1, '0') \mid TRating(rid, pid_2, '0')$$

Intuitively, this ded translates the key constraint for **name** on concept **PopularProduct** in terms of the following constraints over the target database: for each pair of tuples in $TProduct$ with equal values of *name*, one of the following must be true: either the two product ids are equal; or one of the products is not a popular product.

Handling deds is considerably more challenging than ordinary tgds and egds. To provide an example, *universal solutions* [4] are considered the standard notion of what a “good” solution means for standard mappings composed of tgds and egds; in addition, the *chase* is a well-known, polynomial-time procedure to generate universal solutions. On the contrary, it has been shown [3] that universal solutions are no longer sufficient for ded-based scenarios, and that the more appropriate notion of *universal model set* is needed. In addition, universal model sets may have exponential size wrt to the size of the source instance. In fact, to the best of our knowledge, GROM is the first system to tackle the problem of chasing deds.

Handling Complexity. The strategy to avoid such a complexity blow-up is twofold. On the one side, sufficient conditions to avoid the use of deds in the output mappings have been identified under the form of restrictions on the use of negations in view definitions [9]. As a consequence, the system is able to look at the view definitions and tell whether the rewritten mappings may contain deds or not.

On the other side, when deds are unavoidable, GROM takes special care in order to tame the complexity of the chase. To start, it relies on a fast and scalable chase engine from the LLUNATIC project [5]. This guarantees good scalability in executing mappings, even on large databases. In addition, the chase engine has been extended in order to properly handle deds by implementing a greedy chase strategy for deds [9], based on the ideas of searching for solutions to a set of deds by running multiple standard scenarios made of tgds and egds derived from the given deds. Experiments confirm the effectiveness of this approach.

4. EXPERIENCES WITH THE SYSTEM

The demonstration will illustrate what are the main challenges in handling semantic mappings and how the system

Figure 3: GROM in Action.

solves them. Attendees will be able to interact directly with the system, in such a way that the process will resemble a hands-on tutorial. Following are the main lessons that can be learned from these experiences.

Semantic Mappings Work! Our experiences tell us that in many cases the availability of a view over the data may greatly simplify the mapping process. In these cases, data architects may greatly benefit from a tool like GROM.

One of the typical patterns is the one discussed in our running example: one of the data sources somehow rates source objects, and the mapping application requires to classify objects in the target based on these ratings, for example for the purpose of showing them to users under the form of web pages. Often, target relational schemas are not designed to properly address this kind of need. Being able to design a view over the target database that more closely reflects such an application requirement is a great asset in these scenarios.

Another, typical case, is the one of databases that come with poor designs, or lack integrity constraints. It is very difficult in these cases to design proper mappings. On the contrary, a clean-up view over the underlying databases may simplify things.

We intend to challenge the audience with different schemas and mapping scenarios. We will ask attendees to design mappings first using the original, relational schemas, and then over properly designed views, to let them grasp the real advantage of this approach.

Semantic Mappings are Expensive! At the same time, it is important to let users understand the concrete trade-off between having a flexible and expressive view-definition language, and the cost of executing the mappings.

As we mentioned, rewriting and executing the mappings is quite straightforward as soon as conjunctive queries are used as a view definition language. This, however, is not sufficient to capture the actual modeling requirements in many cases.

Negation is a powerful addition, but it comes at a cost. The full power of negation generates output mappings that include deds, so that chasing them is not feasible, even on small instances. Attendees will learn what features GROM offers to solve this problem. As a first solution, the system will run its greedy chase algorithm to search for solutions to the original deds. This amounts to generating several scenarios made of tgds and egds, that capture specific branches in the deds. This strategy is sound, but not complete. How-

ever, it is often surprisingly quick in returning some solution.

In other cases, when the constraints are more intricate, the greedy chase will take considerably more time, due to the fact that many of the generated scenarios fail to generate a solution, and new ones need to be executed. In these cases, a possible alternative is to leverage the syntactic restrictions over the use of negation [9] that guarantee that no deds are generated. In essence, the user needs to inspect the views and change them in such a way to remove perverse negation patterns that will generate deds. GROM supports this process by highlighting problematic views, so that the user may consider alternative formulations.

ABSTRACT

Keyword search over relational databases has gained popularity due to its ease of use. Current research has focused on the efficient computation of results from multiple tuples, and largely ignores queries to retrieve statistical information from databases. The work in [5] developed a system that allows aggregate functions to be expressed using simple keywords. However, this system may return incorrect answers because it does not consider the semantics of objects and relationships in the database. In this paper, we present an interactive keyword search engine called PowerQ to answer queries involving aggregate functions and GROUPBY. PowerQ utilizes an ORM schema graph to capture the Object-Relationship-Attribute (ORA) semantics in the database. Given a keyword query, PowerQ identifies the various interpretations of the query and applies aggregate functions and GROUPBY on the appropriate attributes of objects/relationships. Each query interpretation is denoted as an annotated query pattern, whose meaning can be described in natural language to facilitate user understanding. Through user interactions, PowerQ can determine the user's search intention, and translate the corresponding patterns into SQLs to compute the answers correctly. The PowerQ prototype is available at <http://powerq.comp.nus.edu.sg>.

1. INTRODUCTION

As databases increase in size and complexity, the ability for users to issue SQL queries has become a challenge. Keyword search over relational databases has gained popularity as it enables users to query the database without knowing the database schema or writing complicated SQL queries. Research on relational keyword search has focused on the efficient computation of results from multiple tuples [1, 2, 4], and largely ignores queries involving aggregates and GROUPBY. We call the latter *aggregate queries*.

Aggregate queries provide a powerful mechanism to retrieve statistical information from the database. The work in [5] designed a prototype system called SQAK to handle

aggregate queries. An aggregate query comprises of a set of terms and one of these terms is an aggregate function such as *COUNT*, *SUM*, etc. The terms in the query may match the names of relations or attributes or tuple values.

Consider the sample university database in Figure 1. Suppose we want to know the total credits obtained by the student *Green*, we can issue the aggregate query $Q_1 = \{\text{Green SUM Credit}\}$. However, we observe that incorrect answers may be returned by SQAK. For example, the term *Green* in Q_1 matches the names of two students s_2 and s_3 in Figure 1. This naturally implies that we should find the sum of the credits for each of these students, that is, the total credits for s_2 is 5 while the total credits for s_3 is 8. However, SQAK does not distinguish between these two “different” name matches, and outputs a total credits of 13 for students called *Green*, which is incorrect.

Student			Course			Enrol			Teach		
Sid	Sname	Age	Code	Title	Credit	Sid	Code	Grade	Code	Lid	Bid
s1	George	24	c1	Java	5.0	s1	c1	A	c1	l1	b1
s2	Green	18	c2	Database	4.0	s1	c2	B	c1	l1	b2
s3	Green	21	c3	Multimedia	3.0	s1	c3	B	c1	l2	b1
						s2	c1	A	c2	l2	b2
						s3	c1	A	c2	l2	b3
						s3	c3	B	c3	l1	b4

Figure 1: Sample university database

Next, suppose we issue the query $Q_2 = \{\text{Java SUM Price}\}$ to find the total price of the textbooks that are used in the *Java* course. The term *Java* matches a course title while the term *Price* matches an attribute of the *Textbook* relation. This relation contains 3 foreign keys that reference the *Course*, *Lecturer* and *Textbook* relations respectively, and represents that a course can be taught by more than one lecturer using different textbooks. We see that there are 2 such textbooks, namely, b_1 used by both lecturers l_1 and l_2 , and b_2 used by lecturer l_1 . But SQAK does not detect the duplicate textbook b_1 by different lecturers of the *Java* course (i.e., c_1) in the *Teach* relation, and returns 35 for the total price. This answer is incorrect as students do not need 2 copies of a textbook for the same course.

In this work, we build a relational keyword search engine called PowerQ to answer aggregate queries correctly. PowerQ extends the keyword query language and utilizes the

ORM schema graph [6] to capture the Object-Relationship-Attribute (ORA) semantics in the database. Given an aggregate query, it identifies the various interpretations of the query and applies aggregate functions and GROUPBY on the appropriate attributes of objects/relationships. Each query interpretation is denoted as a graph called annotated query pattern, whose meaning is described in natural language. The query patterns that satisfy the user's search intention are translated into SQL statements to compute the answers. During the query processing, PowerQ utilizes the ORA semantics to distinguish the objects with the same attribute value and detect the duplications of objects/relationships regardless of whether the database is normalized or not. Otherwise, the aggregate function(s) cannot be computed correctly as we have shown in our example queries Q_1 and Q_2 .

2. PRELIMINARIES

The work in [6] extends the keyword query language to include the keywords that match the names of relations and attributes. These metadata keywords provide the context of subsequent keywords and reduce the query ambiguity.

PowerQ further extends the query language to incorporate aggregates and GROUPBY. Thus, a keyword query Q is a sequence of terms $\{t_1 t_2 \dots t_n\}$ where each term t_i either matches a relation name, an attribute name, a tuple value, GROUPBY or an aggregate function *COUNT*, *SUM*, *AVG*, *MIN* or *MAX*.

2.1 ORM Schema Graph

The work in [7] classifies the relations in a database into object relations, relationship relations, mixed relations and component relations. An object (or relationship) relation captures the information of objects (or relationships), i.e., the single-valued attributes of an object class (relationship type). Multivalued attributes of an object class (relationship type) are stored in object/relationship component relations. A mixed relation contains information of both objects and relationships, which occurs when we have a many-to-one or one-to-one relationship. We call these semantics the Object-Relationship-Attribute (ORA) semantics.

The Object-Relationship-Mixed (ORM) schema graph is an undirected graph that captures the ORA semantics in the database. Each node in the graph comprises of an object/relationship/mixed relation and its component relations, and is associated with a type (object, relationship and mixed). Two nodes are connected if there exists a foreign key - key reference between the relations in these two nodes.

In Figure 1, the relations *Student*, *Course*, *Faculty* and *Textbook* are object relations while *Enrol* and *Teach* are relationship relations. Relations *Lecturer* and *Department* are mixed relations because of the many-to-one relationships between lecturers and departments, and the many-to-one relationships between departments and faculties respectively. Figure 2 shows the ORM schema graph of the database.

2.2 Query Patterns

Since keyword queries are inherently ambiguous, [6] introduces the notion of query patterns to represent the various interpretations of a query. These query patterns are generated from the ORM schema graph of the relational database.

Figure 3 shows one of the query patterns for the keyword query $\{\text{Code George Green}\}$. This pattern depicts the

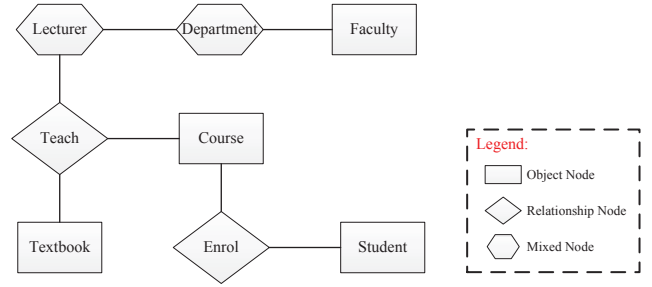

Figure 2: ORM schema graph of Figure 1

Figure 3: Query pattern of $\{\text{Code George Green}\}$

query interpretation to find information on the course which is taught by the lecturer *George* and enrolled by the student *Green*. To generate this query pattern, we identify the matches of each term in the query. The term *Code* matches the name of an attribute in the *Course* relation, while the terms *George* and *Green* match the values of the attribute *Lname* in the *Lecturer* relation and the attribute *Sname* in the *Student* relation respectively. Based on these matches, we know that *Code* refers to a course object, *George* refers to a lecturer object, and *Green* refers to a student object. From the ORM schema graph in Figure 2, the *Course*, *Lecturer* and *Student* nodes can be connected via a *Teach* and an *Enrol* node. Hence, we create these two nodes and obtain the query pattern in Figure 3.

PowerQ utilizes query patterns to capture the interpretations of an aggregate query. However, since an aggregate query includes aggregate functions and GROUPBY, we need to annotate the patterns to indicate the objects/relationships that aggregates and GROUPBY are applicable to. We will discuss how to achieve this in the next section.

3. SYSTEM ARCHITECTURE

PowerQ takes as input an aggregate query, and generates a set of SQL statements for the query patterns that satisfy the user's search intention. Figure 4 shows the architecture of PowerQ. The frontend of PowerQ interacts with the user during the query processing, while the backend communicates with the database and the ORM schema graph to compute the query answers. The main components in PowerQ are *Query Parser/Analyzer*, *Query Interpreter*, *SQL Generator*, *Visualization Module* and *Normalization Module*. The following sections give the details of these components.

3.1 Query Parser/Analyzer

Given an aggregate query, the Query Parser/Analyzer classifies the terms in the query into basic terms and operators. A basic term matches a relation name, or an attribute name, or a tuple value in the database, while an operator matches an aggregate function or GROUPBY. For the basic terms, the Query parser/Analyzer obtains their matches and determines the objects/relationships referred to by these terms based on the ORM schema graph of the database.

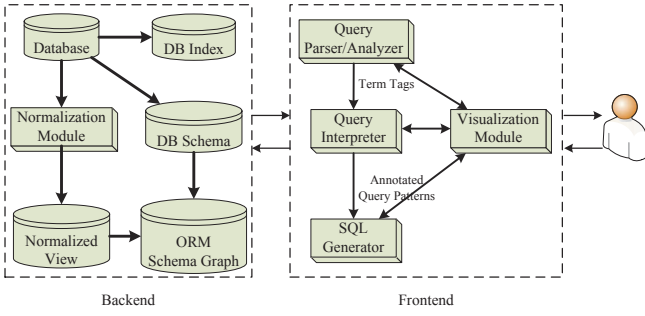

Figure 4: System Architecture

3.2 Query Interpreter

Next, the Query Interpreter generates a set of initial query patterns based on the basic terms of the query and the ORM schema graph of the database. Each query pattern contains a set of nodes that represents the objects/relationships referred to by the basic terms. Then, it annotates the query patterns with operators in the query. For each operator t_i , if its subsequent term t_{i+1} refers to some object or relationship, then the Query Interpreter annotates the corresponding node with $t_i(id)$, where id is the identifier of the object/relationship; otherwise, if t_{i+1} refers to some attribute a of an object or relationship, the Query Interpreter annotates the corresponding node with $t_i(a)$.

Consider the keyword query $\{\text{COUNT Code George Green}\}$. Figure 3 shows a query pattern obtained using the basic terms *Code*, *George* and *Green*. For the operator *COUNT*, since its subsequent term *Code* matches the name of an attribute in the *Course* relation, we will annotate the *Course* node with *COUNT(Code)*, and obtain the annotated query pattern P_1 in Figure 5. This pattern depicts the query interpretation to find the total number of courses which are taught by lecturer *George* and enrolled by student *Green*.

In an annotated query pattern, an object/mixed node with the condition $a = t$ refers to an object such that its value of attribute a matches the basic term t . However, since this condition could be satisfied by more than one object in the database, we have two different query interpretations:

1. apply the aggregate functions(s) for every *distinct* object satisfying $a = t$; or
2. apply the aggregate function(s) for *all* the objects satisfying $a = t$.

The Query Interpreter distinguishes these two interpretations by annotating the object/mixed node in the pattern with *GROUPBY(id)*, where id is the identifier of the object. By applying *GROUPBY* on object identifiers, we can distinguish objects with the same attribute value and compute the aggregate functions for each of them.

In Figure 5, the annotated query pattern P_1 contains a *Student* node that is annotated with the condition *Sname = Green*. From the database in Figure 1, we know that there are two students called *Green*. Hence, we have a second query pattern P_2 that is similar to P_1 , except that we annotate the *Student* node in P_2 with *GROUPBY(Sid)*. Figure 5 shows these two patterns: P_1 counts the number of courses for all the students called *Green*, while P_2 counts the number of courses for each student called *Green* separately.

Note that SQAQ [5] does not distinguish P_1 and P_2 , and thus may return incorrect answers to the query.

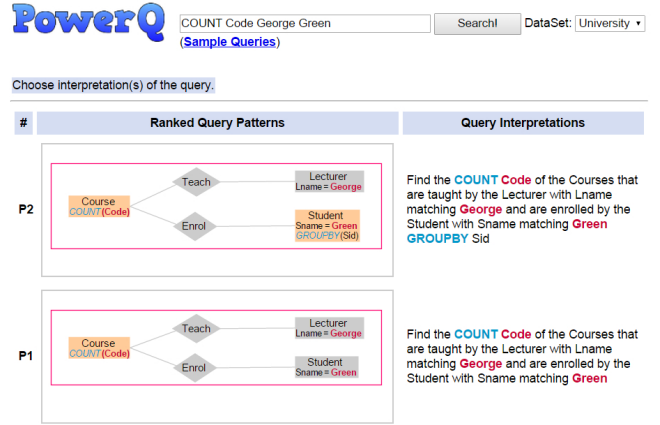

Figure 5: Screenshot of annotated query patterns

3.3 SQL Generator

The SQL Generator translates an annotated query pattern into an SQL statement to compute the answers. The straightforward approach is to join the relations of all the nodes, select the tuples that satisfy the conditions imposed by basic terms from the join result, and then apply aggregate(s) and *GROUPBY* on the selected tuples. However, this may generate an SQL that gives an incorrect answer.

Consider the query pattern P_2 in Figure 5. If we simply translate P_2 into an SQL that joins the relations *Course*, *Teach*, *Enrol*, *Lecturer* and *Student*, selects the tuples with conditions *Lname = George* and *Sname = Green*, and then applies the count aggregate and *GROUPBY* on the course code and the student id respectively, we will obtain wrong answers as the same course may be counted multiple times. This is because the *Teach* node in P_2 is in fact a ternary relationship involving course, lecturer and textbook objects (see the ORM schema graph in Figure 2). The same course can be taught by a lecturer using different textbooks. In other words, the same *Lid* and *Code* are duplicated for different *Bid* in the *Teach* relation.

To avoid this problem, PowerQ examines every relationship node u in the pattern, and checks its corresponding node v in the ORM schema graph. If the pattern only contains a subset of the participating objects in relationship v , then it projects the identifiers of these objects from v . This eliminates duplicates and PowerQ replaces the relation of u with the relation obtained by this projection in the SQL.

For example, since the *Teach* node in P_2 only involves course and lecturer objects, PowerQ generates a subquery “*SELECT DISTINCT Lid, Code FROM Teach*” to project the attributes *Lid* and *Code* in the *Teach* relation. This subquery has a “*DISTINCT*” keyword, thus eliminating duplicates of $\langle Lid, Code \rangle$. We use this subquery result to join the other relations in the FROM clause as follows:

```
SELECT S.Sid, COUNT(C.Code)
FROM Lecturer L, Course C, Enrol E, Student S
  (SELECT DISTINCT Lid, Code FROM Teach) T
WHERE L.Lid=T.Lid AND C.Code=T.Code AND
      S.Sid=E.Sid AND C.Code=E.Code
GROUP BY S.Sid
```

Note that SQAQ does not detect the duplicates of courses in *Teach* relationships, and thus returns incorrect answers.

3.4 Visualization Module

A keyword query is inherently ambiguous. However, the user who issues the query often has some particular search intention in mind [3]. The Visualization Module represents the various interpretations of a keyword query, and actively interacts with the user to obtain the interpretations that satisfy the user’s search intention. In particular, if a term has multiple matches in the database and refers to different objects/relationships, the user is offered the opportunity to choose the matches. Further, if more than one query pattern is constructed for the query, the user is again allowed to choose his/her intended query patterns.

One feature of PowerQ is that it represents query interpretations visually and describes them in human natural language in order to facilitate users’ understanding. For instance, the annotated query pattern P_2 in Figure 5 is represented as a graph annotated with the ORA semantics. The nodes with operators in the graph are highlighted to indicate the objects/relationships that aggregates are applicable to. The description of this pattern is to “Find the count of the courses that are taught by the lecturer with name matching George and are enrolled by the student with name matching Green group by Sid”. The user can easily identify the intended query interpretation by the graph structure, and verify its meaning by the description. After the user chooses a query pattern, PowerQ computes the answers and represents them according to the corresponding search intention. Figure 6 shows the screenshot of the interface which displays the query answers for the query pattern P_2 in Figure 5 and the detailed information for user to verify the answers.

3.5 Normalization Module

Relations in a relational database are often denormalized to improve query processing performance. This denormalization process will duplicate information of objects and relationships in the database and SQAk may obtain incorrect answers for an aggregate query.

PowerQ is able to detect denormalization and keep track of the object/relationship information in the database to answer aggregate queries correctly. This is achieved by examining the functional dependencies hold on the relations. If the database is denormalized, then it generates a normalized view of the database which comprises of a minimal set of normalized relations, and obtains the mappings of relations in the normalized view and the original schema. The normalized view is used to construct the ORM schema graph of the denormalized database and build query patterns of the query, while the mappings are used to generate the SQL statements which continue to compute the answers correctly. Interested readers can refer to [8] for details.

4. DEMONSTRATION

In this demonstration, we will present a web-based browser interface of PowerQ, which communicates with the Java based server. The system is available at <http://powerq.comp.nus.edu.sg>. We intend to show the use of PowerQ against a number of real application scenarios such as the ACM Digital Library (dl.acm.org), and the IMDB database (www.imdb.com).

The demonstration will include three parts. First, we will run a number of sample aggregate queries against these resources. We will demonstrate how PowerQ exploits the ORA semantics in the database, distinguishes objects with the

The screenshot shows a web interface for PowerQ. At the top, it displays the keyword query: "Your keyword query is COUNT Code George Green". Below this, it provides an interpretation: "The interpretation is Find the COUNT Code of the Courses that are taught by the Lecturer with Lname matching George and are enrolled by the Student with Sname matching Green GROUPBY Sid". The results are shown as a table with 2 rows and 4 columns: #, COUNT(Code), Sid, and a Verify link. The first row shows 1 course for lecturer s2, and the second row shows 2 courses for lecturer s3. To the right of the table, there is a 'Verify' section with a 'Verify:' button and a list of results for 'Lecturer' (Lid: l1, Lname: George) and 'Student' (Sid: s2, Sname: Green). An 'OK' button is at the bottom right.

#	COUNT(Code)	Sid	
1	1	s2	Verify
2	2	s3	Verify

Figure 6: Screenshot of answers to query pattern P_2

same attribute value, and detects duplications of objects in relationships to answer aggregate queries correctly. The user can run queries without aggregate functions or GROUPBY to verify the answers of the aggregate queries. Next, we will run the aggregate queries on the denormalized data. We will demonstrate how PowerQ continues to process the aggregate queries correctly. Finally, the user will be free to run their own queries.

Through this demonstration, we will highlight the importance of the ORA semantics to relational keyword search. This is reflected in three aspects. First, the interpretation of keyword queries requires the system to be knowledgeable about the ORA semantics. Second, in order to answer queries involving aggregates and GROUPBY correctly, we need to distinguish objects with the same attribute value and detect duplications of objects in relationships based on the ORA semantics. Third, we need to keep track of the ORA semantics in the database, so that queries on denormalized databases can continue to be handled correctly.

1. INTRODUCTION

Visualization provides a powerful means for data analysis. To be useful, visual analytics tools must support smooth and flexible use of visualizations at a fast rate. This becomes increasingly onerous with the ever-increasing size of real-world datasets. First, large databases make interaction more difficult as a query across the entire data can be very slow. Second, any attempt to show all data points will overload the visualization, resulting in chaos that will only confuse the user.

Many solutions have been proposed to solve these problems,¹ but only one [1] addresses both of them simultaneously: *hierarchical aggregation*. Since it is not feasible to show all answers to a query, a natural way to reduce the size of the answer set is to aggregate it. We also need to support real-time interactivity; that is, to support an efficient way to move between levels of aggregation. Thus, we need a hierarchy of aggregations.

Hierarchical aggregation is not a new idea, of course. For data, it has been explored in OLAP, starting with the *data-cube* model. For images, it is only recent that new visual aggregation strategies have been developed for standard visualization techniques [1]. These strategies turn existing visualizations into multi-resolution versions that can be rendered at any desired level of detail. The *visual aggregate* can convey various information about the underlying data, such as their average, minima and maxima, and distribution.

Thus, data visualization systems face two challenges. First is an issue of *efficiency*. Most visualizations today are produced by first retrieving data from a database, and then using a specialized tool to render it. This decoupled approach results in significant duplication of functionality, while missing opportunities for cross-layer optimizations [5]. Second is an issue of *expressiveness*. Data visualization systems have not exploited modern graphics processing and rendering, due to architectural limitations, and lack of awareness. These graphics *shaders* meanwhile can significantly

improve visualization.

We combine data aggregation with visual aggregation in a tightly coupled system that provides for smooth user interaction. Our implementation is based on a hierarchical data structure we call an *aggregate pyramid*.² By interacting with the pyramid in the back-end (via the database system), the front-end visualization client can quickly filter the data to move up and down in the aggregation hierarchy. We want the visualization mantra, “overview first, zoom and filter, then details on demand,” [4] to be more like *skydiving* than gliding.

SKYDIVE’s general architecture enables us to exploit modern graphics processing and rendering in new ways that other systems have not been able to exploit. Thus, for interactive data visualization, SKYDIVE is innovative in both *expressiveness*, by flexibly enabling new rendering techniques, and *efficiency*, due to tight-coupling in its architecture.

2. EXPRESSIVENESS

In SKYDIVE, a *data visualization* is defined by the user in two parts:

1. the *aggregate-pyramid query*, which defines the *dataset* cut from the database the user wishes to explore; and
2. the *visual mapping*, which maps the aggregate measures of the aggregate pyramid to visual *channels* in the *data texture* the user will explore.

In the next section, we define the concept of the aggregate pyramid in more detail, and how it is used to support *efficient* data visualization and exploration. For now in overview, we consider how it supports *expressive* visualizations.

Anatomy of the aggregate pyramid. The aggregate pyramid represents a hierarchy of aggregation levels we call *strata*. (This is visualized in Fig. 1.) The *base* of the pyramid represents the stratum with the highest resolution of our data (the data aggregated the least); higher strata represent successively lower resolutions (the data further aggregated). As with a *data cube*, the columns of an aggregate pyramid consist of *dimensions* and *aggregates*. Each tuple in the pyramid, called a *cell*, represents the aggregates of the raw data within the cell’s area. The cells of any given stratum *tile* the dataset at the stratum’s resolution. We consider here two-dimensional pyramids, with “X” and “Y” dimension columns.³

²This concept is described in more detail in [3].

³One-dimensional pyramids are also useful for visualization, but with specific presentation models that we do not discuss here. Pyramids generalize to more than two dimensions,

¹See [2] for an overview.

The aggregate columns are defined over the *measures* of the raw data. For the pyramid, an *inductive-aggregate function* is defined in two parts, a *base* and an *inductive function*. The base function aggregates over the raw data to produce the cells of the *base* stratum of the pyramid. The inductive function then aggregates over the appropriate cells of the stratum below the current to compute the aggregate values for the cells of each stratum.

For example, consider scatter-plot data of event points—say fires that have occurred in the Seattle area—that we want to visualize. One aggregate we likely will want is to count events within each cell’s area. The base function can simply be the aggregate count over the group-by into cells for the pyramid’s base stratum. The inductive function is then *sum*, to sum up the counts of the sub-cells to compute the count for the cell.

It is important that the inductive functions are only allowed to look one stratum below, for efficiency of computation. This also means a good deal of care and thought must go into defining appropriate, meaningful inductive-aggregate functions that are effective for visualization.

Even with the simple example of scatter-plot data of events that have no specific qualities—an event simply occurred at a location—there are still a number of aggregates of this information in which one might be interested. *Count-per-area* is an obvious one, as discussed above. Additionally, there are statistical aggregates that can tell us something about how the events are *distributed* in the area represented by the cell. Are they uniformly distributed across the area, or are they highly clustered in given spots? An *entropy* function can be devised that offers a measure of such *dispersion* across the area.

If the scatter-plot data is richer, then there are many more aggregates we might wish to convey. Fire events might additionally carry a measure of *intensity*. We then may wish to convey information about the intensity of events in addition to the count of events. *Maximum* may be a reasonable aggregate over intensity, to convey the highest intensity of event to have occurred in an area (the cell). Another aggregate could carry the *standard deviation* over intensity of events within the cell. Fire events will also have *time* associated with them, and so forth.

The visualization mapping. The second thing that must be specified for a visualization is a *mapping* of the aggregates of the pyramid into visual *channels*. If the presentation model is a 2D image, these channels are the usual suspects from image processing: e.g., *red*, *green*, and *blue* (RGB) or *hue*, *saturation*, and *lightness* (HSL), depending on how one wants to consider the color space.

The mapping consists of functions that *map* (and *normalize*) the aggregates of the pyramid to available channels in the presentation model. The mapping should be done with care to be “orthogonal”, so that each aggregate as mapped can be clearly distinguished. We envision developing a library of standard mappings to be available. SKYDIVE’s architecture, however, is a general platform that allows for devising new, novel mappings.

The problem of channel paucity. A critical problem is the absolute paucity of channels for visual conveyance. If we are mapping to an image, we effectively have but three channels we can use in the mapping (e.g., HSL).

albeit presentation models for these are limited.

Figure 1: The Aggregate Pyramid Model.

While much work in data visualization has strived to address the problem of channel paucity—for instance, by graphical symbols, layout, and such to add effectively “channels” for conveyance—these do not work for interactive visualization in an inductive way, where one can zoom to change dynamically the degree of aggregation. Meanwhile, no work yet has taken advantage of the additional channels that the modern graphics environment afford us. SKYDIVE is designed to exploit just that, to great advantage.

Presentation models. The presentation model defines the “structure” that will be visualized. The model provides a set of channels that can be used by the mapping.

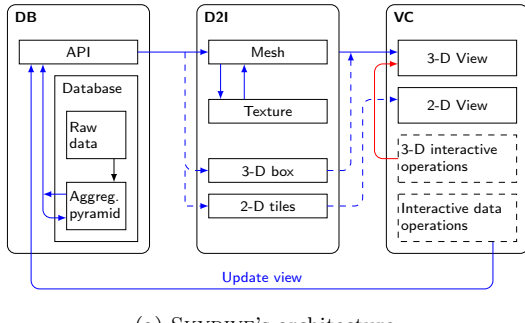

The 2D model. One model is that of a 2D image. The viewer manages the visualization as an image—which we call a *data texture*—within a canvas, allowing the user to zoom and pan around it. This view is, in essence, a *heat-map*. SKYDIVE’s benefit is that the data texture makes it possible to explore dynamically this heat-map view progressively in realtime. This model suffers still from channel paucity, however; it is effective only if one can live within such a constrained channel space.

The 2^{1/2}D model. A second model we call 2^{1/2}D. For this, the model is rendered in 3D. The visualization now consists of two parts: the data texture, as before; and a *terrain*—a *manifold*⁴ rendered as a *mesh*—onto which the texture is overlaid (*UV-mapped*).⁵ This exploits modern 3D graphics rendering, which supports meshes and UV-mapping. This offers SKYDIVE additional channels of conveyance over points in the terrain: *elevation* (Z); *specular*; and *normal*. A specular map determines how “reflective” a point is on the surface. As scenes in 3D have external lighting, this is quite noticeable. A normal map dictates deviations of the normals, the “perpendicular” of a point with respect to the surface. By perturbing the normals of a neighborhood, that part of the surface can be made to look rough; leaving them as dictated by the mesh, the surface looks smooth. These are standard in graphics processing and used in game production for making scenes look more realistic. That is, these channels visually stand out.

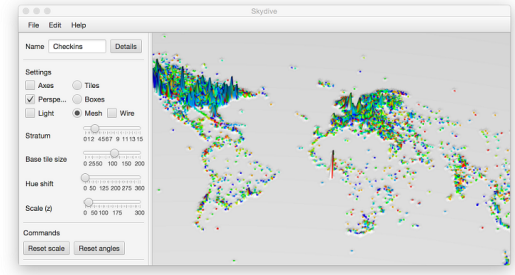

We can use the *alpha* channel additionally, as the terrain can be floated over a flat reference plane; the bleed-through of the reference through *translucency* of the terrain is readily

⁴A *manifold* is function that maps 2D coordinates to values. This can be rendered in 3D using *elevation*, “Z”, over the 2D plane to indicate the 2D points’ values.

⁵2D images are called *textures* in this context, and the mapping of textures onto the mesh surfaces is called the *UV-mapping*.

(a) SKYDIVE's architecture.

(b) SKYDIVE's main window.

Figure 2: The SKYDIVE System.

obvious. This means we have effectively *seven* channels of conveyance in the $2^{1/2}D$ model, versus just the three in the 2D model.

Mixed models. SKYDIVE can mix presentation models for the same pyramid to provide simultaneous, synchronized alternative viewports into the same data. We also intend to support “cross-product” pyramids that could, for example, let one zoom and pan on XY and on T (*time*) independently.

3. EFFICIENCY

Structure of the aggregate pyramid. The idea behind this mirrors approaches taken by *progressive image formats* such as JPEG-2000. The image “pyramid” is multi-resolution data structure that represents a $2^d \times 2^d$ image as a sequence of copies (2D arrays) of the original image, each “half” the resolution—half on the rows and half on the columns—of the next. Thus the base stratum of the pyramid is the full resolution version of the image, while the top stratum is a single pixel approximation of it.

Similarly, the *aggregate pyramid* represents $2^d \times 2^d$ data cells at its base, with each subsequent stratum halving the “resolution” (doubling the aggregation). Construction of an aggregate pyramid can be accomplished efficiently by the database engine by building it from the base upwards. First, the base stratum is created by aggregating the raw data into the base cells. Then subsequent strata can be produced recursively by aggregating spatially the constituent quadrant cells of the stratum below. The cells can be indexed by stratum, and by Hilbert order that linearizes their order, which then can be indexed via a B+-tree. As such ordering preserves locality of sub-cells that are needed to merge for the next higher stratum, a stratum can be produced in proper order by a single scan of the cells of the stratum below it.

SKYDIVE employs the aggregate pyramid to preprocess data so the visualization process can be handled efficiently. Given a query defining the dataset to explore, the database system *materializes* the aggregate-pyramid version of the dataset query, and indexes the pyramid by stratum and Hilbert order, as discussed above.

The materialized pyramid is managed by the database engine during the visual exploration of that dataset. Interactive operations at the visualization client are then supported by querying into the aggregate pyramid at the appropriate stratum and range (bounding box), which can be handled efficiently and at real-time, interactive speeds. Thus, SKYDIVE tightly couples database support for processing the

data with the interactive visualization.

Operations. SKYDIVE is designed to support the following visual operations over the dataset for visualizing. Each, in turn, can be supported efficiently by the database system over the materialized aggregate pyramid.

Resizing. The user can change the current viewport by changing the size of the visualized data (up or down). In sizing, the visualizer may need to present a different level of resolution. For instance, in a size-up operation, the user requests a higher resolution image. As a result, the system needs to retrieve the aggregated data from a higher resolution stratum in the pyramid.

Zooming. The user can request to view more detail of a part of the image by specifying a *window of interest*, selecting a portion of the image by zooming in. The system maps the requested window to the stratum with high enough resolution to fit the canvas, and selects the appropriate range.

Panning. In panning, the user changes the viewport in the image, but within the same level of resolution. If the user pans, the system will check the availability of the visual data in the current stratum, and request the additional range from the pyramid in that stratum.

4. ARCHITECTURE

Skydive's components. SKYDIVE is composed of three main components, as shown in Figure 2:

- the Database Module (DB);
- Data-to-Image module (D2I); and
- the Visualization Client (VC).

Each is designed to use a different type of *computer memory*. The DB module uses *disk* to store and manage the raw data, and materialized aggregate pyramids. The D2I module works with a small subset of the aggregated dataset, and stores data in *main memory* (RAM). The VC module uses the *graphic card's* capabilities to perform more advanced operations—such as zooming, scaling, panning, and rotation—over the graphical representation of the data.

This separation of concerns provides useful flexibility. Each component can be implemented as a separate service, deployed on a different machine. This leverages the idea of *compression* of data conveyed between the modules, letting us implement a tightly coupled visualization system. The SKYDIVE prototype is implemented as a desktop application with the three modules as described above and shown in Fig. 2a. The main window of SKYDIVE, shown in Fig. 2b, is

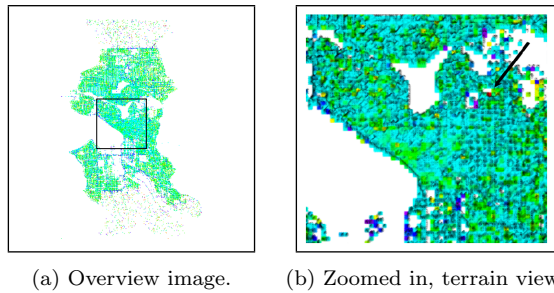

Figure 3: Visualizations of the Seattle 911 Dataset.

composed of a few simple elements: an upper menu for performing basic file operation; a left panel for tuning a loaded and currently displayed visualization; and a visualization view for rotating, panning and zooming.

Graphical variables. The user also defines the presentation model to be used and the visualization mapping (of aggregates to channels) to be employed, as discussed in §2. The system prototype supports three presentation models:

- a 2D heat-map;
- a $2^{1/2}$ D heat-map by 3D barchart; and
- a $2^{1/2}$ D terrain (by mesh and UV-mapping).

Generating meshes and textures. The data texture is generated by the D2I module by selecting the appropriate window out of the aggregate pyramid, and applying the visualization mapping. For the $2^{1/2}$ D terrain model, a mesh is additionally computed by the D2I. The mesh is created based on a stratum of lower resolution, for better visual appeal, and for efficiency in the VC.

User interface. The user interface, as shown in Fig. 2b, allows the interactive visualization operations, as discussed above. The user can scale, translate, and rotate the currently displayed visualization in the Visualization Client (VC). The VC is implemented using JavaFX, which natively supports these functions. Scaling, translation, and rotation do not require to query the aggregate pyramid, hence are performed entirely within the VC, supported by the GPU.

Other *interactive* functions do require queries to be issued from VC to the DB module. For instance, if the user wants to focus more on a certain area of a visualization, then the system must request the data from the appropriate stratum; of higher resolution for zooming in, and lower for zooming out. Issuing such a request results in the loading and generating of the mesh and texture by the D2I. The VC then displays this using the GPU’s graphics pipeline.

5. DEMONSTRATION SCENARIO

Datasets. We test SKYDIVE using several datasets, two of which are described below.

9-1-1 calls. The Seattle Police Department 911 Incident Response dataset⁶ contains over one million records. Each represents the police response to a 911 call within the city. Fig. 3a shows a *density* map of the calls. Color denotes the number of calls made within the area represented by a pixel. Based on the plotted heat-map, a user is not able to conclude anything more than that there are some areas of slightly higher density than their neighbors.

⁶<https://data.seattle.gov/>

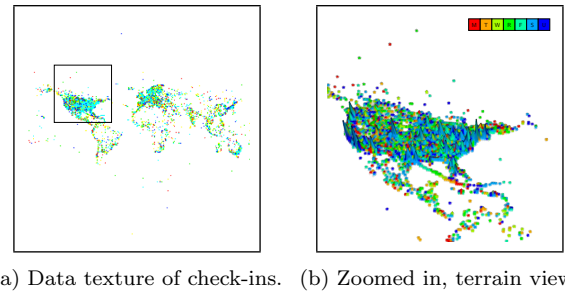

Figure 4: Visualizations of the Brightkite dataset.

In Fig. 3b, we have switched to the terrain view, where elevation indicates the density, and color refers to a most frequent type of a call within the cell. In this view, we see more detail. For example, the red pixel indicated by the arrow represents unusual activity within the magnified area.

Brightkite check-ins. The Brightkite Check-ins Dataset⁷ consists of over four millions records of geographical positions reported by users of a geo-location social service. In Fig. 4a, the heat-map represents the dataset over one measure: color represents days of week for which user activity was highest within the areas represented by the pixels. In Fig. 4b, a terrain map is shown of a zoomed in portion with more in the mapping. The texture color again denotes day of week with highest activity. Elevation denotes number of check-ins. We can deduce that weekends were most active days for Brightkite users in the USA. We can additionally see the areas in which the most users were active.

Richer mappings. We will demonstrate the richer mappings offered by the $2^{1/2}$ D model with normal, specular, and alpha channels. These are not easy to show in static pictures, but stand out in display in the demo. With these, additional aggregates can be conveyed to a viewer simultaneously. Roughness of the surface (a normal map) can be used to represent variance of a measure within cells. Shininess (a specular map) can be used to show spatial dispersion within the area represented by a point on the terrain.

ABSTRACT

Microblogging streams contain information pertaining to emerging real world events. Due to the rapid pace at which these data streams are generated, it is often difficult for users to discover the most relevant messages in the context of their keyword queries. Search over such data streams returns the most recent messages only; most recent messages may not be the most relevant messages. Hence users have to resort to the cumbersome task of sifting through a large amount of information to obtain the context of a live event.

We present a novel real time search system – *Contextual Event Search* – on dynamic message streams, to extract meaningful summaries for live events in real time. Our technique is unsupervised and automatically identifies different facets of the live events in a scalable and effective manner.

We demonstrate that for a given keyword search, users are presented with meaningful, compact and complete contextual event summaries for the most relevant events in a given time window, thus exposing the full context behind the messages.

Dynamic Graph, Indexing, Search, Summarization.

1. INTRODUCTION

Highly dynamic unstructured data streams – sequences of chronologically ordered messages posted by multiple users at a fast pace – occur in various social media and enterprise domains. In microblog streams (e.g., Twitter), messages are posted at a high rate due to their large user base. Twitter is often the first medium to report emerging events [1][2], ranging from globally important events to the events relevant only for a small community.

An *event* is a real world or an abstract activity, relevant for a group of people or a community. An *event* in a data stream is defined by “*messages, posted by multiple users, in the same context, within a bounded time window*”, for example, messages posted by the fans during the course of a football match. It is only natural that in a fast moving world, a large number of events occur concurrently.

Existing unsupervised approaches identify emerging events as clusters of keyword over dynamic message streams [1][2][3]. Each keyword cluster forms an ‘event-topic’. The technique described in [1], when used to discover events from the tweets posted during the Nairobi terrorist attack [7], discovered many event-topics including one containing the keywords:

- **A: UK, #kenya, #westgate, #nairobi**

Clearly, the context behind the keyword cluster is not available to the users – the keywords are insufficient to describe the underlying event. The same is true of another event-topic:

- **B: was, 69, kofi, among, #ghana, attacks, ghanaian, awoonor, killed, poet, prof., #kenya**

To better understand the event-topic, i.e., what the event is about, users are needed to search for the most relevant messages in the data stream by themselves. Besides burdening the users with the task of understanding the emerging events manually, for example, to determine if there is connection between **A** and **B**, this approach suffers from many shortcomings:

- (1) Message search is primitive, e.g., Twitter just returns the most recent tweets for a given search query [5]. It is not necessary that the recent tweets alone are the most relevant tweets for the event.
- (2) Simple keyword search results can produce an information overload for a fast moving data stream. Often a large number of tweets are returned by Twitter in response to a search query [6].
- (3) In such fast moving data streams, typically the rate at which messages are generated is high but messages are short. Therefore, it is often difficult for the users to understand the context of a standalone message even if the message is informative.
- (4) Events evolving in real time comprise different facets. Search results are continuously updated with recent messages and it becomes difficult for the user to keep pace with evolving events.

1.1 Contextual Search on Live Data Streams

We demonstrate our system for *Contextual Event Search*, to extract the complete contextual summaries for the events unraveling in a live message stream in real-time. The summaries are stored in an event thread as shown in Figure 1. Live real-world events are not just point events – they evolve continuously. The event summary must be updated every time there are significant changes in the event. When these changes are arranged temporally, an event thread results. The event thread captures the passage of time naturally. Challenges involved in discovering such event threads are many:

¹ The author list is in alphabetical order.

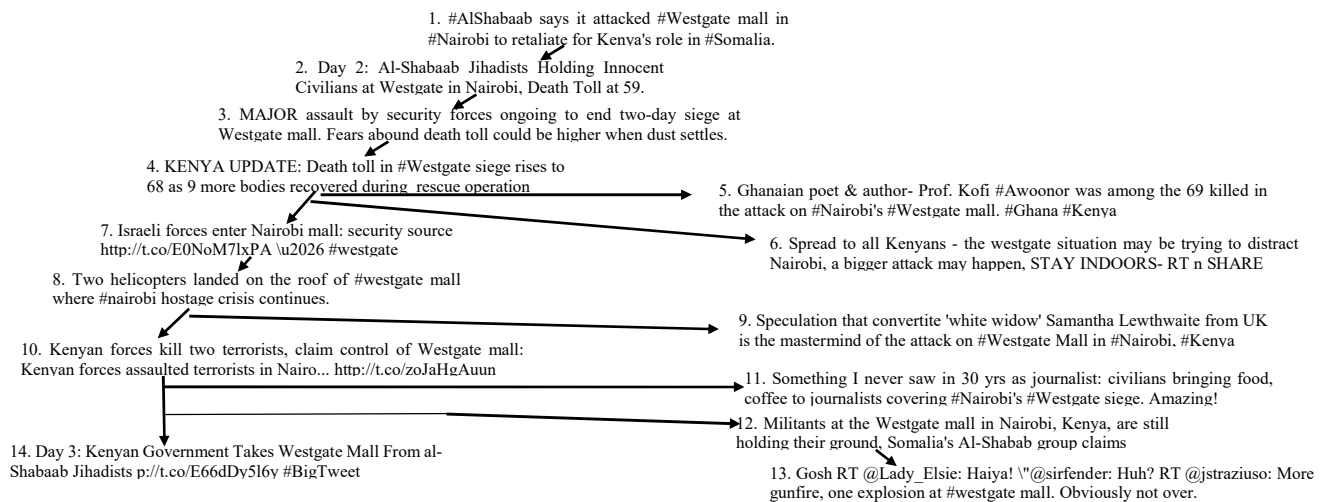

Figure 1. Contextual Event Summary Thread Discovered by our system for Nairobi Attack

- The first challenge is to identify and associate the relevant messages to the corresponding ‘event topic’.
- Secondly, most real world events do not evolve linearly and comprise several facets. Therefore, the summary for an event is represented as a Directed Acyclic Graph (DAG). It is non-trivial to discover such ‘contextual event threads’. Each unique path in the event thread is a different facet of the event.

The *contextual event summary* displayed in Figure 1 was constructed by our approach automatically for the event ‘Nairobi terrorist attack’. The event summary starts with a message that a mall has been attacked, followed by how the action against attackers was progressing, rumors, claims and counter claims by authorities and citizens, etc. were also discovered in real time. The important sub-events were discovered from approximately 164K tweets and arranged in a chronological sequence. For each of the sub-events in the event thread, our technique identified an appropriate summary as shown in Figure 1. Sub-event 9 corresponds to **A** and sub-event 5 corresponds to **B**.

We demonstrate our system that automatically constructs such summaries as shown in Figure 1, for a live data stream. Our system summarizes the event in a fast moving data stream in real time in an *unsupervised* manner. The event thread represent a compact, complete and meaningful event summary. A *minimal* set of related messages are identified that represent the *complete* event summary. The event summary discovered by our system is *stable*, i.e., it is updated only with additional information, which is appended to the summary discovered thus far. Our system also exposes the different *facets* of live events which are presented as a contextual event summary thread. The details of discovering the event threads are beyond the scope of this paper.

To the best of our knowledge, ours is the first system that discovers contextual event threads automatically for a fast moving data unfiltered data stream in real time in an unsupervised manner. Lin et al., explore the problem of generating storylines from microblog data [4]. Their system is only applicable to retrospective data analysis where on relevant tweets a storyline is generated via graph optimization. In [6], Shou et al. present a technique to summarize a twitter data stream, filtered in the context of a given user query. In [9], authors present a method to summarize a pre-specified event topic. Their methodology is applicable for structured and recurring events such as sports events and need the prior knowledge of similar events.

1.2 System Components

With the aid the event summaries, we enable the contextual search over data streams. Following are the components of our system:

Discovery: The event threads are discovered in a live data stream. They contain the most relevant messages in a chronologically ordered event threads representing its story line. Event thread is associated with a rank based on event popularity and its dynamicity. If an event is highly dynamic with fast updates, its rank increases.

Indexing: An index is maintained over the events threads. Since the index is updated in real time, we adopt a *lazy-update* strategy, i.e., index is updated only for the most popular events. For events, which are less popular, only a subset of these events are updated in the index, unless the underlying changes in the event result in significant increase in event rank.

Search: For a keyword query, a ranked list of most relevant event threads is returned. Hence, even the messages which may not contain the query keywords but are part of the event threads are returned. Thus, our system is able to find the most relevant contextual messages for a given keyword query.

The architecture of our system is shown in Figure 2. It contains three components; *Event Discovery and Summarization Engine* to discover event thread over a live data stream. The discovered events are pushed to the *Indexing Engine*, which maintains an index over them as well as keeps the index updated for live events. Finally, the *Search Engine* finds and returns the most relevant *topK* events, upon receiving a keyword query. *topK* is a tunable parameter. *Event Discovery and Summarization Engine* is based on the model in [1] but its details are beyond the scope of this paper. In next section, we present the details of other two components.

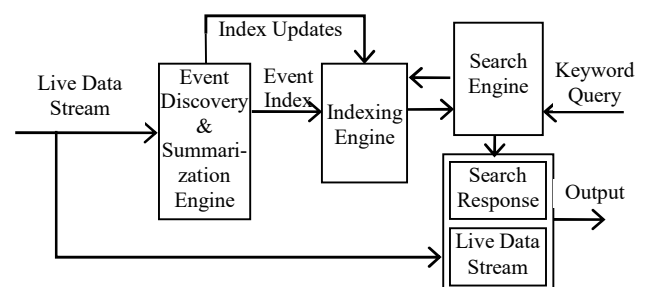

Figure 2: The system Architecture

2. REAL TIME CONTEXTUAL SEARCH

Each event is identified by a unique event ID e . As an event evolves, its summary is appended with the most recent updates. Each node in the event tree represents an ‘event topic’ and has a set of relevant tweets associated with it [1]. The algorithm to find meaningful summary of an ‘event topic’ and discovery of different event facets is beyond the scope of this paper. Each event topic, i.e., keyword cluster c_{ei} has a summary s_{ei} and a ranking score r_{ei} . For an event e , there is a list of clusters $c_{ei} \mid_{i=1}^n, n \geq 1$ associated with it.

Ranking score r_e for an event e is computed as $r_e = \sum_{i=1}^n c_{ei}$. Event summary s_e is defined by arranging the cluster summaries ($s_{e1}, s_{e2}, \dots, s_{en}$) in a (multi-faceted) event thread.

2.1 Indexing Engine

The search engine maintains an inverted index. The inverted index consists of words mapped to a posting list of event IDs. For each word w , its posting list L_w contains event IDs which have w in its summary. In the posting lists, events are sorted in the decreasing order of their ranking scores. One of the challenges is to maintain the posting lists sorted, since inserting an event in L_w would take $O(|L_w|)$ time; $|L_w|$ is the number of events in L_w . To reduce the cost of insert operation, we adopt the following approach: List L_w is organized as a list L_w' containing sequence of buckets B_1, B_2, \dots, B_m where $m = |L_w'|$. Each bucket contains a max-heap and a min-heap. Both heaps contain same event IDs. We define the size of the bucket as the size of its max-heap. Each bucket B_i has an event with maximum score s_i^{max} and an event with minimum score s_i^{min} . The sequence of buckets is such that the following property is satisfied:

$$s_i^{min} \geq s_{i+1}^{max} \mid \forall i \quad \square$$

The size of buckets B_i s increases by a factor of 2 ($|B_{i+1}|/|B_i|=2 \mid \forall i; i < m$). Therefore, $m = |L_w'| = O(\log(|L_w|))$. The time complexity of the insert operation is equal to the time complexity of a) searching the bucket B in which the event should be inserted ($O(m)$); b) inserting the event in B ($O(m)$), since the size of each bucket is $O(|L_w|)$ and the bucket is maintained as a heap; c) adjusting the size of B (its size increases by 1 on inserting an event). Step (c) takes $O(m^2)$ time since the event with minimum ranking score is removed from B and inserted in next bucket and this procedure may continue till the first bucket in the sequence. If the size of the last bucket is larger than the maximum allowed, then the event with minimum ranking score is removed and is inserted in a new bucket appended at the end (number of buckets in list L_w increases by 1).

- The insert operation in each bucket is performed by inserting the event in max-heap and min-heap ($O(m)$ time complexity).
- The remove operation in a bucket is performed by removing the minimum element in its heaps. This is $O(1)$ for min-heap but for max-heap it takes $O(|L_w|)$ if done naively. We store the pointer to the location of the minimum ranking score event in max-heap hence removal takes $O(m)$ time.

Since there are m buckets and insertion and removal in each bucket takes $O(m)$ time, step (c) takes $O(m^2)$ time. Therefore, the overall insert operation takes $O(m^2)$ time.

For each list, we maintain a mapping of event ID to the bucket which contains it. This is useful when an event has to be removed from a posting list or its ranking score has to be updated. With this map searching an event in a list takes $O(1)$ time. Buckets are implemented as locator heap in which a map is maintained which contains the location of event IDs inside the bucket (i.e., heap) thus making the deletion of an event from the bucket $O(m)$.

Lazy Update: With more tweets flowing-in, events are updated which results in the update of its ranking score. We need to reflect these changes in the index. However, updating the index is costly as the event clusters get updated at a fast pace. Thus, we trade-off the minor drop in output accuracy for greater efficiency of the search engine. Whenever the score of an event changes, we check if the new score is greater than the score of the event at the $2 \times topK^{th}$ position in the relevant posting list. If not, we assume that the event will not affect the final output for any query and hence the change is ignored. Otherwise, we update its score.

2.2 Search Engine

In this section, we describe our query processing system or search engine. The search engine takes a keyword query and returns $topK$ most relevant event summaries. Suppose a user enters a query Q of length $l: q_1, q_2, \dots, q_l$, where $q_i \mid 1 \leq i \leq l$ is a query word. To define $topK$ relevant events, we compute $maxScore(Q, e)$ [8] of an event e for a query Q . We define a function $p(w, e)$ for a word w and an event e . $p(w, e) = 1$, if e is present in the posting list of word w , otherwise $p(w, e) = 0$.

$$maxScore = r_e \times \sum_{i=1}^l p(q_i, e)$$

where r_e is the event rank. $topK$ events with highest $maxScore$ form the output. We next define some important terms and data structures before describing the algorithm to find $topK$ events:

partial_maxScore: Initial *partial_maxScore* of all events is set to 0. Maximum *partial_maxScore* of an event e is the product of r_e and the words in the query for which e is present in their respective posting list.

topEvents: We maintain a min-priority queue of *topEvents* which stores candidate events and is initially empty. An event e_1 is considered “less than” event e_2 if *partial_maxScore* of e_1 is less than that of e_2 .

min_topEvents: It is the event with minimum *partial_maxScore* among all the events in *topEvents*.

fcEvents: It stores final candidate events. Any event evicted from *topEvents* is stored in *fcEvents*.

getMax(B) returns the event with maximum ranking score in the bucket B .

We search for the posting list for each word in the query. Words for which no posting list is found are discarded. For all the posting lists in consideration, an iterator is set to the first bucket. The highest ranked event from each bucket is inserted in *topEvents*. We take the event *min_topEvents* and compare it to the event next to it, called e_n , from the posting list it belongs to. We check if e_n is a candidate event. e_n is a candidate event if either the number of events in *topEvents* and *fcEvents* is less than $topK$ or $r_{e_n} \times l \geq min_topEvents.partial_maxScore$; $r_{e_n} \times l$ is $maxScore(Q, e_n)$ which is the maximum possible value of *partial_maxScore* for event e_n . Hence, if this value is less than *min_topEvents.partial_maxScore* and at least $topK$ events are already present in *topEvents* and *fcEvents*, then e_n cannot occur in the final output. If it is a candidate event, it is inserted in the *topEvents*; otherwise the *min_topEvents* may occur in the final output and hence moved from *topEvents* to *fcEvents*. If the event e_n is already present in *topEvents* or *fcEvents*, then we just update its *partial_maxScore*. Once no more events can be inserted in *topEvents*, we move the remaining events from *topEvents* to *fcEvents*. $topK$ events with highest *partial_maxScore* in *fcEvents* form the Output. For faster retrieval, no posting list is traversed beyond $2 \times topK^{th}$ event (which lies in $\log(2 \times topK)^{th}$ bucket).

```

1 Create an array currB of the iterators;
  /* currB[i] stores the iterator of  $i^{th}$  query word
   for which posting list exists */
  /* Iterators are pointing to the first bucket of
   corresponding posting list */
  /* Each event e in topEvents also stores the
   position of the bucket of its posting list in
   currB which is expressed as e.posInList. */
2 numPostingList := Size of currB;
3 while numPostingList ≠ 0 do
4   e := min_topEvents;
5   if The bucket B at currB[e.posInList] is empty
   then
6     if B is the last bucket in the posting list then
7       Remove e from topEvents and insert it in
       fcEvents;
8       numPostingList − −;
9       continue;
10    end
11   else
12     Set currB[e.posInList] to the bucket next to
     B in the posting list;
13   end
14 end
15 en := getMax(currB[e.posInList])
16 Remove en from currB[e.posInList];
17 if en is present in topEvents or in fcEvents then
18   en.partial_maxScore :=
19   en.partial_maxScore + ren;
20 end
21 else if en is a candidate event then
22   en.posInList := e.posInList;
23   Insert en in topEvents;
24 end
25 else
26   Remove e from topEvents and insert it in
   fcEvents; numPostinList − −;
27 end
28 end
29 Output summaries of topK events with highest
   partial_maxScore.

```

Our experiments have shown that typically in a posting list, initial top ranking events are followed by a long tail of low ranking events. Hence, it is unlikely that if any event beyond $2 \times topK^{th}$ position in the any of the posting list under consideration, are in final *topK* list. This the reason behind this heuristic.

Correctness of the algorithm: The algorithm traverses all the posting lists of the query words present in the index. However, instead of traversing them completely, whenever an event *e* does not qualify to be a candidate event, *min_topEvents* is removed from *topEvents*. This ensures that the corresponding posting list is not considered again as all the following events have lower ranking score. Hence, they can never become candidate events.

Time Complexity: In the worst case, each event can be a candidate event. So all the top $2 \times topK$ events in the posting lists of query words are inserted in *topEvents*. The time complexity for all the insertions in *topEvents* for a query *Q* of length *l* is $O(\log(l \times topK))$ as $l \times 2 \times topK$ is the maximum number of events in *topEvents*. The time complexity of traversing the posting lists is $O(l \times topK \times \log(topK))$ since each event is removed from a bucket on traversal. Hence, the time complexity of the algorithm is $O(l \times topK + l \times topK \times \log(topK)) = O(l \times topK \times \log(topK))$.

3. DEMONSTRATION

We demonstrate the ability of our system to find the most relevant messages in the context of a user keyword query. Specifically, for a given keyword query, we demonstrate;

- The ability of our system to find the most relevant messages in real time over live data streams.
- The discovery of contextual tweets in a live data stream, for a given user query, i.e., those tweets that do not even have the query keywords but are relevant.
- The ability of our system to create a story line for events unraveling in a live data stream in an unsupervised manner.

Our system returns a ranked list of the most relevant events for the user query. We will demonstrate the statistical summary of the live event including the number of tweets posted for that event and its ranking score. We will also demonstrate that the event summary discovered by our system is complete. At the demo, a user can see a fraction of randomly selected tweets from a live data stream and be able to compare our summary with the raw data. We will demonstrate our system on recorded as well as live Twitter stream.

The screenshot in Figure 3 shows the output of our search system for a given user query. For each event present in the result set, for the given keyword query, users can see a chronologically ordered DAG of most relevant tweets, representing contextual event threads, by clicking on the link.

Answering Controlled Natural Language Questions on RDF Knowledge Bases

Giuseppe M. Mazzeo
University of California, Los Angeles
mazzeo@cs.ucla.edu

Carlo Zaniolo
University of California, Los Angeles
zaniolo@cs.ucla.edu

ABSTRACT

The fast growth in number, size and availability of RDF knowledge bases (KB) is creating a pressing need for research advances that will let people consult them without having to learn structured query languages, such as SPARQL, and the internal organization of the KBs. In this demo, we present our Question Answering (QA) system that accepts questions posed in a Controlled Natural Language. The questions entered by the users are annotated on the fly, and an ontology driven autocompletion system displays suggested patterns computed in real time from the partially completed sentence the person is typing. By following these patterns, users can enter only semantically correct questions which are unambiguously interpreted by the system. This approach assures high levels of usability and generality, which will be demonstrated by (i) the superior performance of our system on well-known QA benchmarks, (ii) letting attendees suggest their own test questions, and (iii) accessing an assortment of RDF KBs that, besides the encyclopedic DBpedia from Wikipedia, will include others on specialized domains, such as music and biology.

1. INTRODUCTION

The last few years have seen major efforts toward organizing as RDF knowledge bases (KBs) both general and specialized knowledge. In the first group, we find DBpedia [1] that encodes the encyclopedic knowledge extracted from Wikipedia, and in the second group we have the thousands of projects that cover more specialized domains [2]. While these KBs can be effectively queried through their SPARQL [3] endpoints, the great majority of web users are neither familiar with SPARQL nor with the internals of the KBs. Thus, the design of user-friendly interfaces that will grant access to the riches of RDFKBs to a broad spectrum of web users has emerged as a challenging research objective of great social interest

The importance of this topic has inspired a significant body of previous work, which includes the approaches de-

scribed in [6, 9, 10] and several others that rely on user-friendly graphical interfaces.

While some of these approaches [6] allow users to enter complex queries through a web browser, Natural Language (NL) interfaces remain the solution of choice when the used devices do not support well a full browser, or when voice recognition is used instead of typing. Translating NL questions into formal language queries represents an old, challenging, and widely studied problem [7, 8, 11], for which a general solution has not been found yet. This is, in fact, a very complex problem, combining several non-trivial sub-problems, such as parsing the syntactic structure of the question, mapping the phrases of the question to resources of the KB, and resolving ambiguities. The last problem is quite serious, because syntax often leaves much room for ambiguity, which cannot be resolved without much knowledge about the underlying application domain and understanding the context in which the question is asked.

In order to reduce the complexity of the problem, techniques replacing the ‘full’ natural language with a *controlled natural language* (CNL) have been proposed. A CNL system restricts the grammar that can be used to input questions, with the objective of making the language (i) ‘formal’ enough to be accurately interpreted by machines, but still (ii) ‘natural’ enough to be readily acquired by people as an idiomatic version of their NL. These systems are based on the idea that it is worth giving up the great flexibility and eloquence of the natural language in order to make the questions unambiguous to the machine that can thus produce answers of better accuracy and completeness.

In this demonstration session we will present our system for querying RDF data, called **CANaLI** (acronym for Context-Aware controlled Natural Language Interface). **CANaLI** has been applied to various QA testbeds [4], producing results of superior precision and recall. We will let **CANaLI** answer these testbed questions along with new questions suggested by the conference attendees, as needed to prove the usability and generality of the system. The attendees will thus be able to observe how **CANaLI** guides the users in typing questions, by allowing users to type only questions that are semantically correct w.r.t. the underlying KB, and syntactically correct w.r.t. the grammar of its CNL. Moreover, as soon as the user hesitates with typing, the system suggests correct completions she can select from. This allows people to self-learn **CANaLI** easily and quickly.

This short paper is organized as follows. Section 2 provides an overview of **CANaLI**, describing its basic operation, by means of some examples (Sec. 2.1 and 2.2), the index

Figure 1: The main states and transitions of the automaton used by CANaLI

used to suggest valid tokens (Sec. 2.3), and the system architecture (Sec. 2.4). Experimental results are presented in Section 3. Finally, we describe the demonstration scenario in Section 4.

2. OVERVIEW OF CANALI

CANaLI is a system that enables users to enter questions in a controlled and guided way, as a sequence of tokens, that define:

- KB resources: entities, properties, and classes,
- operators (e.g., equal to, greater than, etc.),
- literals: numbers, strings, and dates,
- NL phrases, such as “having”, that play a syntactic sugaring role.

Each token is represented by an NL phrase, consisting of one or more words from the application domain, since operators, variables or URLs used in SPARQL are not allowed. CANaLI operates on tokens in the style of finite state machines, with (currently) 12 states, including the initial and final state. Despite its simplicity, CANaLI is very general, since it can be used with arbitrary RDF KBs, and supports most of the common questions asked by users, including those contained in previous papers and various testbeds (see Section 3).

2.1 Answering Simple Questions

The operation of CANaLI can be explained with the help of the transition diagram in Figure 1, and a simple example¹. For examples, say that the user wants to enter the question: “What is the capital of United States?”. When the user starts typing a new question, CANaLI’s automaton is in the initial state (S_0), ready to accept tokens representing the question start. In this case, CANaLI sees “What is the” and it moves to the state S_1 . At S_1 , the system can accept a token representing an entity, a property, or a class. In our example, the user enters “capital”, that is a property recognized by CANaLI. Thus, the system loops back to S_1 , ready to accept as next input token another property, entity, or class. In our simple example the user enters “United States”, that is an entity, and the system moves to S_2 , after recognizing “United States” as an entity with “capital” as valid property. Thus, in order to be consistent with the semantics of the KB, our user must enter entities that have the property “capital”, and the system will stop her from progressing any further if that is not the case. Of course, to reach this ‘no progress’ point

¹Here, the system response is based on the context provided by the question typed so far and the underlying KB, rather than just the current state and last token as a finite state automaton would.

the user must have ignored the suggestions that the system had previously generated as valid completions of the typed input. CANaLI shows completions under the input area: if the user selects any such completion its text is added to the input area. In S_2 the question mark can be accepted, which marks the end of the question, whereby CANaLI moves to the final state S_F and launches the actual query execution. Alternatively, the user can enter conditions, using tokens such as “having”, which will be discussed later.

Let us now consider an example involving a chain of properties: “What is the population of the capital of United States?”. In this case, at S_1 , user inputs the property “population”, whereby the system loops back to S_1 . CANaLI now accepts “of capital” because the capitals have a population, and loops back to S_1 , where “of United States” takes us to state S_2 where the question mark completes the processing of the input and launches the query.

Thus, the four basic states S_0 , S_1 , S_2 , and S_F , support a large set of very simple questions asked by everyday users². More complicated but nevertheless common questions are those adding constraints, i.e., query conditions. For instance, assume that the user wants to ask³: “What is the capital of countries having population greater than 100 millions?”. After the input “What is the capital”, has moved us to S_1 , CANaLI accepts “countries”, as a class that has “capital” as a valid property, and moves to S_2 . In S_2 , CANaLI accepts “having”, and other uninterpreted connectives used as syntactic sugar, to move to S_3 , where it will accept only a valid property. In this case, “population” can be accepted since countries have this property. However, this example illustrates the ambiguity that beset all NL interfaces, no matter how sophisticated their parser is. Indeed, this constraint is also applicable to “capital”, since capitals have population too. Clearly every NL system would suffer from the same problem, and only a person who knows that currently no city has more than 100 millions people, might be able to suggest that the question is probably about countries rather than capitals. However, CANaLI finesses this inherently ambiguous situation by displaying all alternative interpretations whereby the user has to make a choice. Once the property “population” is accepted, and its context clarified, the automaton moves to the state S_4 , that accepts an operator. Thus, the user can input “greater than”. The automaton thus moves to state S_5 , that accepts the right-hand side of the constraint. In general, the right hand side of a constraint can be an element of the KB or a literal. In our example, only a number can be accepted, since the right-hand side must be of the same type as the left-hand side, “population,” which is numerical. Thus, the user enters 100 millions and the automaton moves back to S_2 . From this state, the user can specify more constraints, or input the question mark, ending the question.

Examples of constraints using resources of the KB as right-hand side are the following: “Give me the country having capital equal to Washington.”⁴, “Give me the movies having

²Indeed, the most frequent web questions are definition questions (e.g., What is Ebola?), that are even simpler.

³This provides a good example of the broken but effective English now supported by CANaLI.

⁴Indeed, the complete automaton of CANaLI has also a transition from S_4 to S_2 that allows to implicitly assume the equality operator. This allows to accept questions such as “Give me the country having capital Washington.”

director equal to a politician.”, “Give me the cities having population greater than the population of Los Angeles.”. In all the cases, the token accepted in S_5 is a token whose type is semantically coherent with the property previously accepted in S_3 . However, while accepting an entity or a class moves the automaton to S_2 , accepting a property (e.g., *population*) moves the automaton to S_1 , where the element possessing the property must be specified (e.g., *Los Angeles*).

2.2 More Complex Questions

For the sake of presentation we have shown in Fig. 1 only the states that are most commonly used in queries. In reality CANaLI has five more states which support the additional patterns which are discussed next via illustrative examples:

- “Give me the cities having population greater than that of Los Angeles.” The use of the pronoun *that* in place of the already used attribute *population*, makes the question more natural than the question where “population” is repeated. However, a special state for handling pronouns had to be added to CANaLI.
- “Give me the actors having birth place equal to their death place.” The use of the possessive determiner implies that the properties *birth place* and *death place* are related to the same variable. A new state is needed here too, since there is no simple way to rephrase the question using the grammar accepted by the basic automaton in Fig. 1.
- “Give me the actors having birth date greater than that of their spouse.” This question combines the two situations described above.
- “Give me the country having the 2nd largest population”. Questions like this require to sort the results by the value of the attribute accepted in a specific state and to set the offset and number of returned results according to the token accepted in another state, i.e., a token such as *the nth greatest* or *one of the nth greatest*.
- “Give me the drugs without specified side effects”. This question requires negation. We remark that a token such as *without specified* can not be handled as the tokens like *having*, which defines a comparison between two operands.

2.3 How CANaLI suggests valid tokens

To achieve real-time response, CANaLI uses an index supported by Apache Lucene, which handles our tokens as if they were Lucene documents. Every acceptable token is associated with one or more phrases of the natural language. When the user types a string S , a query is performed on the Lucene index, to ensure that the returned tokens (i) have a phrase that matches S , (ii) have a type that is among the acceptable ones, according to the current automaton state and the previous token, and (iii) are semantically correct, according to the KB, as explained below.

To achieve (iii) above, besides indexing the elements of the KB by their label and type (i.e., entity, property, or class), we use two additional fields: *domain of*, and *range of*. The first is needed in cases such as “What is the population of”: a token can follow if it is domain of “population” (e.g., “capital”, “countries”, “United States”, etc.). The second is used in cases such as “...having capital equal to”: a token can

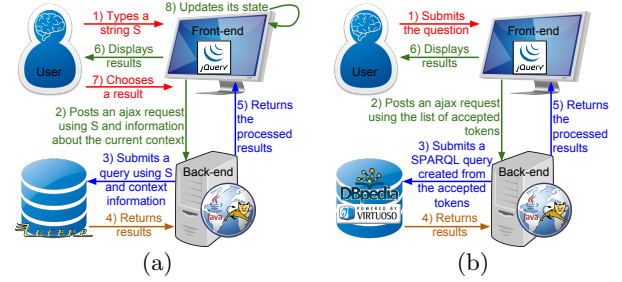

Figure 2: CANaLI’s architecture & work-flow guiding users in (a) typing questions, (b) retrieving answers.

follow if it is range of “capital” (e.g., “birth place”, “city”, “Washington”, etc.). In the case of properties, we also rely on the field *domain*, as needed for cases such as “What is the capital of countries having”, that can be followed by a property having as domain the property “capital”⁵ or the class “country” (e.g., “population”, “language”, etc.).

We created the Lucene index using the elements of the 2014 DBpedia release, using all the entities, and all the properties and classes of the DBpedia KB (those in name space <http://dbpedia.org/ontology/>). Also some classes of the Yago KB and the 20k most frequent raw properties (those in name space <http://dbpedia.org/property/>) were indexed. Furthermore, for all the indexed properties having non-literal range, we created an inverted property, and indexed it. The time needed to create such index, by processing the ~100 millions triples of the English DBpedia, is ~25 minutes using a single machine with 32GB of RAM, starting from the raw files downloaded from the DBpedia website. The obtained Lucene index is ~1.1 GB large and can be easily stored in the main memory of a server, thus assuring a nearly instantaneous response to our search queries.

2.4 The Architecture of CANaLI

Figure 2 shows the architecture of CANaLI and its work-flow in suggesting and accepting tokens (a), and computing the answers to the submitted question (b). CANaLI provides a web client, that uses an autocompleter implemented in *JavaScript*, using *jQuery* libraries. The client keeps track of the input tokens and the current state of the automaton, and when the user types a string S in the auto-completer, an Ajax request is sent to a web server, implemented in Java. The server uses the string S and the status of the automaton to query a Lucene index, that enables to quickly extract the results matching the string S and coherent with the current status of the automaton. Specifically, the suggested tokens must be syntactically coherent, according to the grammar of the language, and semantically consistent, according to the semantics defined by the KB. Completions are returned to the user, and refined as she types more input. Alternatively the user can select one of the suggested completions, and this selection is used to update the question text entered so far and to select the next state of the automaton. When the final state is reached, a request is submitted from the client to server, that uses the sequence of accepted tokens to create a SPARQL query, that is submitted to DBpedia, or the corresponding endpoints for the other KBs, and the results are shown to the user in a user-friendly snippet format.

⁵Specifically, the range of the property “capital” must be domain for the property “population”

YodaQA	33	8	2	0.26	0.18

Figure 3: Results on QALD-5 benchmark - Total number of questions: 49.

3. EXPERIMENTAL EVALUATION

A popular set of benchmarks was used to measure the performance of QA systems, i.e., the QALD (Question Answering over Linked Data) benchmarks [4]. The benchmarks consist of sets of NL questions, each associated with a gold standard query in SPARQL, representing the translation of the question. The accuracy of the systems is measured by comparing their results with those obtained by the gold standard queries. We assessed the performances of CANaLI on these benchmarks and the result obtained on each query are presented in [5].

Figure 3 summarizes the results obtained on QALD-5, that consists of 49 questions (the results obtained on the previous benchmarks are equivalent), reporting the results obtained by CANaLI, together with the official results of the participating systems. The columns in the table represent the number of processed questions (“Proc.”), the number of questions answered with F-measure equal to 1 (“Right”), the number of questions answered with F-measure strictly between 0 and 1 (“Part.”), the average F-measure achieved over the processed questions (“F proc.”), and the F-measure over the whole set of questions (“F glob.”), assuming 0 as F measure for the non-processed questions.

CANaLI allows to process 46 questions. The 3 questions that could not be processed require two currently unsupported features: (i) sorting by an aggregate function (e.g., “Which musician wrote the most books?”), and (ii) using arithmetic (“What is the height difference between Mount Everest and K2?”). CANaLI provided a completely wrong answer to one question, namely, “Who is the heaviest player of the Chicago Bulls?”. The question was input in CANaLI by using the property *team*, while the gold standard query used the UNION of both *team* and *draftTeam*, and the correct result was a player associated to *Chicago Bulls* through the latter property. Therefore, CANaLI missed the correct answer. CANaLI provided a partially wrong answer to another question, “Which programming languages were influenced by Perl?”, whose gold standard query used the union of two properties in its constraints (*influence* and *influenced by*). Since CANaLI does not support the UNION operator, only one property was used (*influenced by*), thus missing some of the correct results. Finally, with 44 right answers and a higher F-measure on both the processed and the whole questions, CANaLI proved to be superior to the other systems. Clearly, restrictions imposed by a CNL make an interface like CANaLI a bit less user friendly than full NL interfaces. However, considering that, besides Xser [12], the accuracy of the other full NL systems is far from being acceptable, we believe that an accurate answer is worth a bit extra effort spent in rephrasing the question.

4. DEMONSTRATING CANALI

In this demonstration session, we will exhibit the power, usability and flexibility of CANaLI, by starting from simple questions and moving to more complex ones. The attendees will see how CANaLI guides users in typing questions by allowing to type questions that are only semantically correct w.r.t. the underlying KB: as soon as the typist hesitates or halts even momentarily, the system comes to the rescue by suggesting a list of correct completions the user can select from. This enables people to self-learn CANaLI easily and quickly. In fact, in our demo, after asking the attendee for new questions, we will invite them to enter their questions directly into CANaLI. We will then demonstrate the QA effectiveness of the system by testing its superior precision and recall on complex questions taken from published testbeds that have thwarted the efforts of other QA systems. Finally, we will explain briefly the working of the system, and how the SPARQL queries are generated. This will also allow us to clarify the reasons for the flexibility and generality of the approach, whereby we will show CANaLI in action on several KB, including MusicBrainz and biomedical KBs, and discuss our current work-in-progress to extend it to support temporal questions on the archived history of Wikipedia/DBpedia.

ABSTRACT

Too much stress is easy to do harm to the physical and psychological health of teenagers, because most teenagers neither have the ability to cope with the stress by themselves nor like seeking adults' help initiatively. Social media has demonstrated its feasibility in detecting teenagers' stress with the micro-blog having become a popular channel for teenagers' self-expression. In this demonstration, we present a system called *tPredictor*, which can predict teenagers' future stress based on the social media micro-blog. Two questions are to be resolved: (1) what will the stress level of the teenager(s) be in the next time unit? (2) how will the stress level of the teenager(s) change (increase, decrease, remain unchanged) in the next time unit? *tPredictor* tackles the above prediction questions, taking into account the influence of future stressful events on teenagers' emotion. Considering the similarity of stock price movement and the stress level change, we define the stress candlestick charts and the stress reversal signals for stress change trend prediction. *tPredictor* can predict the stress of both individuals and a group of teenagers, which provides a platform for teenagers themselves, their parents or some institutions such as schools to know teenagers' future stress for taking measures timely to prevent the serious consequences.

Keywords

Micro-blog, teenager, psychological pressure, prediction

1. INTRODUCTION

Nowadays, teenagers are inevitably suffering much stress from various aspects. A survey, conducted by the American Psychological Association in August 2013, showed that the teenagers were the most stressed-out age group in the U.S [1]. Due to the unsoundness of teenagers' psychological regulation mechanism, too much stress contributes to teenagers' bad consequences more easily such as sleepless-

ness, depression and even suicide. However, for most teenagers, they lack experience and can't realize the seriousness of their stress so that they seldom actively seek for adults' help. And for guardians, parents can't be around and focus on teenagers every minute and even abundant teachers are not sufficient to attend to each student. Therefore, it is very useful to find methods for teenagers to understand their own stress, for parents to timely know teenagers' stress situation when teenagers don't initiatively reveal their stress to them and for teachers to be able to get hold of all the students' stress status. Nowadays, micro-blog has become a major channel for teenagers' self-expression. Teenagers post so many tweets expressing their personal emotions everyday, which provides abundant available data to detect teenagers' stress and further predict their stress change. In the literature, many researchers have studied using micro-blog to analyze people's mental health. [8] found the difference between depressed and non-depressed people through analyzing their tweeting contents and behaviors. [9] proposed a depression detection model based on the sentiment analysis of the micro-blog. [10, 5] provided a machine learning method to detect teenagers' stress of study, affection, inter-personal and self-cognition. However, all the studies aimed to detect the existing psychological problems where the harm has done in fact. To prevent bad consequences, [3] investigated people's social media behaviors and built a statistical classifier to predict the depression. Our previous work focused on the teenagers group and predicted their future stress using a stress level time series detected from micro-blog. It integrated the stressful event to predict future stress level and defined the stress candlestick chart to predict future stress general change trend [7, 6].

In this demonstration, we present a system called *tPredictor* to predict teenagers' future stress value and change trend. It is a system implementation of our previous work [7, 6] which can visualize the prediction results and enable users to easily understand the stress prediction results. For the functionalities, we further extend the system to the group stress prediction. It aggregates all the prediction results of teenagers and presents some statistical results of the group stress prediction. It also picks up the teenagers needing help based on out predicted future stress status from a group of teenagers. *tPredictor* provides a straightforward way for users to obtain the most important information, as well as get hold of the overall stress situation and meanwhile know well each teenager's stress status. Therefore, our system can be applied to both institutional users, such as schools and

Figure 1: System Architecture

individual users such as teenagers themselves and parents.

2. SYSTEM ARCHITECTURE

Fig.1 shows the system framework including the *User Interaction*, the *Data preparation* and the *Stress Prediction*.

2.1 User Interaction

User Requests receives users' requests including adding new teenagers to their concerning list, choosing teenagers to be predicted, and setting prediction parameters like the time granularity and the event information.

Result Presentation aims to visualize the prediction results for users' easy understanding. It analyzes the group prediction results and picks up the most important information to users. In details, it aggregates teenagers by different predicted stress values and change trends, and presents their distributions through lucid charts, which helps users get hold of the overall stress situation. Besides, it demonstrates each teenager's predicted stress together, which enables users to do the comparative analysis and quickly find the teenagers whose future stress will be severe.

2.2 Data Preparation

The *Data preparation* preprocesses the original stress sequences which detected from teenagers' micro-blog [10].

Stress Sequence Aggregation aggregates the tweets' stress sequence with different time granularity (day, month, etc.) to obtain six stress-related indexes. The stress sequence is the $Stress(T): (t_1, l_1), (t_2, l_2) \dots (t_n, l_n)$, where t_i represents the time of i_{th} tweet, and the l_i represents the stress level of the i_{th} tweet. The six stress-related indexes include the max stress level L_{max} , the min stress level L_{min} , the average stress level L_{avg} , the sum stress level L_{sum} , the number of stress tweets L_{scount} , the total number of tweets L_{count} , and the proportion of stress tweets $L_{proportion}$ in the aggregated time interval.

Missing Data Imputation aims to solve the missing data problem which is because of the casualness of users' tweeting time and frequency. We apply the Gaussian Process Regression to do the data imputation. The adjacent data, including the stress value before and after the missing data, will be used to inference the missing value. The $(\Delta t, L)$, where Δt and L denote the time distance and the stress level of the adjacent time unit, is used as the input feature vector form. We use non-missing data as the training data and then get the estimated value of the missing data through the trained model. Our experiments showed that the Gaussian Process Regression performed better than other imputation methods including the nearest mean approach, the linear interpolation and exponential smoothing.

Figure 2: The Stress Candlestick Charts

Stress Candlestick Chart Generation generates the stress candlestick chart SC and its corresponding feature vector SCF . The stress candlestick derives from the candlestick chart of stock price due to some similarities between stock price movement and stress level change. For instance, the stock price is influenced by the game between sellers and buyers and the related events of companies while the stress level is influenced by the personal self-regulation mechanism and the stressful events. The stress candlestick chart SC is defined as $(L_{first}, L_{last}, L_{high}, L_{low})$, namely the first, last, highest and lowest stress level in the time unit respectively. The stress candlestick chart feature vector SCF is defined as a five tuples $(shape, bodylen, upperlen, lowerlen, changeslope)$ which represents the shape, body length, uppershadow length, lowershadow length of the SC as Fig. 2 (a) shows and the stress change rate between two SC s.

2.3 Stress Prediction

2.3.1 Stress Value Prediction

Stress Value Prediction aims to predict the max, min and average stress level of the next time unit. The three stress values can comprehensively represent the teenagers' stress status and are also the major concerns to their followers.

Feature-Aware Time Series Prediction. According to Granger Causality analysis, the L_{max} , L_{min} and L_{avg} are related to not only their past values but also the other stress-related indexes such as the L_{sum} , L_{scount} , L_{count} and $L_{proportion}$. Based on the confidence of 95%, we find that the L_{max} is correlated to L_{sum} , L_{min} is correlated to $(L_{proportion}, L_{count})$, and L_{avg} is correlated to $(L_{sum}, L_{proportion})$. We apply the seasonal Autoregressive Integrated Moving Average (SVARIMA)[2] approach to our problem. The key function of the stress value prediction is:

$$L_{n+1} = C + \sum_{i=0}^{k-1} A_i L_{n-i} + \sum_{i=0}^{k-1} B_i \bar{X}_{n-i} + \sum_{i=0}^{r-1} \theta_i \varepsilon_{n-i} + \varepsilon_{n+1}$$

L_{n+1} is the stress value we want to predict, where L is the past values of the corresponding predicted stress indexes (max, min and average). The \bar{X} represents different features of the other correlated stress value sequences such as the $(L_{sum}, L_{proportion})$ to L_{avg} . The order k and r is determined by the Akaike's Information Criterion (AIC) and other parameters are estimated through damped least squares method. ε_i is the white noise error terms satisfying $E(\varepsilon_i) = 0$, and C is a constant.

Stressful Event Influence. The SVARIMA model predicts stress values based on the historical stress change pattern. However, some happened or forthcoming stressful events may add extra influence which can't be neglected. Hence, we use the Moving Average Convergence/Divergence(MACD) to depict the extra stressful event influence. We first find

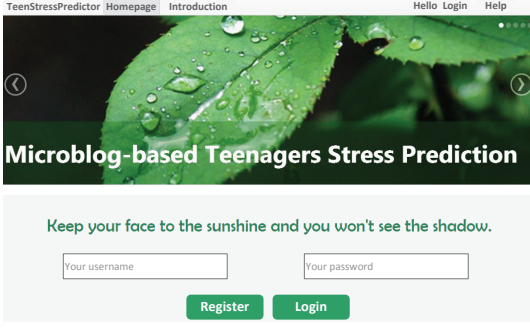

Figure 3: The System Homepage

Marry	Girl	5051232217	Class1	Good

Figure 4: User Requests

the stressful events and divide them into study and emotion event sets according to the users' tweets. Then we determine the start and end of the event influence cycle along with the stress value: 0. In the event influence cycle, we compute the MACD of the stress values, which can get a sequence representing the extra event influence. For the two event influence sequence sets, we use the Generalized Sequential Pattern(GSP) mining algorithm to mine the frequent sequence with 50% confidence to represent the extra influence of the two kinds of events. Finally, we divide equally the mined sequence into early, middle and later stage, and use the average MACD value of each stage as the adjustment value, which will be added to the original value predicted by SVARIMA model, if the predicted time is in the corresponding stage of different kinds of stressful events.

2.3.2 Stress Trend Prediction

Stress Trend Prediction aims to predict the future stress change trend including increase, decrease and remaining unchanged. We explore the candlestick chart to predict the stress trend. It outperforms the trend prediction method using the predicted stress values to subtract the last one, which might be a small fluctuation within the future trend.

Stress Reversal Signals. Fig. 2 (b) shows the decreasing reversal signals in a increasing process and Fig. 2 (c) shows the increasing reversal signals in a decreasing process. We take the decreasing reversal signals as examples for interpretation. For the 1-4 decreasing reversal signals, their

last stress level is lower than the first stress level, which represents a decrease in the time unit of the stress candle stick and indicates a continual decrease trend in the future. For the 5-6 decreasing reversal signals, their max stress level is much higher than the last stress level. It indicates the heavy stress is gradually released through teenagers' stress regulation mechanism in the time unit of the stress candle stick, where the release mechanism is likely to remain effective in the future. For the 8-9 decreasing reversal signals, their first stress level is the same as the last stress level which means the power of stress release balances the stress accumulation. In the past increasing process, the power of stress accumulation is stronger than the stress release and now they are balanced. Therefore, the power of releasing stress may become stronger than accumulating stress next, which signifies the stress will decrease in the future.

Trend Decision Making. Let n be the current time, we trace back to the nearest local highest or lowest stress level and form a stress pattern $P_{current}$: $(SCF_{n-k+1}, \dots, SCF_n)$ sequence, where k is the length of $P_{current}$.

[Case 1] If SCF_n is not the reversal signal, the stress change trend will continue.

[Case 2] If SCF_n is the reversal signal, we decide whether the stress change trend will reverse according to the past experience. Firstly, we define the distance $D(SCF_i, SCF'_i)$ between two SCF s to find similar past stress pattern P_{past} to the current stress pattern $P_{current}$.

$$D(SCF_i, SCF_j) = \sum_{k=1}^5 w_k D(f_{ik}, f_{jk}), \quad \sum_{k=1}^5 w_k = 1.$$

Here, f_{ik} and f_{jk} denote feature values of SCF_i and SCF_j , and w_k is the parameter determined by the analytic hierarchy process (AHP). For the nominal feature *Shape* of SCF ,

$$D(f_{i1}, f_{j1}) = \begin{cases} 1, & \text{if } f_{i1} \neq f_{j1} \\ 0, & \text{if } f_{i1} = f_{j1} \end{cases}.$$

For other four numeric features, $D(f_{ik}, f_{jk}) = |f'_{ik} - f'_{jk}|$, $j = 2, \dots, 5$, where f'_{ik} and f'_{jk} are the normalized f_{ik} and f_{jk} between 0 and 1. We set a distance threshold to judge whether two SCF s match successfully. After matching the last SCF_{n-k+1} , we get a past pattern P_{past} with length of t . If the $matchrate = k/t$ is higher than a threshold, we consider the two patterns match successfully. Finally, we obtain a set of matched patterns $P_{matched}$ and observe the future trend after the reversal signals in $P_{matched}$, where the stress level time series have been segmented [4] to eliminate the influence of fluctuation to get the general change trend. We choose the majority change trends of $P_{matched}$ as the predicted result. If there is no matched sequence, the stress change trend will be predicted to reverse.

3. EVALUATION

We collect stress sequences of 91 teenagers obtained by the stress detection method whose precision is proved to be 82.6% [10], for the prediction results evaluation. For the stress value prediction, integrating stressful events and SVARIMA model reduces the MAPE (Mean Absolute Percentage Error) of the predicted max, min and average stress level by 18%, 43%, and 3% separately, compared to the single SVARIMA model. For the stress trend prediction, the precision of our method achieves 83.79% which outperforms the time series (74.82%), MACD (63.59%) and KDJ (Stochastic Oscillator) (66.73%) based prediction approaches.

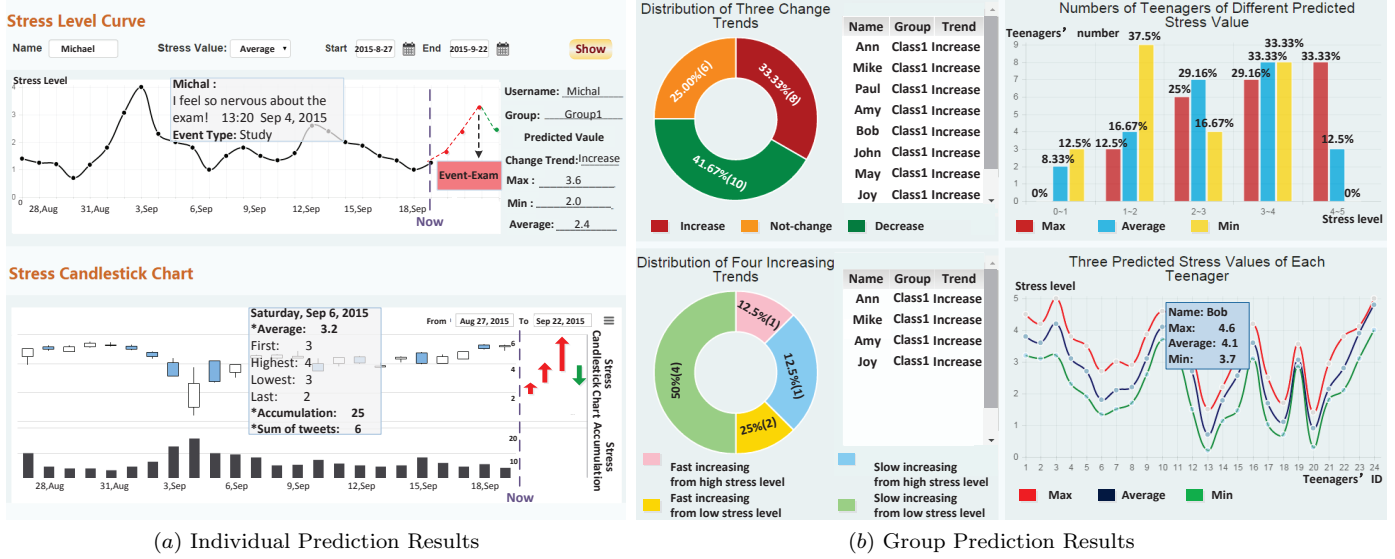

Figure 5: Prediction Results

4. SYSTEM DEMONSTRATION

During the demonstration, attendees can access *tPredictor* through the browser and experience our friendly interaction.

First, the user enters the home page of *tPredictor* and logins with his/her account as Fig. 3 shows.

After logging in, the user enters the second page as Fig. 4 shows. In this page, the user can view the profile of the teenagers listed based on the user's search. The user can click teenagers in the list to see more detailed information such as the photo and self-introduction. Besides, a new teenager can be added to his/her teenagers list. For the prediction, the user chooses one or a group of teenagers to be predicted and sets the parameters including the time granularity and the stressful event information. Here the user set the time granularity to be day, event type to be study and the event stage to be early about the upcoming exam.

When the user chooses one teenager to be predicted, the prediction results are presented through two charts as Fig. 5 (a) shows. The stress curve exhibits the past and predicted stress values of the teenager, where the original tweets content and event information can also be presented in this chart when the user clicks the corresponding point. The stress candlestick chart is to demonstrate the future stress change trend of the teenager and the detailed stress-related indexes are also shown in this chart.

When the user chooses a group of teenagers to be predicted, he/she can see both individual prediction results of two charts in Fig. 5 (a) and the statistical group prediction results as Fig. 5 (b) shows. The two doughnut charts tell the user about the teenagers proportion of different future stress change trends and the corresponding teenagers will be listed directly when the user clicks one part of the doughnut chart. It helps the user easily know whose stress will increase. The histogram shows the corresponding number of teenagers whose future stress values are in different stress level range. Through the histogram, the user can understand the overall stress situation of the group in the future. For example, the stress situation of the group is severe when most teenagers' future stress values are between 2-5. The line

chart shows the predicted stress value of each teenager of the group, through which the user can easily find teenagers who have much higher stress level

ABSTRACT

This paper presents the Online Social Network Investigator (OSNI), a scalable distributed system to search social network data, based on a spatiotemporal window and a list of keywords. Given that only 2% of tweets are geolocated, we have implemented and compared various state-of-art location estimation techniques. Further, to enrich the context of posts, associations of images to terms are estimated through various classification techniques. The accuracies of these estimations are evaluated on large real datasets. OSNI's query interface is available on the Web.

1. INTRODUCTION

The amount of user generated data increases every year, as more social interaction tools like Twitter, Instagram and Facebook are being created and more users use them to share their everyday experiences. Most research on analyzing social data has focused on detecting trends and patterns such as bursty topics [11] and popular spatiotemporal paths [10], event extraction [7], studying how information is spread [12], or analyzing properties of the social graph.

In contrast, in this paper, we study how to search social network data items, posts and images, based on spatiotemporal keyword queries. That is, we created methods to find the right needles (social data items) in the haystack (social networks), which we refer to as *investigative search*, to contrast it to the trending queries studied by previous work. Investigative search can also be viewed as exploring the currently untapped long tail of the distribution of topics in social networks. We use law enforcement as our focus application. The system capabilities and user interface were created in consultation with the University of California Police Department.

Figure 1 shows the user interface of the developed OSNI, available at <http://dblab-rack30.cs.ucr.edu/IARPA/>, where a user may select a spatial area on the map, a time range, and specify keywords. OSNI returns a list of posts (tweets)

ranked by their relevance to the query. The relevance is computed using a combination of the relevance of the text (based on an Information Retrieval function) and of the image (based on the confidence of the relevance of the query to an image) to the query. Only posts that belong to the specified spatiotemporal window are returned.

A key challenge is that only about 2% of the tweets are geolocated (have GPS location). Another challenge is how to associate images with terms. For example, if a tweet's image shows a "bike" we would like to return this tweet for the query "bike" even if it does not contain this word in its text. And a third key challenge is how to scale OSNI to a throughput of millions of posts per day, and how to facilitate interactive query response times.

This demo paper has the following contributions:

- We have adapted and implemented several social posts location estimation methods, and we have evaluated them on a dataset of millions of posts.
- We implemented a method to classify images based on the terms they are relevant to. We evaluated this classifier for various datasets.
- We built a scalable overall architecture, by combining several leading big data technologies. We experimentally evaluate the throughput and distributed performance of the system. We make the system publicly available on the Web.

2. ARCHITECTURE

The architecture of OSNI is shown in Figure 2. OSNI was written in approximately 8K lines of Java code. The whole OSNI, including all modules in the figure, is deployed on a cluster of two machines, which host instances of several systems (Cassandra, ElasticSearch, Spark). The Web server runs on one of the two servers.

The OSNI uses the Twitter Streaming API to collect tweets from Twitter. We specify a keyword-based filter on the Streaming API to only retrieve tweets that contain at least one of a collection of 64 keywords (provided by the law enforcement agency). This makes our data more focused to our domain, given that a single machine can only receive up to about 1% of Twitter's traffic. Matching records are stored in a Cassandra [5] database cluster of two nodes with replication factor 2 (each tweet is copied in both machines).

The preprocessing module continuously queries Cassandra for unprocessed records and runs a distributed job on a

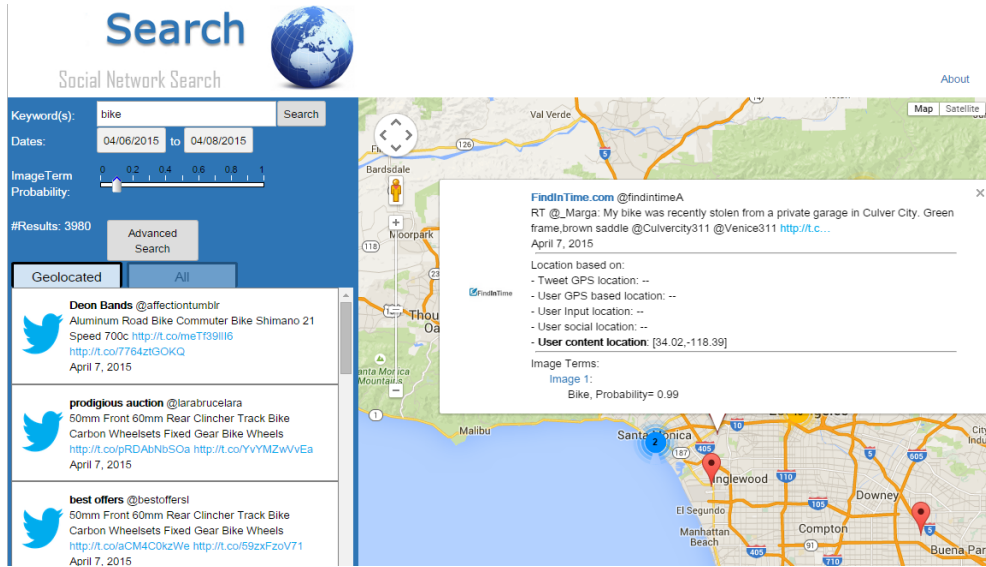

Figure 1: User Interface

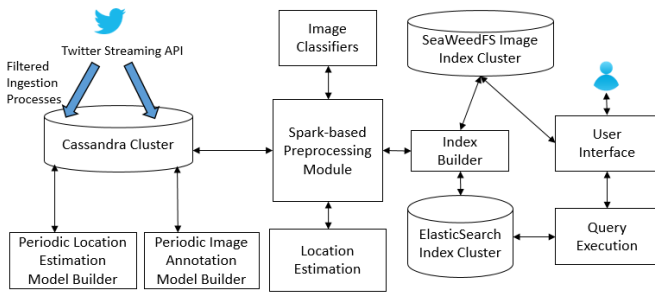

Figure 2: Architecture

Spark [1] cluster to process these records. For each record, we perform location estimation to determine the approximate location of the user at the time the tweet was posted (Location Estimation module in Figure 2, details in Section 3). Further, if the tweet contains an image, we also apply an image classifier, which downloads the image(s) from the Internet (only a URL is stored in the tweet record), and then runs the classification algorithm (Image Classifiers module in Figure 2, details in Section 4). If desired, images can be stored locally in SeaweedFS [4], a distributed storage system tuned towards storing images.

The enriched posts (enriched by location and image terms) are inserted into Elasticsearch [3], a distributed document search system. The Web-based query user interface, shown in Figure 1, is built using Google’s Web Toolkit (GWT), which is a Java-based Web toolkit. It is hosted on Apache Tomcat.

3. LOCATION ESTIMATION

We found that only about 2% of tweets are geolocated (e.g., using the GPS of a mobile phone). Hence, we need effective ways to estimate the location of the majority of tweets. We consider several methods to assign location:

User Location String. Here we use the user’s location as

an estimate of the tweet’s location. Twitter allows users to enter a location on a text field. Many users specify their city, e.g., “Riverside, CA”, but others specify imaginary addresses, e.g., “On the moon.” We use Google’s Map API to map a location string to latitude and longitude.

Places. Users may check-in or otherwise specify a place in the tweets (there is a *place* field in the JSON of a tweet), which can be something like “UCR Campus, Riverside, CA.” Again we use Google’s Map API to get coordinates.

User GPS. As in *User Location String*, we use the user’s location as an estimate of the tweet’s location, but here we compute the user’s location as the median of that user’s GPS locations in the last 30 days. Only users with at least 3 geotagged tweets are assigned a location using this method.

Social Network Approach. This approach is based on Compton et al. [9], where the assumption is that users are often located close to their friends. Users A and B are considered “friends” if User A has tweeted at least 3 times to User B and User B has tweeted at least 3 times to User A. We first calculate GPS medians for the users that have at least three geotagged tweets in the past and store the information in the user table. Afterwards, we build a social graph and estimate the locations that are still unknown using an error minimization technique. Our approach differs from the original approach [9] in a few ways. First, the number of tweets needed to be a “friend” is decreased from 3 to 2 to increase the size of the graph because our graph was too sparse. The graph size increased by 21% and the accuracy went down only by 2%. Second, we are making use of the places field used in the user’s tweets to assign more locations in the graph.

Content-based. This method looks for “local” words – e.g., “howdy” in Texas or “White House” around the White House in Washington, DC – in the body of the tweets to assign location to them. We build upon the method proposed in Cheng et al. [8], where instead of using cities, we use zipcodes (over 31,000 zipcodes in the US), that is, we assign terms to zipcodes. Further, we use a much larger number of tweets to increase the accuracy. Specifically, we use over

100 million geotagged tweets to calculate the focus and dispersion for each word to decide if it is a local word. Then, we build an index that maps terms to zipcodes with a probability, and assign to a tweet the zipcode with the highest probability among its words.

Implementation considerations. The *social network approach* has two parts. The preprocessing and the graph processing. The first step of the preprocessing is to create a unidirectional graph based on who tweets to whom so we can later build the friendship graph. The second is to collect tweets that have GPS locations and places location. In the graph processing, we first calculate the GPS medians for users with more than 3 geotagged tweets. Next, we build the graph and estimate the locations of their friends. The graph processing takes more than one day to run on a single machine, and hence we execute it once a week. The preprocessing is performed once per day. Similarly, for the *content-based approach* the local words are calculated once per day using gathered data from the last week.

Dataset and Evaluation. To measure the *accuracy* of our approaches, we used as ground truth 100 million geotagged tweets and compared the estimations of the various methods to these GPS locations. The *coverage* is the percentage of tweets that are assigned a location using a method; note that a tweet may be assigned a location based on multiple methods.

Type	10 miles	30 mile	50miles	coverage
Tweet GPS	100%	100%	100%	1.97%
User String	71%	73%	74%	27.6%
Places	81%	82%	83%	2.3%
User GPS	92%	95%	96%	1%
Social	82%	83%	85%	3.31%*
Content-based	24.7%	25.9%	27.3%	76%

Table 1: Tweet Location Estimation Accuracy and Coverage Evaluation. In Social Network approach, we only consider posts that have not already been assigned a location through Tweet GPS, User String, Places or User GPS.

4. IMAGE ANNOTATION

In this section we study how to extract keywords from the images of tweets to enhance the accuracy and effectiveness of our query interface. That is, a tweet that shows a picture of a bike, should be returned for query ‘bike’ even if it does not contain the word ‘bike’ in its body. We found that about 25% of Tweets have images.

Specifically, the image annotation module inputs an image and outputs a set of (term, confidence) pairs, e.g., (bike, 0.72), where the confidence denotes how probable it is that the image is related to the term. We use a vocabulary of terms that we want to detect in images and for each term we build a classifier.

After experimenting with various classifiers and image feature extraction methods, we chose Support Vector Machine (SVM) as classifier and SURF Detector [6] based Bag-of-Words Model [13]. We found that single-class classifiers are more accurate than multi-class ones.

The method for training the classifier works in two major steps. At the first step, SURF features are extracted from the training set (described below) that contains all images of all classes. A visual vocabulary of features (Bag of Words)

is created by reducing the number of features through quantization of feature space using K-means clustering. The resulting space has 5000 features. Then, in second step, occurrences of all visual features in the vocabulary are calculated from each of the images. A histogram of features is created per image, which is a 5000-entries long feature vector, which is a reduced representation of the image. Using these feature vectors and corresponding known labels for images in the training set, the SVM classifier is trained (offline, once per week). In the online system, when a new image comes, SURF features for the image are calculated and the image is represented as a feature vector. The label of the image and the confidences are estimated by feeding the feature vector into the SVM models created during the training phase.

Search Engine	Sample Images for query ‘bike’
Google	
Twitter	

Table 2: Examples of a few top ranked and relevant images collected from Google and Twitter based on textual query ‘bike’.

Data Collection and Evaluation. We consider 12 terms, and we build a training set as follows. We query Google Images and Twitter Images interfaces for each of the terms. Then, the retrieved images are checked manually to remove false matches. In total, we keep 200 images from Google and 200 from Twitter per term, that is, we have a total of 4800 images. The query words are: bike, gun, robbery, crowd, car, concert, murder, drunk, fire, helmet, family and friends. These words were chosen based on the law enforcement focus of the project.

The reason behind collecting training images from Google and Twitter is twofold. First, there is no existing image dataset, that contains images corresponding to all possible query words. Second, carefully chosen images from web search and social media search will make the training set both diverse and relevant. Table 2 shows examples of diverse images collected from Google and Twitter for ‘bike.’ We see that the Google images are generally more “clean”, whereas the Twitter images offer more diversity. As we will see later the combination of the two leads to better accuracy.

K-fold ($k = 10$) cross-validation is used to test the classification performance. Table 3 shows the performance of the image classifier significantly varies, when trained with different training sets. The results demonstrate that incorporating images from both Google and Twitter for training improves classifier accuracy, as more diverse and informative set of images are included.

Our classifier has high accuracy (more than 80%) on categories like bike, gun, crowd etc. On the other hand, the accuracy on complex categories like drunk and murder was lower (around 50%). Some interesting examples of correctly identified and incorrectly identified images for category ‘bike’,

‘friends’ and ‘gun’ are shown in Table 4.

Testing \ Training	Google	Twitter	Google & Twitter
	Google	Twitter	Google & Twitter
Google	63%	36%	49.5%
Twitter	43%	31%	37%
Google & Twitter	79%	55%	67%

Table 3: Accuracy of Image Classifier with different sets of training and test images

JavaCV (Java interface to open computer vision library) is used to extract the image features. When running as a stand-alone application, the image classifier takes 5.98 millisecond on average to classify an image for a term on a system of quad-core Intel Core i5-4200M 2.50GHz CPU, 8 GB DRAM, 500 GB 7.2K RPM HDD.

True Positive	 Bike(0.652)	 Bike(0.879)	 Friends(0.437)	 Friends(0.673)	 Gun(0.828)	 Gun(0.99)
False Positive	 Gun(0.805)	 Gun(0.89)	 Friends(0.374)	 Friends(0.332)	 Bike(0.722)	 Bike(0.247)

Table 4: A few True-Positive and False-Positive examples from Image Classifier. The detected class is given below the images; confidence is in parenthesis.

5. SCALABILITY

Our OSNI is currently deployed on a cluster with two servers, each with two 6-core Intel Xeon E5-2630 2.30GHz CPUs, 96 GB DRAM, 4x 4 TB 7.2K RPM SATA HDDs, and connected via gigabit Ethernet.

Total records	3.46M	100%
Records w/ image URL	863.62K	24.96%
Records w/ non-image URL	1.32M	38.15%
Records w/ no URL	1.59M	45.95%

Table 5: Tweet record statistics for July 2015.

Latency. Based on our current set of 65 keywords used by the Twitter Streaming API to scrape Twitter’s data, we store approximately 3.5 million tweet records per day. On average, it takes 18 hours to process 1-day worth of tweet records, or 18.5 ms per record. Table 5 shows the average daily composition of these records over a one-month period (July 1, 2015 to July 31, 2015). We see that about half of the posts have no URL, which support our intuition that there are many non-news related posts, which can be uses for investigative exploration (viewing a user as a witness).

P	Location	Image	Index	Total
1	17.42	10.32	534.45	6.68
8	168.0	67.79	1622.67	38.44

Table 6: Throughput, in records per second, of the OSNI indexer for different levels of parallelism (P).

Throughput. We evaluate the throughput of our OSNI indexer on a sample set of 50K records to understand the

performance of the location and image classifiers, and inserting into the Elastic Search index. We compare performance using parallelism level 1 and 8. In Spark, parallelism determines the number of shards the data is split into before being distributed for processing. We show the throughput of each component and the full indexer in Table 6. We show clear speedup improvement when increasing the parallelism, and expect further improvements on a larger-scale cluster.

6. CONCLUSIONS AND FUTURE WORK

We presented OSNI, an interdisciplinary system to facilitate searching in social networks. The key contributions are the location estimation, the terms extraction from images, and the scalable architecture. To scale to more terms in the image annotation phase, we will study how multi-class classifiers can be effectively applied – single-class classifiers performed better in our experiments. Further, we are working on building a system that can collect informative training example images without human effort in filtering out irrelevant images. Finally, instead of utilizing different modules (eg. Cassandra, Spark), we are examining how to implement OSNI over a unified framework like AsterixDB[2].

ABSTRACT

Many modern applications involve collecting large amounts of data from multiple sources, and then aggregating and manipulating it in intricate ways. The complexity of such applications, combined with the size of the collected data, makes it difficult to understand the application logic and how information was derived. *Data provenance* has been proven helpful in this respect in different contexts; however, maintaining and presenting the full and exact provenance may be infeasible, due to its size and complex structure. For that reason, we introduce the notion of approximated summarized provenance, where we seek a compact representation of the provenance at the possible cost of information loss. Based on this notion, we have developed PROX, a system for the management, presentation and use of data provenance for complex applications. We propose to demonstrate PROX in the context of a movies rating crowd-sourcing system, letting participants view provenance summarization and use it to gain insights on the application and its underlying data.

1. INTRODUCTION

Complex applications that collect, store and aggregate large-scale data, and interact with a large number of users, are commonly found in a wide range of domains. Notable examples are *crowd-sourcing applications* such as Wikipedia, social tagging systems for images, traffic information aggregators such as Waze, or recommendation sites such as TripAdvisor and IMDb. In the context of such applications, several questions arise relating to *how data was derived*. As a user, what is the basis for trusting the presented information? How do crowd contributions vary among the crowd members, based on their characteristics? If some contribution seems wrong, how does the information change if we discard it? These questions are of fundamental importance for better understanding the application and its results.

At its core, the answer to these questions is based on the *provenance* of the collected data and resulting information, that is, *who* provided the information, in *what* context and *how* the information was manipulated. As shown in e.g. [10, 4], provenance is much more powerful than simply a log of the application execution. In particular, the algebraic model of provenance (based on semirings) has been shown to allow to correlate input data with output data; to track important details of the computational process that took place; and to further ([8]) *provision* the computation result with respect to hypothetical scenarios, namely to observe changes to the result based on changes to the input (without actually re-running the process). Detailed tracking of provenance was thus proved to be a suitable (and necessary) vehicle for the applications that we have mentioned above.

Consider a crowd-sourcing application for movie reviews. The number of movies may be quite large and so is the number of reviewers for every movie; the *aggregated score* for the movie is computed by combining the scores of multiple users, possibly accounting for their previous reviews and for their preferences. These features and the way in which they are used in the computation should all be reflected in the provenance. In turn, provenance may be presented to *explain* results (computed ranking of movies), or to *provision* them (e.g. “how would the average movie rating change if we ignore ratings by some (group of) users?”).

However, the complexity of processing and the large scale of data also mean that detailed semiring provenance information is extremely intricate; and so presenting it in full, as an explanation to the computation, would be extremely difficult to understand. To this end, we present PROX, a system that provides approximated summarization of provenance information for complex applications. The summarization is based in part on the semantics of the underlying data (such as gender, age or occupation of users), where annotations of “similar” data items are intuitively more amenable to be grouped together. But importantly, it is also geared towards the intended use of provenance (namely explanation and/or provisioning): we define a distance function between provenance expressions that is based on the intended use, and optimizing this distance (while obtaining small expressions) is an important consideration guiding the summarization.

Demonstration. We will demonstrate the system in the context of a movies recommendation website called *MovieLens* [1]. We will show that while full provenance is too large

to present, PROX allows for a summarized representation of the provenance that provides a concise explanation of the reviews, and further allows for approximate provisioning.

We next provide details on the technical background underlying PROX (Sec. 2), on the system implementation (Sec. 3), and on the demonstration scenario (Sec. 4).

2. TECHNICAL BACKGROUND

We (informally) introduce the main technical notions involved in the development of PROX, through examples. The full details can be found in [3].

Semiring provenance model. We first explain in general the provenance model described in [10, 5, 4]. We start by fixing a finite set X of *provenance annotations*, corresponding to the basic units of data manipulated by the application, and which can be thought of as abstract variables identifying the data. Depending on the application, these annotations may correspond to different tuples in a database, to different users, to different questions, etc. Given our set X of basic provenance annotations, the *provenance semiring* is the semiring of polynomials with natural coefficients, with indeterminates from the set X . It was shown in [10] to capture provenance for positive relational queries. Intuitively, the $+$ operation corresponds to the *alternative use* of data (as in union and projection) and \cdot to the *joint use* of data (as in join); 1 annotates data that is present, and 0 annotates data that is absent. To capture aggregate queries, in [5], relations were further generalized by extending their data domain with *aggregated values*. In this extended framework, relations have provenance also as part of their values, rather than just in the tuple annotations. Such a value is a *formal sum* $\sum_i t_i \otimes v_i$, where v_i is the value of the aggregated attribute in the i^{th} tuple, while t_i is the provenance of that tuple. We can think of \otimes as an operation that pairs values (from a monoid M) with provenance annotations. Each such pair is called a *tensor*. The formal sum, presented by the \oplus operation is used to capture the aggregation function.

EXAMPLE 2.1. Consider a crowdsourcing application, similar to IMDb, that allows users to rate different movies and aggregates their ratings. A possible provenance expression for the movie “Pretty Woman”, may e.g. be $\mathbf{P}_1 = \text{UID}_1 \otimes (5, 1)$ where UID_1 is a user id, and as aggregation we use a monoid of pairs to capture the aggregated rating (MAX rating with value 5 here) and how many users contributed to this aggregated value (1 here). Multiple reviews (say, for “Free Willy”) can be combined using the formal sum operation, e.g. $\mathbf{P}_2 = \text{UID}_2 \otimes (1, 1) \oplus \text{UID}_3 \otimes (3, 1) \oplus \text{UID}_4 \otimes (5, 1)$. The \oplus operation is given a “concrete semantics” depending on the aggregation function used to aggregate the ratings (e.g. SUM, MAX or AVG¹).

Valuations and provisioning. An important use of semiring provenance is for provisioning, i.e. examining changes to the application’s execution that are the result of some hypothetical modifications to the data. Examples include “how would the movie ratings change if we ignore some reviews (suspected as spam)?” Provenance expressions enable this using *truth valuations* applied to annotations. Intuitively,

¹These correspond formally to a choice of operation for the aggregation monoid

specifying that UID_1 is a spammer corresponds to mapping it to *false* (and that UID_1 is reliable to mapping it to *true*), and recomputing the derived value w.r.t this valuation. Such valuation can again be extended in the standard way to a valuation $V : \mathbb{N}[X] \mapsto \{\text{true}, \text{false}\}$.

Summarization through mappings. Full description of the provenance may be extremely long and convoluted, and so instead we would like to summarize the provenance expression. We formalize such summarization through the notion of mappings. Let X be a domain of annotations (for the $\mathbb{N}[X]$ semiring) and X' be a domain of annotation “summaries”. Typically, we expect that $|X'| \ll |X|$. We then define a mapping $h : X \mapsto X'$ which maps each annotation to a corresponding “summary”. Abusing notation, this extends naturally to a homomorphism $h : \mathbb{N}[X] \mapsto \mathbb{N}[X']$ (i.e. define $h(x + y) = h(x) + h(y)$, $h(x \cdot y) = h(x) \cdot h(y)$) and further extends to $\mathbb{N}[X]' \otimes M$ by the standard construction $h(k \otimes m) = h(k) \otimes m$. Essentially, to apply h to a provenance expression p (we denote the result by $h(p)$), each occurrence of $x \in X$ in p is replaced by $h(x)$. The mapped expression is a “summary” of the real provenance, in the sense that we lose track of some exact annotations and summarize the provenance using the “abstract” annotations in X' .

EXAMPLE 2.2. We may map user annotations to annotation summaries that intuitively reflect values of attributes of the corresponding users. Then if we map UID_3 and UID_4 to an “annotation summary” called “Female”², we obtain (by applying congruences in the tensor structure and the use of max as aggregate function), an expression describing a maximum female score of 5 collected from two users):

$$\mathbf{P}_2' = \text{UID}_2 \otimes (1, 1) \oplus \text{Female} \otimes (5, 2)$$

Another possible summary may e.g. be the result of mapping annotations UID_2 and UID_3 to the annotation “Student”:

$$\mathbf{P}_2'' = \text{Student} \otimes (3, 2) \oplus \text{UID}_4 \otimes (5, 1)$$

Both of these mappings do not concern the provenance expression \mathbf{P}_1 which stays intact.

In the example, we used two possible mappings h that combine reviews based on gender or occupation. In general there may be many possible mappings and the challenge is, given a provenance expression p , to (a) define what a good mapping h is (correspondingly, what is a good summary $h(p)$), and (b) find such good h .

Quantifying Summary Quality. Several, possibly competing, considerations need to be combined.

Provenance size. Since the goal of summarization is to reduce the provenance size, it is natural to use the size of the summary, the number of annotations it consists of after simplifications, as a measure of its quality.

Semantic Constraints. The obtained summary may be of little use if it is constructed by identifying multiple unrelated annotations; it is thus natural to impose constraints on which annotations may be grouped together. One simple example of such a constraint is to allow two annotations $x, x' \in X$ to be mapped to the same annotation in X' (or to 0 or 1) only if they annotate tuples in the *same input table*, meaning that they belong to the same domain. We further allow user-defined constraints based on equality of values of

²We later describe which mappings are possible and which are preferable to ours.

these annotated tuples in user-selected attributes, such as occupation or gender in the above examples.

Distance. Depending on the *intended use* of the provenance expression, we may *quantify the distance* between the original and summarized expression. As an example, consider a distance function designed to use provenance for *provisioning in presence of spammers*. For that we use again the notion of valuations, and consider as input to the problem a subset \mathcal{V}_X of all possible valuations w.r.t. the original provenance. Intuitively \mathcal{V}_X reflects possible scenarios that are of interest to the user. A central issue is how we transform a valuation in \mathcal{V}_X , on the original annotations to one in $\mathcal{V}_{X'}$, on the annotation summaries. We propose that this will be given by a combiner function ϕ , that sets a boolean value to $x' \in X'$ based on the truth values assigned to x annotations that were mapped to it. E.g. ϕ may be a disjunction of these values, then intuitively an annotation summary is cancelled only if all of the annotations it summarizes are cancelled.

We next define the distance between a provenance expression p and its summary $h(p)$ as an average over all truth valuations, of some property of p , $h(p)$, and the valuation. This property is based on yet another function we call VAL-FUNC, whose choice depends on the intended provenance use. For provisioning, we may e.g. use the absolute difference between the two expressions values under the valuation or, alternatively, a function whose value is 0 if the two expressions agree under the valuation, and 1 otherwise (so the overall distance is the fraction of disagreeing valuations). Similarly, when dealing with multiple expressions (such as one for each movie) we need a function to combine the VAL-FUNC values; here a natural choice is Euclidean distance.

EXAMPLE 2.3. *To simplify the example we assume that the scenarios include at most a single spammer. So the class of valuations consists of those assigning 0 to some single user annotation, and 1 to all others. Observe that P_2'' is at distance 0 from P_2 with respect to this class of valuations: all these valuations yield the same value with respect to the two provenance expressions (if UID_4 is mapped to true then the aggregated MAX value is 5 regardless of other truth values, and otherwise both UID_2 and UID_3 are mapped to true and so is Student). In contrast, P_2' differs from P_2 for the valuation that maps UID_4 to false and the rest to true.*

Computing Summarizations. We can show that computing an optimal summarization is $\#P$ -hard, since even computing the distance (even under highly limiting restrictions) is already $\#P$ -hard. On the other hand, we have implemented an *absolute approximation* algorithm for computing the distance between two such provenance expressions, based on sampling the possible valuations. This leads to a simple greedy algorithm. The details of the algorithm are omitted for lack of space and can be found in [3].

Related Work. Provenance models have been extensively studied in multiple lines of research such as provenance for database transformations (see [6]), for workflows (see [7]), for the web [2], for data mining applications [9], and many others, but typically full and exact provenance is presented. Provenance views have been proposed in context of workflows (see e.g. [7]), but the summarization obtained through these views is based on a notion of granularity levels, and is lossless rather than approximate. A notion of approximate

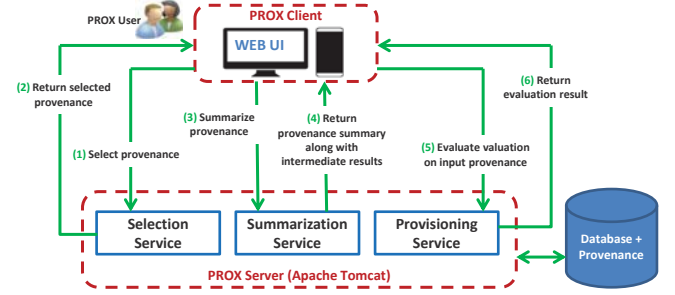

Figure 1: System Architecture

provenance was proposed in [11], and somewhat resembles ours, but is limited to UCQs (and in particular allows no aggregates), geared towards probabilistic computation, and does not account for semantic constraints. Our notion of mapping to summarized annotations is also reminiscent of clustering, however the function that we optimize is one that depends on the provenance expression itself and its intended uses, which leads to different design choices and results.

3. SYSTEM IMPLEMENTATION

PROX Architecture. PROX server-side is implemented in Java and its client-side is implemented in Angular JS. This web application is deployed to Apache Tomcat server on a Windows 7 machine. The system architecture is depicted in Figure 1. The server is comprised of three major services: a selection service that allows simple restriction of the provenance according to user-defined selection criteria, the summarization service that summarizes the selected provenance; and a provisioning service that allows to use the summarized provenance for exploration of hypothetical scenarios.

PROX Web UI. We developed a web UI which contains three views. The selection view allows the user to choose movies, whose provenance she would like to observe, according to title or genre and year (as shown in Figures 2a and 2b respectively). The summarization view presented in Figure 2c shows the selected provenance and allows the user to configure parameters for the summarization algorithm. The third view presents the summary in two views shown in Figures 2d and 2e: the expression view that shows the summary in its polynomial form, as exemplified throughout this paper and the groups view that shows the groups of users that the algorithm chose to map together. For instance, for the Female group in the figure, we can see the group size (9), its aggregated (MAX) rating (AGG:4), its users, the movies they rated and their aggregated ratings. Also, on hover on group user or movie their meta data is displayed. Using this last view, the user can choose a valuation to evaluate on the current provenance by selecting annotations or attributes to cancel (assign to *false*), as shown in Figure 2f. Using the left and right arrows, the user can also view and provision the algorithm’s intermediate results.

4. DEMONSTRATION SCENARIO

We will demonstrate the usefulness of PROX in the context of a movies review system. We will use a real-life movies data set taken from [1]. The first example will demonstrate how PROX can be used for provisioning. We will first select provenance by title, e.g. the movie “Free Willy”. Before

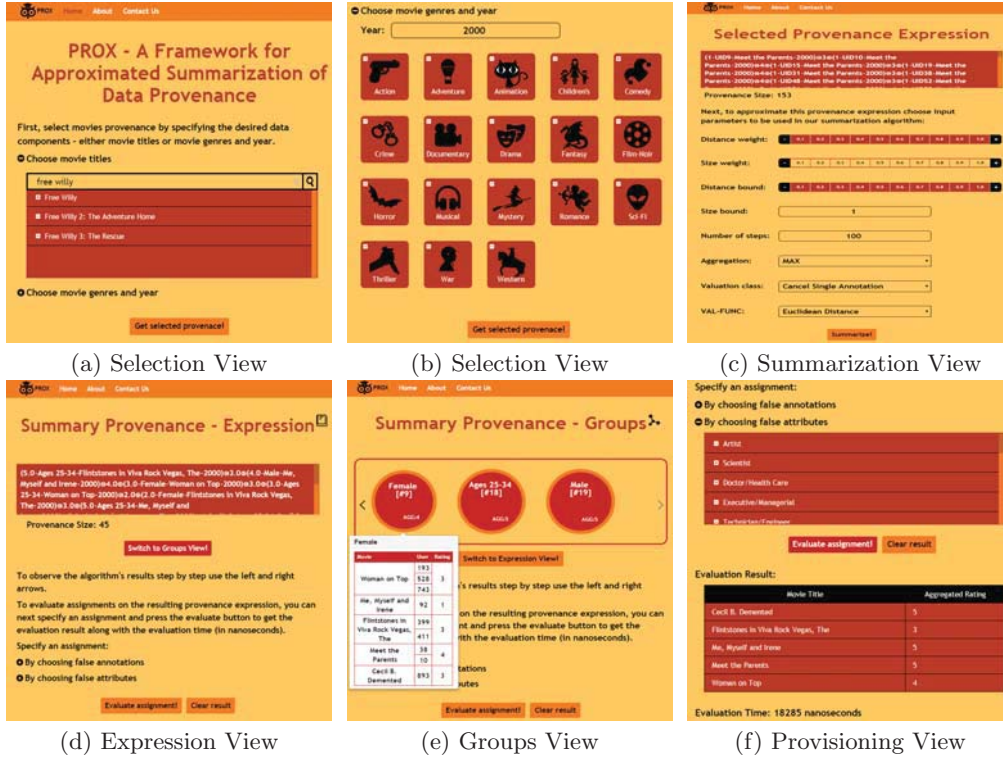

Figure 2: PROX Web UI

we compute the summary, we will show the different parameters for the summarization algorithm. We will use the default values e.g. MAX for aggregation and will limit the number of steps to 1 for this example. Using the groups view, we will show the user the two annotations that the algorithm chose to map to an annotation summary. For the same reasons discussed in Example 2.3, we expect that the algorithm would prefer to first map the annotations of users that did not give the movie the MAX rating and we will show that this is indeed the case. To end this example, we will provision the result, by choosing a valuation that cancels the two annotations. We expect that the result would be the same as if we applied the valuation on the original expression. To prove this, using the left arrow for navigating back, we will evaluate the valuation on the original expression as well. By summarizing the original provenance, we are able to provision the result by evaluating valuations on the summary, which is more efficient.

The second example will demonstrate another important provenance use which is presentation. For this example, we will choose a large provenance expression, e.g. provenance of "Comedy" movies released in the year 2000. We will summarize it using Average aggregation and a large number of steps. We will next show the groups of annotations along with their meta data and then switch to the expression view and compare its size to the original expression size which is much greater. Finally, we will let a volunteer user select her own provenance, summarize and provision the result.

PAW: A Platform for Analytics Workflows

Maxim Filatov

ABSTRACT

Big Data analytics in science and industry are performed on a range of heterogeneous data stores, both traditional and modern, and on a diversity of query engines. Workflows are difficult to design and implement since they span a variety of systems. To reduce development time and processing costs, automation is needed. We present PAW, a platform to manage analytics workflows. PAW enables workflow design, execution, analysis and optimization with respect to time efficiency, over multiple execution engines, namely a DBMS, a MapReduce engine, and an orchestration engine. This configuration is emerging as a common paradigm used to combine analysis of unstructured data with analysis of structured data (e.g., NoSQL plus SQL). The demonstration of PAW focuses on the usability of the platform by users with various expertise, the automation of the analysis and optimization of execution, as well as the effect of optimization on workflow execution. The demonstration scenarios are based on synthetic and real workflows on real data.

1. INTRODUCTION

Enterprises today employ a variety of data repositories and processing engines to meet their needs for analytics. Analytics workflows are becoming longer and more complex. Currently, analytics workflows are designed and implemented manually. This is time-consuming and labor-intensive. To address this, we demonstrate a platform to automate part of this process.

Workflow management is not a new topic [17]. However workflow optimisation is a relatively new field of research, but there are already some promising results.

Commercial Extract-Transform-Load (ETL) tools (e.g. [5], [10]) provide little support for automatic optimization. They provide hooks for the ETL designer to specify for example which flows may run in parallel or where to partition flows for pipeline parallelism. Some ETL engines such as PowerCenter [5] support PushDown optimization, which pushes operators that can be expressed in SQL from the ETL flow

Figure 1: Workflow for a product marketing campaign

down to the source or target database engine. The rest of the transformations are executed in the data integration server. The challenge of optimizing the entire workflow remains.

Towards this direction, HFMS [13] performs optimization and execution across multiple engines. Work related to HFMS [14] focuses on optimizing flows for several objectives: performance, fault-tolerance and freshness over multiple execution engines. HFMS uses many optimization strategies, such as parallelization, recovery points, function shipping, data shipping, decomposition, etc. Complementary to the above, our work focuses on the automation of the total process of workflow manipulation, from the creation till the execution of a workflow. Furthermore, our work focuses on the challenge of enabling users with various levels of data management expertise to create a workflow for the same application logic.

In this paper, we demonstrate our work through PAW, a platform for the design, analysis and execution of analytics workflows. PAW implements a novel workflow language [7, 8] that allows the design of a workflow that spans multiple engines and data stores by either giving specific details on execution semantics of tasks and data stores or leaving the platform to determine the execution semantics and data stores, through an automated workflow analysis phase. Then, the workflow goes through an automated optimization phase, before being sent for execution. PAW is part of the ASAP project [1], which develops scalable solutions for complex analytical tasks over multi-engine environments.

In the following, Sections 2 and 3 give an overview of the workflow model and the platform architecture, respectively. Section 4 summarizes the functionalities of the platform and Section 5 describes the proposed demonstration.

2. WORKFLOW MODEL

PAW implements a novel workflow model [7, 8]. The workflows are directed, acyclic graphs (DAGs). The vertices represent data processing and the edges represent the flow of data. Data processing is computation or modification

Figure 2: The generic metadata tree for operator

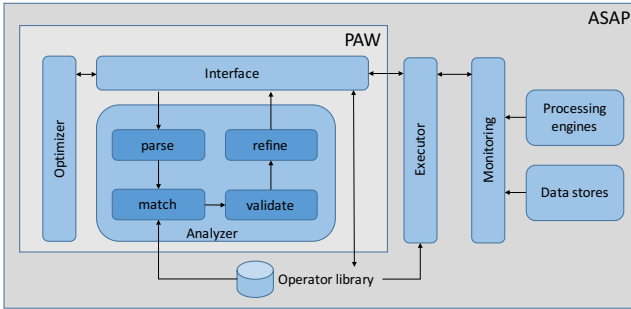

Figure 3: The architecture of PAW

of data. Each vertex in a workflow represents *one or more* tasks of data processing. Each task is a set of *inputs*, *outputs* and an *operator*. Tasks may share or not inputs, but they do not share operators and outputs. The inputs and outputs of the tasks of a vertex can be related to incoming and outgoing edges of this vertex, but they do not identify with edges: inputs and outputs represent consumption and production of data, respectively, and edges represent the flow of data. Figure 1 displays a workflow about a product marketing campaign. It combines sales data with sentiments about the product, gleaned from tweets crawled from the Web.

Data and operators can be either abstract or materialized. Abstract are the operators and datasets that are described partially or at a high level by the user, when composing the workflow, whereas materialized are the actual operator implementations and existing datasets, either provided by the user or residing in a repository. Both data and operators need to be accompanied by a set of metadata, i.e., properties that describe them. Such properties include input data types and parameters of operators, location of data objects or operator invocation scripts, data schemas, implementation details, engines etc. These metadata are used to:

- Match abstract operators to materialized ones.
- Check the usage of a dataset as input for an operator. If the dataset does not match the operator's input, its metadata can be also used to check for appropriate transform/move operators that can be applied.
- Provide optimization parameters, e.g. profiling of input/output.
- Provide execution parameters like a file path or arguments for the execution of the operator script.

The internal representation of a workflow is in the Tree-

metadata language, which captures structural information, operator properties (e.g., type, data schemas, statistics, engine and implementation details, physical characteristics like memory budget), and so on. The metadata tree is user extensible. Figure 2 shows the generic metadata tree for an operator. To allow for extensibility, the first levels of the metadata tree are predefined. Users can add their ad-hoc subtrees to define their custom data or operators. Moreover, some fields (like the ones related operators and data) are compulsory, while the rest are optional and user-defined. Materialized data and operators need to have all their compulsory fields filled in with information. Abstract data and operators do not adhere to this rule.

3. ARCHITECTURE & IMPLEMENTATION

PAW is part of a larger system, called Adaptable Scalable Analytics Platform (ASAP) [1], but it can also stand as an independent tool for workflow management and optimization. Other ASAP components include execution, monitoring, visualization of results, online adaptation, etc. PAW presents a unified interface for users to create, modify, analyze, optimize and execute analytics workflows over a diverse collection of data stores and processing engines. Figure 3 depicts the architecture of PAW, as well as its interaction with the rest of ASAP. The components of PAW communicate using the internal workflow representation and are:

- **Operator library.** This library shows operator implementations imported from the ASAP library. The operators are classified as, either analytics operators, which perform the core analytics jobs over the data, or the associative operators, which serve as 'glue' between different engines and perform move and transformation operations.
- **Interface.** The interface enables users to interactively create and/or modify a workflow.
- **Analyzer.** The analyzer parses the workflow, identifies operators and data stores and maps them to the library of operators, generates metadata of edges, finds edges where the data conversion should be applied and adds the appropriate conversions.
- **Optimizer.** The optimizer generates a functionally equivalent workflow, optimized for performance objective.
- **Executor.** The executor receives workflows from the optimizer and schedules them for execution. When a workflow is ready for execution, it dispatches the workflow to the engines and monitors its execution.

Code generation and the executor is implemented in Java. The interface is a web application in Jade [6] and CoffeeScript [2], and Grunt [3] compiles it in HTML and JavaScript, respectively. The interface communicates with other modules using Nginx web server [9] and PHP-FPM [11]. The analysis and optimisation modules are implemented in Python.

4. FUNCTIONALITY OF PAW

This section describes the PAW functionalities and discusses relevant aspects of the components.

4.1 Management of operators

Each operator can have an abstract definition and several implementations, i.e. one or more implementations per engine. For example, a 'join' of two inputs, has an abstract definition, and can be implemented for a relational DBMS

Operator	Blocking	Non-blocking	Restrictive
Filter		x	x
Calc		x	
Filter Join	x		
groupBy Sort	x		
PeakDetection	x		
Tf-idf	x		
k-Means	x		

Table 1: Categorization of operators

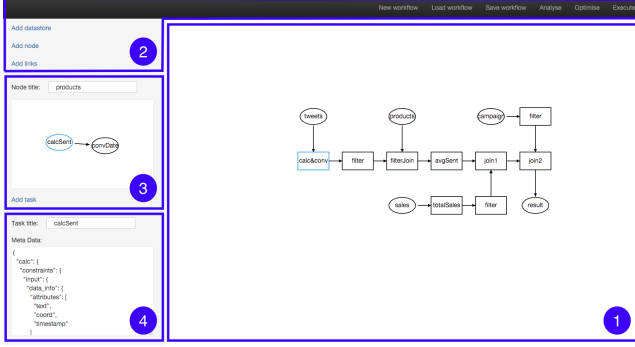

Figure 4: Interface of PAW

and a NoSQL database. An operator that performs a simple operation or a complex algorithm computation needs to have a tailored implementation for every engine on which it is going to be executed. An operator definition includes restrictions on the type and number of inputs and specifies the number and type of outputs.

Operators are categorized as:

- **Blocking operators** require knowledge of the whole data, e.g., a grouping operator or an operator *join* or *sort*.
- **Non-blocking operators** process each tuple separately, e.g., operators *filter* or *calc*¹.
- **Restrictive operators** output a smaller data volume than the incoming data volume, e.g. *filter*.

Defined and implemented operators form a library from which a user can select operators to describe tasks. Table 1 shows operators from the library and their categorization.

Users can register their own operators, provide respective implementations and define optional attributes of a new operator. These attributes include functions to compute cardinality and processing cost, and characteristics of the operator. In most cases, the operator developer or provider does not disclose a cost formula for the operator. Then, PAW can use the ASAP profiling process for operators using micro-benchmarks. As an optional step, PAW allows users to run their workflows with a data sample and uses the obtained statistics to fine-tune our cost models before workflow optimization.

4.2 Design of a workflow

A workflow is created in the PAW interface, which consists of several areas (Figure 4) that perform the following:

- Display the workflow (Area 1).
- Design a new workflow adding vertices and edges, save and load it (Area 2).
- Perform workflow analysis or optimization (Area 2).
- Add tasks from a library or create new ones (Area 3). A task from the library is accompanied by a set of metadata.

¹*calc* is a generic operator that can be customized for a specific numeric calculation

Figure 5: Analysed workflows for a multi-task vertex

A task created from scratch has a metadata tree with predefined first levels; users can add their ad-hoc subtrees to define their custom data or operators.

- Display metadata of the selected task (Area 4).

4.3 Analysis of a workflow

The workflow model alleviates from the user the burden of determining any or some execution semantics of the application logic. The execution semantics of the workflow includes the execution of tasks in vertices and the execution of input-output dependencies of edges. The determination of the execution semantics of vertices and edges leads to an execution plan of the workflow. We refer to this plan as the *analysed* workflow. The latter is actually an enhancement of the initial workflow with more vertices and substitution of vertices and/or edges in the initial workflow with others.

PAW analyses a workflow in several steps:

1. Parses the workflow.
2. Categorizes operators (see Section 4.1).
3. Validates consistency. A workflow is checked for cycles and correspondence of metadata of adjacent vertices. Cycles cannot be resolved, the analysis stops and returns a list of errors. If possible, metadata mismatches are solved by adding associative tasks in Step 6.
4. Generates metadata of edges, as a join of input and output metadata of source and target vertices, respectively.
5. Splits multi-task vertices to several single-task vertices: A vertex that corresponds to multiple tasks is replaced with an *associative subgraph* that contains a set of new vertices that correspond to these tasks. New vertices may correspond 1-1 to tasks, but it can be the case that two or more vertices correspond to the same task (task replication).
6. Augments the workflow with associative tasks that are converting data flow: buffers and format conversions.

Users may describe the same application logic by creating workflows with different levels of detail concerning the execution planning of this logic. The analysis phase determines missing execution semantics. Figure 5 shows an example: A user defines a vertex with two tasks, algorithmic processing on some data, and a join of these with some other data. The user is not interested or does not know the execution details of this complex task. This representation depicts that the two tasks should be executed together, after the tasks of the vertices on which this vertex depends, and before the tasks of vertices that depend on this vertex. Another user, represents the same tasks with two connected vertices, dictating that the join should be executed on the data processed first by the algorithm. A third user dictates even more detail in the execution plan, by adding one more vertex that includes a task that moves the data, e.g. from one disk to another.

4.4 Optimization of a workflow

After the analysis phase, a workflow is optimized for performance. The optimization uses the following operations:

- **Swap.** The *swap* operation applies to a pair of vertices, v_1 and v_2 , which occur in adjacent positions in an workflow graph G , and produces a new graph G' in which the positions of v_1 and v_2 have been interchanged. The goal of *swap* is to change the execution order of tasks.
- **Merge.** The *merge* operation takes as input two vertices and produces one new vertex that includes the tasks of both initial vertices. The latter may either be connected with an edge, i.e. there is some task dependency(ies), or not. The goal of *merge* is to allow for a united optimisation of the tasks included in the two vertices, e.g. joint micro-optimization on an execution engine.
- **Split.** The *split* operation takes as input one vertex and produces two new vertices that, together, include all the tasks included in the initial vertex. The new vertices may or may not be connected. The goal of *split* is to lead to separate optimisation of subgroups of the tasks.

The Optimizer applies to the analysed workflow a series of the above operations, each producing a functionally equivalent workflow with possibly different cost. The goal is to find an optimal workflow in the state space of equivalent workflows (for the optimization algorithm see [16]). To improve search, the space is pruned employing heuristics:

- **H1:** Move restrictive operators to the root of the workflow to reduce the data volume, e.g., rather than *extract* \rightarrow *function* \rightarrow *filter* do *extract* \rightarrow *filter* \rightarrow *function*.
- **H2:** Place non-blocking operators together and separately from blocking operators, require knowledge of the whole dataset, e.g., rather than *filter* \rightarrow *sort* \rightarrow *function* \rightarrow *group* do *filter* \rightarrow *function* \rightarrow *sort* \rightarrow *group*.
- **H3:** Parallelize adjacent non-blocking operators so that they can be executed concurrently on separate processors, e.g., split *filter1* \rightarrow *filter2* to two new parallel paths. Parallelized workflow parts should be chosen such that their latency is approximately equal.

5. DEMONSTRATION

In the following, we describe the demonstration of PAW.

System setup. PAW is demonstrated on a cluster, with the following configuration: The cluster consists of 4 server-grade physical nodes. Each one of those is equipped with a 3rd generation i5 CPU (@ 2.90 GHz) and 16GB of physical memory and an array of two HDDs on RAID-0. The operating system is Debian 6 (squeeze) Linux. For the time being, three software platforms are running: Hadoop [4], Spark [15] and Weka [18]. The distribution of Hadoop is CDH 4.6.0 and the version of Spark is 1.4.1.

Workloads. The demonstration uses synthetic and real workflows on real data. The synthetic workflows are constructed based on ETL benchmarking [12]. Real workflows and data come from the two use cases of ASAP [1] and belong to the domains of telecommunications and web analytics. The telecommunication use case involves processing anonymised Call Detail Records (CDR) data for Rome, from 01/06/2015 until 30/06/2015 and stored in CSV format. For the computation on graph-structured data workflows are implemented in Apache Spark.

The web analytics use case involves anonymization of web

content (WARC files) stored in Elasticsearch. The workflows are implemented in Spark and run over varying data set sizes ranging from 1 million to 1 billion rows. There are two types of workflows: one models entity recognition/disambiguation and k-means, and another models continuous processing of incoming data, e.g., subscription/notification at scale.

Demonstration scenarios. The demonstration aims to exhibit the functionalities of PAW, focusing on the following aspects: (a) the usability of the platform for workflow creation by users that have different expertise, (b) the effectiveness of the automated analysis of the execution of the workflow, and (c) the effectiveness of the automated optimization in workflow execution. The demonstration includes interesting scenarios for all (a,b,c) to be shown to the audience, but also interactive scenarios, especially for (a) and (b), which allow the audience to experience the functionalities of PAW. The interactive scenarios enable the participant to create workflows from scratch or change existing ones, watch the automated management of the workflow as well as review the internals of the platform, e.g. internal workflow representation. Concerning (a) and (b), the scenarios exhibit how the same application logic can be expressed via workflow versions that have different level of detail of execution semantics, and how the analysis phase specifies missing execution semantics through already executed workflows and/or by giving alternative choices to the user. Concerning (c), the scenarios show how new operators are added, including cost functions, and how the latter may be tuned by running a workflow with sampling for statistics collection; finally, the scenarios show actual workflow execution and the optimization benefit and tradeoffs on different engines.

ABSTRACT

ETL (Extraction-Transform-Load) tools, traditionally developed to operate offline on historical data for feeding Data-warehouses, need to be enhanced to deal with big and fresh data and be executed at network level during data streams acquisition. In this paper, we present StreamLoader, a Web application for the specification of conceptual ETL dataflows on heterogeneous sensor data that leverages the peculiarities of network configuration, data stream management, and specification and deployment of ETL operations in a programmable network. It can be used for feeding traditional/real-time data-warehouses or visual analytic tools.

1. MOTIVATION

Nowadays we are witnesses of the proliferations of different sensor devices able to produce heterogeneous types of data that can be profitably used for detecting, handling and advising people of the verification of events such as natural disasters (like flooding, storming, extreme temperatures etc.), traffic congestions (due to accidents, strikes, football matches), and social web interactions. Beside the physical sensors, able to detect data about physical phenomena (like, temperature, humidity, wind, rain, pressure, level of sea water), there is a proliferation of social sensors able to collect data from people (like, twitter data, traffic information, train or flight schedule). These data are characterized both from the temporal, spatial and thematic dimensions that can be exploited from for the identification of meaningful events in a given context.

Several challenges should be faced for handling sensors and their data especially in emergency situations. First, sensors (both physical and social) are located in different networks and made available by different institutes, agencies and NPOs. In this context, network configuration, sensor detection and discovery are difficult issues to be solved. Moreover, data produced by sensors are heterogeneous in structures (different types), in spatial and/or temporal granularities (e.g. temperature in a room versus temperatures in

a geographical area), in thematics (data about traffic jams vs data about pollutions). Therefore, there is the need of ETL (Extract-Transform-Load) operations that can be applied on data streams for their reconciliation. These operations should be applied during data acquisition and bound with reactive capabilities in order to properly identify the relevant streams when abnormal events occur and undertake the proper actions. Finally, the specification and actuation of the ETL operations should be efficiently performed on-line and on fresh and timely data in order to properly handling big real-time data streams. All these technical requirements should be addressed in graphical, user-friendly environments supporting the user in the design and execution of the operations.

Many systems have been proposed for configuring programmable networks ([4, 2, 9]), for data stream management (e.g. Niagara [14], TelegraphCQ [5], Borealis [1]), for the specification and actuation of ETL operations (e.g. [16, 10, 13]) and dataflow (e.g. Talend www.talend.com, Pentaho-kettle www.pentaho.com, CoverETL www.cloveretl.com), and for complex event processing (e.g. Apache S4 [15], Storm [12], StreamBase www.tibco.com). However, all of them are quite complex to use, seldom provide web GUIs for designing and monitoring dataflows and are not integrated in a single tool. This limits their use in the management of emergency situations.

In this paper we propose StreamLoader, a Web application for the specification of conceptual ETL dataflows on heterogeneous sensors to be applied during data stream acquisition on a programmable network. It exploits different technologies (AngularJS, Cytoscape, SparkJava) for providing the graphical environment. StreamLoader is equipped with an interactive environment that supports the user in charge of handling events to discover the sensors useful in a given situation, specify the adequate dataflow for extracting, filtering, integrating, (eventually) storing, and analyze the data coming from the identified sensors, optimize the schedule for the execution of the dataflow and visualize the results. By exploiting samples produced by the involved sensors, the user can easily debug the developed dataflow. Once the dataflow is consistent (i.e. it can be soundly activated at network level), the translation is automatically invoked. Then, the underlying network is configured and the processes associated with the ETL operators executed. At this point, logs of the execution of the dataflow components are directly shown in the interactive environment to provide statistics on the dataflow execution.

In the remainder, Section 2 presents the requirements we

started from. The main characteristics of the system and of the interactive environment are discussed in Section 3. Section 4 presents the features of the system we wish to demonstrate and discusses the system significance.

2. StreamLoader REQUIREMENTS

Starting from the idea to develop a tool that is easy to use for people without a computer science background, the following requirements have been posed at the basis of the development of our tool.

Dynamic (and automatic) configuration of ETL dataflow on events. Starting from several data streams, the user interface should offer the possibility to identify relevant sources of information depending on the verification of events. For example, suppose we have several sensors for detecting the humidity and temperature of a given area; apparent temperature represents the temperature that is perceived by humans and depends on both temperature and humidity. The computation and acquisition of the apparent temperature in a given area can be triggered when the temperature is greater than 24° C. Events can be used both for triggering or stopping the acquisition and elaboration of streams. Moreover, ETL dataflows should be generated on the fly depending on the needs, immediately actuated and its execution monitored in the same tool. The dataflow should become “live” and give execution feedbacks to the user.

ETL operations for integrating heterogeneous streams.

The heterogeneity of the data flows requires the application of common operations developed in the context of data integration and data fusion in order to identify different representations of the same real world entities. For this purpose, the system should be equipped with transformation operations: (1) for changing the unit of measure (e.g. from yards to meters) or geographical coordinates (from one standard to another one); (2) for introducing virtual properties relying on the values assumed by other attributes (e.g. the apparent temperature discussed above); (3) for checking that data conform to given validation rules (e.g. dates conforming to given patterns). Moreover, operation for filtering data relying on different conditions should be included and for culling data belonging to a temporal interval or a geographical area according to a reducing factor. Finally, operations for aggregating and joining streams should be included for combining information coming from different streams.

Discovery of sensor data sources. The large amount of sensors with different levels of availability that can be monitored by the developed system imposes the adoption of different solutions for their discovery and management. First, sensors should be handled by means of a publish-subscribe system in order to handle the dynamicity with which they can join and leave the network. Then, sources of dataflows should be specified by means of the sensor and location characteristics. Finally, sensors can be organized according to different criteria (temporal/spatial, type/location) in order to facilitate the specification of dataflows.

Isolation of data traffic based on the ETL dataflow. Hard-coded configurations of network architectures and paths where data traffics are routed are not an easy task and prevent the possibility to adapt to new user requirements. Approaches based on declarative networking [4, 2, 9] have been recently proposed for the application of database query-

Figure 1: StreamLoader Architecture

language and processing techniques to the domain of networking. In [8] an extension of the declarative networking [4] approach has been proposed that consists of two components: declarative service networking (DSN) and network control protocol stacks (SCN). DSN provides a method to model and describe a high-level network of information services for an application, which includes service discovery, service monitoring, execution control, and service message exchanges. SCN aims at capturing application requirements and requesting appropriate configuration to the network platform more directly and effectively. The network control protocol stack interprets the DSN description and dynamically coordinates the network configurations, such as data flows, segmentations, and QoS parameters. The dataflow graphically described by the user should be then translated in DSN/SCN language to be actuated in the network and monitored.

3. StreamLoader OVERVIEW

Architecture. Figure 1 reports the architecture of the StreamLoader system. At the bottom there is a network. Each node of the network is in charge of managing a bunch of sensors and can execute the proposed ETL stream processing operations. Sensors are handled through a distributed publish-subscribe system [3]. Each time a sensor is published, its type, schema, and frequency of data generation are made available to subscribers.

Our Web environment is made available for the design and monitoring of dataflows. When a conceptual dataflow is realized, the **translator** module is in charge to translate it in DSN/SCN and execute it at network level. Processes are generated for each operation of the dataflow and executed on a network. The **executor** module coordinates their execution. For the execution, the sources are bound to specific sensors handled by the network nodes, and operations located on the machines that, depending on workload, apply the logic specified in the conceptual dataflow.

Logs of the activities are then collected by the **monitor** module and made available to the Web Interface to show statistics on the dataflow execution. Specifically, we are able to report on the Web Interface the number of tuples that each operation handle per second, the node that suffers because of high workload, which node is in charge of executing an operation and when the assignment changes.

Operation	Symbol	Meaning
Aggregation	$@_{op}^{t, \{a_1, \dots, a_n\}}(s)$	Every t time intervals, aggregate s on the attributes $\{a_1, \dots, a_n\}$ and apply the aggregation function $op \in \{\text{COUNT, AVG, SUM, MIN, MAX}\}$
Cull Time	$\gamma_r(s, \langle t_1, t_2 \rangle)$	Culling the tuples in the temporal interval $[t_1, t_2]$ by a reducing rate r
Cull Space	$\gamma_r(s, \langle coord_1, coord_2 \rangle)$	Culling the tuples that fall in the area delimited by $coord_1, coord_2$ by a reducing rate r
Filter	$\sigma(s, cond)$	Filter out tuples in s that do not adhere to the condition $cond$
Join	$s_1 \bowtie_{pred} s_2$	Every t time intervals, s_1 and s_2 are joined according to the join predicate $cond$
Transform	$\diamond_{trans} s$	The transformation function $trans$ is applied on the tuples in s
Trigger On	$\oplus^{ON, t}(s, \{s_1, \dots, s_n\}, cond)$	Every t time intervals the condition $cond$ is checked on the tuples collected from s . If the condition is verified, the streams of the sensors $\{s_1, \dots, s_n\}$ are activated
Trigger Off	$\oplus^{OFF, t}(s, \{s_1, \dots, s_n\}, cond)$	Every t time intervals the condition $cond$ is checked on the tuples collected from s . If the condition is verified, the streams of the sensors $\{s_1, \dots, s_n\}$ are de-activated
Virtual property	$\Psi_s(p, spec)$	A new attribute p is added to the schema of s according to the specification $spec$

Table 1: Stream Processing Operations

Stream Processing Operations. Sensors produce streams of tuples according to the multigranular space, time and thematic (STT) data model [7]. Relying on the concepts of temporal and spatial granularities, we exploit the concept of *event*, that is a value associated with a spatial object at a given time according to given thematic. Therefore, an event is a value represented at a given spatio-temporal granularity for which thematic information is added. Granularities are used for identifying correlations among data produced by different sensors and for imposing consistency constraints in the composition of sensor data produced by heterogeneous devices. We remark that whenever a sensor is not able to produce the spatio-temporal information of the produced data, this information is added by the Publish-Subscribe system that we adopt in our architecture.

Several operations have been developed for processing and combining the streams produced by the sensors in accordance with the requirements previously discussed at network level. Table 1 reports the principal operations concerning the application of filters, transformation, aggregation and composition, and event detection. Among the operations we point out those that are non-blocking (filter, cull-time/space, transform, virtual property) from those that are blocking (aggregation, trigger, join). The former are directly applied on each tuple when they are processed, whereas the others require the maintenance of a cache of tuples that are processed every t time intervals (e.g. 1 second, 2 minutes).

Visual Interactive Environment. By using a visual interface in Figure 2, users can drag-and-drop data-sources and apply the proposed operations on streams. In a window placed at the bottom of the canvas used for designing the data-flow, the user can see the schema of data that are processed by the operation, specify the conditions of each operation and visualize a data sample coming from each source. The user interface provides different checks in order to draw only dataflows that can be soundly translated in the DSN/SCN specification. We remark that data schema are not fixed but depend on the sensors. Finally, at the use phase, the dataflow developed at design time will be annotated with information coming from the SCN about the execution of the dataflow. In this way, the dataflow becomes “live” and the domain expert can monitor its execution.

Scenario. There are different sensors in the area of Osaka that produce data about the temperatures and levels of rains monitored in the current year. Moreover, tweets and traffic information from the same area in the current year

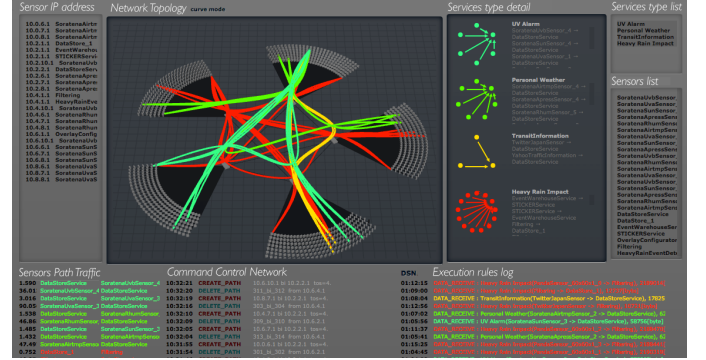

Figure 3: Monitoring the execution of the dataflow

can be acquired. Suppose, that there is interest in acquiring the data about torrential rain, tweets and traffic only when the temperature identified in the last hour is above 25° C. The dataflow reported in the canvas of Figure 2 realizes the proposed behavior. The acquired data can be stored in a data-warehouse or sent to a visualization tool in order to perform further analysis. Moreover, Figure 3 shows the flows of data that are monitored for this and other dataflows that are under control.

4. DEMO WALKTROUGH

In the demonstration of StreamLoader we will considering a network (established at NICT in Japan) in which different physical and social sensors related to the described scenario are connected and produce continuous data streams to be processed. By using this setup, we will show the capabilities of our tool in an interactive demo for the automatic configuration (and re-configuration) of a programmable network by means of our visual tool for *more efficient and interactive* analysis when transmitting data from sensors (sources) to the Event Data Warehouse (destination) [6]. The demo will consist of the following parts:

- P1 By exploiting the Web interface of our tool, users can create their own dataflows. Specifically, they will be able to identify the different sensors that are currently available in the network and select those on which they wish to specify ETL operations. Moreover, they will be able to apply different processing operations on such sources and check, step-by-step, their results on samples made available from the source.

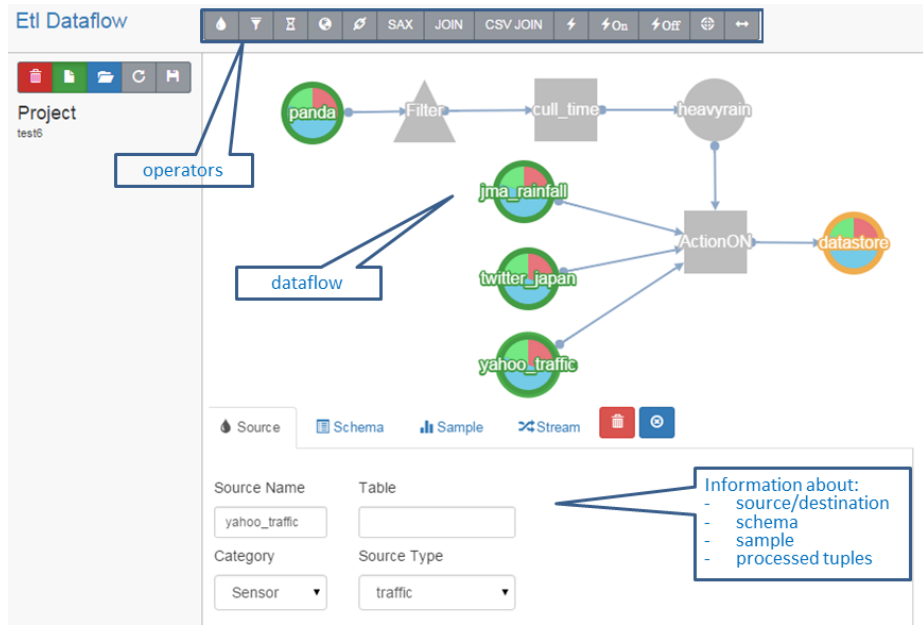

Figure 2: Main screen of the Web Application

P2 Once the dataflow is consistent, we will show its translation in the DSN/SCN language and deployment at network level. Then, we will monitor its execution by means of the tools presented in this paper. Finally, we will show how the data processed by means of the dataflow can be stored in the Event Data Warehouse [6] or visualized in the Sticker visualization tool [11]. Both tools have been developed by NICT.

P3 In the last part of the demo, we will show how it is easy to plug-and-play new sensors to the network and make them directly available to StreamLoader. We will also show how the system react when sensors or operators in the dataflow are modified on the fly. Finally, we will show statistics on the execution of the dataflow and on the performances of the network.

The demonstration will thus prove the flexibility of the developed system in the specification of dataflows to be executed at network level and actuated on the fly. All the ETL operations that have been considered can be applied on-line on fresh data arriving from sensors of different types. Different controls have been included in the dataflow specification in order to guarantee the sound translation and execution of the corresponding DSN/SCN specification.

The code of SCN and ETL dataflow editors are open source and can be freely downloaded from GitHub (<https://github.com/nict-isp>).

ABSTRACT

We present TINTIN, a tool to perform efficient integrity checking of SQL assertions in SQL Server. TINTIN rewrites each assertion into a set of standard SQL queries that, given a set of insertions and deletions of tuples, allow to incrementally compute whether this update violates the assertion or not. If one of such queries returns a non empty answer, then the assertion is violated. Efficiency is achieved by evaluating only those data and those assertions that can actually be violated according to the update. TINTIN is aimed at two different purposes. First, to show the feasibility of our approach by implementing it on a commercial relational DBMS. Second, to illustrate that the efficiency we achieve is good enough for making assertions to be used in practice.

Keywords

Integrity checking, SQL, Assertions

1. INTRODUCTION

In standard SQL, users can specify general constraints using the `CREATE ASSERTION` statement. The basic technique for writing assertions is to specify a query that selects those tuples that violate the desired condition. By including this query inside a `NOT EXISTS` clause, the assertion will specify that the query result must be empty. Thus, the assertion is violated if and only if the query result is not empty [2].

Assertions were initially defined in SQL-92 [1] and they serve as a means for expressing global integrity constraints not tied to a particular table, but ranging over several ones. They are sufficient for expressing most constraints since almost the full expressiveness of SQL can be used to define the query inside the `NOT EXISTS` clause. It is also well known that many integrity constraints can only be expressed via assertions since the other constructs provided by SQL are not powerful enough. Thus, assertions provide an elegant way to define general constraints in SQL.

However, assertions are still not supported by any of the most well-used commercial RDBMS (Oracle, MySQL, SQL

Server, PostgreSQL, DB2). It might be argued that assertions can be emulated via manually writing a set of triggers, which is a widely supported feature of RDBMS. However, its manual definition is error prone and the whole set of necessary triggers to write might not be evident when given a complex constraint, thus, compromising the integrity of the data if just one trigger is missing or ill-defined. Hence, it is better to delegate this complex checking code to RDBMS capabilities [8], as we do in TINTIN¹.

TINTIN is a tool that provides incremental integrity checking of assertions in SQL Server. Given an SQL Server DB, and a set of SQL assertions written on its schema, TINTIN automatically builds all the necessary procedures/queries to efficiently check whether any update satisfies the assertions.

As an example, consider the schema of the well-known TPC-H benchmark [7] shown in Figure 1, a benchmark for illustrating decision support systems that examine large volumes of data, execute complex queries, and give answers to critical business questions.

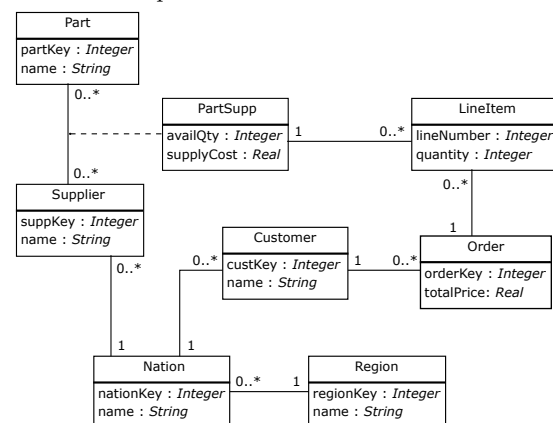

Figure 1: The TPC-H Schema.

Now, assume that we want to define a general constraint over the previous schema stating that all orders have at least one line item. This constraint could be specified by means of the SQL assertion shown below:

```

CREATE ASSERTION atLeastOneLineItem CHECK(
  NOT EXISTS(
    SELECT * FROM ORDERS AS o
    WHERE NOT EXISTS (
      SELECT * FROM LINEITEM AS l
      WHERE l.L_ORDERKEY = o.O_ORDERKEY)))

```

¹<http://www.essi.upc.edu/~xoriol/tintin/>

TINTIN allows checking the assertion *atLeastOneLineItem* efficiently in data sets consisting of 1GB to 5GB of data and with 1MB to 5MB of tuple insertions/deletions, with times ranging from 0.01 to 0.04 seconds depending on the scenario. These results are much better than the time required for directly executing the query inside the assertions on the database, ranging from x89 to x2662 times faster.

The approach we follow in TINTIN is to automatically generate, for each assertion, several standard SQL queries which incrementally determine whether the update violates the original assertion or not. If the queries return a non-empty answer, then, the assertion is violated, otherwise, it is satisfied. The queries are incremental in the sense that they are stated in terms of the current database tables and also some automatically generated auxiliary tables containing the insertions/deletions of tuples requested by the user.

This is the crucial point for achieving efficiency of integrity checking. When a user requests an update, the tuples s/he wants to insert/delete are put in some auxiliary tables. Then, the generated queries join these tuples being inserted/deleted with the current data, and return those that violate the assertions. For each assertion, the generated queries only join those insertions/deletions of tuples that might cause its violation. Therefore, an update not including any of those insertions/deletions trivially makes the query result to be empty. For this reason, no current data of the database is accessed unless some update may cause the violation of an assertion.

The join between the current data and the tuples being inserted/deleted ensures also that only the tuples affected by the update are checked. Thus, the rest of the data, potentially the major part of the database, is skipped.

These incremental SQL queries are generated outside the database and then stored in it as views. Since we use standard SQL to define them, they could be used for checking assertions on any relational DBMS. However, and for the purpose of checking the feasibility and the efficiency of our approach, we have chosen SQL Server to implement TINTIN because of our previous expertise on this system.

Once the incremental SQL queries are defined, TINTIN builds a stored procedure called **safeCommit** to allow SQL Server to check the assertions. This procedure must be invoked at the end of each transaction, so that the procedure can check whether it violates any of the assertions. More specifically, the procedure checks whether the incremental SQL queries are empty or not. If they are, the update does not violate any assertion, so, the procedure commits the update stored in the auxiliary tables. Otherwise, the procedure shows the tuples answering the queries, i.e., the tuples violating the assertions.

2. PROBLEM AND SOLUTION

Integrity checking is the problem of efficiently determining whether a given update satisfies a set of integrity constraints, SQL assertions in our case. This is an important problem in data management since any violation of an integrity constraint would indicate an invalid state of the database. One possible way to achieve efficiency relies on, first, just checking the assertions which may actually be violated by the update and, second, considering only the relevant updated data for computing whether the assertions are violated.

We assume in this work that the update consists of a (possibly large) set of insertions and/or deletions of database

tuples and that the queries defining the assertions are specified by means of the fragment of SQL that is equivalent to relational algebra. In particular, TINTIN accepts assertions to be defined through selection, projection, join, subselect (**exists**, **in**), negation (**not exists**, **not in**) and union but it does not allow functions (e.g. aggregates, arithmetic functions) for the moment.

TINTIN is aimed at providing to an SQL Server database with the capability of performing integrity checking of SQL assertions efficiently. For this purpose, TINTIN allows a user to specify assertions according to the fragment of SQL stated above, and the tool automatically builds a stored procedure in the database, called **safeCommit**, that the user will have to call at the end of each transaction. Whenever called, **safeCommit** checks whether the updates in the transaction violate any of the assertions. If no violation is found, the update is committed to the database. Otherwise, it provides the answers to the queries that detected the violation of the assertions.

The **safeCommit** procedure works by executing several SQL queries, stored as views in the database, for each one of the assertions that need to be checked. Each query captures a different situation in which some updates may lead to the violation of the assertion. These updates are explicitly stated in the query definition itself and provide the key for efficiency of integrity checking.

In the rest of this section we explain the approach we follow to obtain the SQL queries that allow checking incrementally an assertion; which is based on our previous work for handling integrity checking of OCL constraints in conceptual models [4, 5]. We only require the users to define their desired assertions. From there, all the following steps are automatically performed.

The first step consists in rewriting each SQL assertion into a logic *denial* in the same way as we did in [6]. A denial is a formula stating a condition that must not be true in any state of the database. These denials are the basis for obtaining the incremental SQL queries.

For instance, the assertion **atLeastOneLineItem** of our running example would be rewritten as:

$$order(o) \wedge \neg lineIt(l, o) \rightarrow \perp \quad (1)$$

Clearly, the previous denial states that if there is an order o without any line item l , an inconsistent state will be reached, which is exactly the condition to be avoided by **atLeastOneLineItem**.

Then, for each denial, TINTIN obtains its corresponding *Event Dependency Constraints* (EDCs, for short). Each EDC is a logic rule identifying a particular situation where some update applied to a certain state of the database D causes the violation of the denial, i.e., of the corresponding assertion. The main idea for obtaining EDCs is to replace each literal in the logic rule obtained from the assertion by the expression that evaluates this literal in the new state of the database D^n , i.e., the state obtained after applying the update. Positive and negative literals in the denial are handled in a different way according to the following formulas:

$$\forall \bar{x}. p^n(\bar{x}) \leftrightarrow (\iota p(\bar{x})) \vee (\neg \delta p(\bar{x}) \wedge p(\bar{x})) \quad (2)$$

$$\forall \bar{x}. \neg p^n(\bar{x}) \leftrightarrow (\delta p(\bar{x})) \vee (\neg \iota p(\bar{x}) \wedge \neg p(\bar{x})) \quad (3)$$

Rule 2 states that a literal $p(\bar{x})$ will be true in the new state of the database D^n if it has been inserted or if it was already true in the initial state D and it has not been deleted.

In an analogous way, rule 3 states that $p(\bar{x})$ will not hold in D^n if it has been deleted or if it was already false and it has not been inserted.

By applying the substitutions above to all logic denials, we get a set of EDCs which states all possible ways to violate the assertions by means of insertions and/or deletions of tuples.

In particular, we get the following EDCs for the denial 1 of our running example:

$$\iota order(o) \wedge \neg lineIt(l, o) \wedge \neg \iota lineIt(l, o) \rightarrow \perp \quad (4)$$

$$\iota order(o) \wedge \delta lineIt(l, o) \wedge \neg aux(o) \rightarrow \perp \quad (5)$$

$$order(o) \wedge \neg \delta order(o) \wedge \delta lineIt(l, o) \wedge \neg aux(o) \rightarrow \perp \quad (6)$$

$$aux(o) \leftarrow \iota lineIt(l, o)$$

$$aux(o) \leftarrow lineIt(l, o) \wedge \neg \delta lineIt(l, o)$$

Intuitively, EDC 4 states that *atLeastOneLineItem* will be violated if a new order o is inserted and there was no line item for o in the initial state of the database and no line item for o has been inserted by the transaction. EDC 5 behaves in a similar way, while EDC 6 determines that the assertion will be violated if a line item for an existing order o has been deleted and neither a new line item has been inserted for o nor the database contains any other line item for o (given by the rules defining $aux(o)$).

Note that, in this example, EDC 5 can be safely discarded assuming that the foreign key constraint from *lineitem* to *order* is satisfied in the current state of the data. TINTIN incorporates some semantic optimizations like this one that allow obtaining a reduced and simplified number of EDCs which allow performing integrity checking more efficiently.

The idea of obtaining EDCs to identify the different situations that may lead to the violation of a constraint is grounded on the concept of *event rules* [3], which were aimed at performing integrity checking in deductive databases.

Finally, each EDC is translated into an SQL query as proposed in [4]. Roughly, each positive literal in the EDC is translated into a table reference placed in the **FROM** clause of the query, possibly with a **JOIN** condition with some previously translated literal that shares a common variable with it. Built-in literals and constant bindings are directly translated to the **WHERE** clause, and negated base and derived literals are translated as correlated subqueries.

In our running example, we would translate EDC 4 as:

```
CREATE VIEW atLeastOneLineItem1 AS
SELECT *
FROM ins_orders AS T0
WHERE NOT EXISTS(SELECT *
  FROM lineitem AS T1
  WHERE T1.l_orderkey = T0.o_orderkey)
AND NOT EXISTS(SELECT *
  FROM ins_lineitem AS T1
  WHERE T1.l_orderkey = T0.o_orderkey)
```

We have defined the query as a view to store it into the database. It is worth noting the usage of the auxiliary tables storing the insertions and the deletions of tuples for each table of the database, as it happens with *ins_orders* and *ins_lineitem* in the previous view. TINTIN automatically builds them, together the necessary triggers to capture the insertions/deletions of tuples to place them into such auxiliary tables. Thus, the existence and maintenance of these auxiliary tables is fully transparent to the database users.

Note also that the key for incrementality is not based on batching updates for delaying the assertions checking, but on the join in the SQL queries between the update and the current data. First of all, any SQL query joining an insertion/deletion which is not being applied (i.e., whose corresponding SQL table is empty) is immediately discarded since it trivially returns the empty set. Therefore, we only check those constraints that can be violated according to the ongoing update. Second, the data considered by an SQL query during its execution is necessarily the data joining the update applied, thus, avoiding to look through all the database.

3. DEMO DESCRIPTION

The demo that we will present is intended to show the usage and efficiency of our prototype tool TINTIN by means of applying it to the checking of some assertions in the TPC-H benchmark SQL schema.

We will first request TINTIN to build the necessary auxiliary tables and triggers to capture any insertion and deletion applied to the TPC database. As a result, we will see a newly generated database event_TPC with an ins/del table for each TPC SQL table. At this point, whenever we apply an insertion/deletion of any tuple in TPC, the tuple will be captured and inserted in the corresponding ins/del table of event_TPC. In this way, the contents of TPC remains unchanged, and event_TPC contains the requested update.

Next, we will introduce in TINTIN some SQL assertions of different complexity. Consequently, TINTIN will create a procedure called **safeCommit** in TPC. This procedure, when called, will check whether applying the updates contained in event_TPC raises the violation of any assertion. If no violation is found, the procedure will commit the events into TPC; otherwise, it will report the violations. Lastly, the procedure will truncate all the events stored in event_TPC, so that a new set of events can be proposed.

At this stage, TINTIN will have created all the necessary elements to automatically check the satisfaction of the assertions when updating TPC, and will have persistently stored them in the database. Thus, TINTIN can be disconnected from SQL Server, and users might operate with the database normally with the unique consideration of invoking **safeCommit** at the end of each transaction.

To make the demonstration, we will apply some updates mixing both: updates that violate some assertion and updates that do not violate any of them. After each update, we will call the **safeCommit** procedure to see its effects, that is, we will see that it rejects the update if some violation occurs, or that it commits them if they satisfy the assertions.

With this demonstration, we will show that TINTIN enjoys the following features: 1. *Portability*: it can be easily installed in any SQL Server database—no need for special plugins nor additional technologies—. 2. *Clean installation*: all the necessary logics of the method is installed in another database—without modifying the original one—, except the **safeCommit** procedure and the triggers to capture the events, which are necessarily placed in the target database. 3. *Easy of use*: users can update the database without modifying their SQL statements/procedures. The unique mandatory requirement is to call the automatically generated **safeCommit** procedure at the end of each transaction. 4. *Efficiency*: the incremental nature of our method provides better execution times than executing non-incremental queries to perform the integrity checks.

Figure 2: Tintin architecture

4. PROTOTYPE

The architecture of TINTIN is shown in Figure 2, while its GUI is depicted in Figure 3. Basically, the GUI asks the user for a database (DB) connection, and the assertions that s/he wants to check in that database.

When the user introduces the DB connection, the SQL Server Controller creates a new auxiliary database event_DB to store the different events applied to it; that is, for each table T in DB, the SQL Server Controller builds two new tables (ins_T and del_T) to store the different tuples being inserted and deleted in T . In order to capture these tuples, the SQL Server Controller creates two different **INSTEAD OF** triggers, which capture the tuple insertions/deletions and place them in the corresponding ins_T or del_T table.

Afterwards, when the user introduces the SQL assertions, they are firstly mapped into logic denials. Then, these denials are translated into EDCs and, finally, EDCs are rewritten as SQL queries. Each of these steps is implemented in a different module following the previously presented method.

The resulting SQL queries are stored as views in event_DB. Then, the SQL Server Controller builds the **safeCommit** procedure. This procedure, when called, performs the following: 1. queries the previous views. 2. if all queries are empty, it disables the triggers, applies the update (insert in the DB the tuples contained in the ins tables, and remove from the DB the tuples contained in the del tables), and enables again the triggers. 3. truncates the ins/del tables.

The prototype has been developed in Java, with the exception of the *Assertions to denials* translator component, for which we have reused a previously existing C# software.

We made some experiments to evaluate the efficiency of our tool. We have checked some assertions of different complexity with TINTIN (like the one of our running example), in data sets consisting of 1GB to 5GB of data and with 1MB to 5MB of updates, and compared its efficiency with that of a non incremental method consisting of directly querying the assertions to the database. The time TINTIN required for checking the assertions ranges from 0.01 to 1.29 seconds and it is always better than in the non incremental approach, with a benefit of orders of magnitude when considering 5MB of updates (up to x2662 times faster).

5. CONCLUSIONS

TINTIN is a tool for checking assertions in SQL Server databases. The tool takes as input a set of assertions and it automatically builds a procedure called **safeCommit** which efficiently checks whether an update violates any of the assertions and, afterwards, commits the update if no violation is found or shows the tuples causing the violation otherwise.

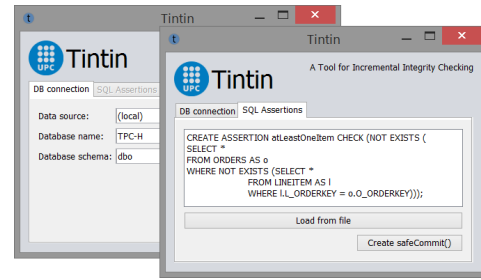

Figure 3: Graphical User Interface Design

TINTIN works almost transparently for the database users since it only requires the users to invoke **safeCommit** at the end of each transaction. Internally, the tool builds several triggers to capture the update requested by the user and to place it in some SQL auxiliary tables. These auxiliary tables are queried with the current database tables to check whether applying the update in the current data may cause any assertion violation. This join between the update and current data is the key for efficiency.

The fundamentals of TINTIN are the Event Dependency Constraints (EDCs), which we previously used to handle integrity checking of OCL constraints in conceptual models. More details about these rules, and also on their translation to SQL queries, can be found in [4, 5].

As further work, we plan to extend TINTIN to handle aggregate functions in assertions. We also expect to make it available for other DBMSs apart from SQL Server and to exploit other DBMS capabilities such as temporary tables.

ABSTRACT

We demonstrate the use of localized path indexes in generating efficient execution plans for regular path queries. This study is motivated by both the practicality of this class of queries and by the current dearth of scalable solutions for their evaluation. Our proposed solution leverages widely available relational database technology and is often orders of magnitude faster than currently known approaches. We aim in this hands-on demonstration to both highlight the promise of our approach and to stimulate further discussion and study of engineering solutions for this practical yet challenging class of graph queries.

1. INTRODUCTION

Massive graph-structured data collections are ubiquitous in contemporary data management scenarios such as social networks, linked open data, and chemical compound databases. A fundamental paradigm in graph query languages are the so-called *regular path queries (RPQs)* [16]. RPQs specify a regular expression over the edge labels in a graph, and the query answer consists of every path in the graph such that the sequence of edge labels along the path forms a word in the language recognized by the regular expression. Variations and extensions of RPQs are supported in recent query languages such as SPARQL 1.1 [8] and the Cypher language of the Neo4j graph database.¹

State of the art. Indexing of paths occurring in data has been shown to be effective for query processing in the context of object-oriented and semistructured databases [1, 15]. To our knowledge, however, there has been no investigation of using path indexing for the evaluation of RPQs over graph databases. In particular, three general approaches to RPQ evaluation have been proposed in the literature:

1. Automata- and search-based processing (e.g., [5, 10, 13]), where queries are evaluated by strategies such

as breadth-first-search pattern matching of the query graph on the data graph;

2. Datalog-based processing (e.g., [3, 17]), where the Kleene star operator is translated into recursive Datalog programs or recursive SQL views;
3. Reachability-index-based processing (e.g., [6]), where restricted uses of Kleene star are translated into reachability queries, which are then evaluated using off-the-shelf reachability indexes.

Contributions. We present an overview of our ongoing study of the use of path indexes for generating efficient execution plans for RPQs. Our approach supports the evaluation of arbitrary RPQs (unlike approach (3) above), and exhibits significant improvement (often by several orders of magnitude) in query processing times over approaches (1) and (2).

In the next section we briefly define the problem. In Section 3 we introduce the main data structures used in our solution. We then discuss query plan generation and execution in Section 4. We conclude in Section 6 with an overview of our system demonstration.

2. PRELIMINARIES

2.1 Data Model

We consider finite, directed, edge-labeled graphs. A *graph vocabulary* is a finite non-empty set \mathcal{L} of *edge labels* drawn from some universe of labels. Let N be an infinite universe of atomic data objects. An *edge relation* is a finite subset of $N \times N$. A *graph* over vocabulary \mathcal{L} is an assignment G of an edge relation ℓ^G to each $\ell \in \mathcal{L}$, i.e., there is an edge labeled ℓ from m to n if $(m, n) \in \ell^G$. In the sequel, we will sometimes denote this by $\ell(m, n)$ or $m \xrightarrow{\ell} n$. As an example, a graph G_{ex} over the vocabulary $\{\text{supervisor, knows, worksFor}\}$ is shown in Figure 1.

The *node set* of G is the collection $nodes(G) = \{n \mid \exists m \in N, \ell \in \mathcal{L} : (n, m) \in \ell^G \text{ or } (m, n) \in \ell^G\}$. For example, the node set of the example graph contains nine elements: $nodes(G_{ex}) = \{\text{ada, jan, \dots, zoe}\}$.

Let k be a natural number. If $k = 0$, we say there is a *k-path* from s to s , for every $s \in nodes(G)$. If $k > 0$, for $s, t \in nodes(G)$, we say there is a *k-path* from s to t if there exist $n_0, \dots, n_k \in nodes(G)$ and edge labels $\ell_1, \dots, \ell_k \in \mathcal{L}$ such that $n_0 = s$, $n_k = t$, and, for $0 < i \leq k$, $(n_{i-1}, n_i) \in \ell_i^G$ or $(n_i, n_{i-1}) \in \ell_i^G$.

¹<http://neo4j.com>

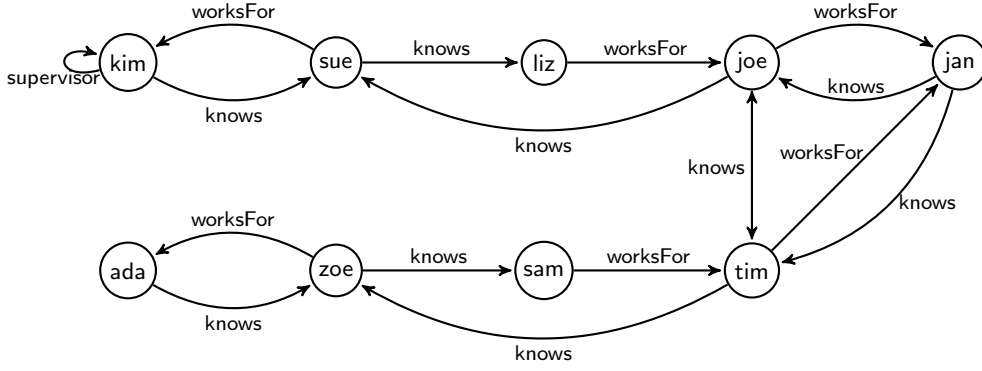

Figure 1: A graph G_{ex} over vocabulary $\mathcal{L} = \{\text{supervisor, knows, worksFor}\}$.

We denote by $paths_k(G)$ the set of all pairs of nodes $(s, t) \in nodes(G) \times nodes(G)$ such that there is an i -path from s to t , for some $i \leq k$.

As an example, in the graph G_{ex} we have that $(\text{sam}, \text{ada}) \in paths_2(G_{ex})$ via the paths $\text{sam} \xleftarrow{\text{knows}} \text{zoe} \xrightarrow{\text{worksFor}} \text{ada}$ and $\text{sam} \xleftarrow{\text{knows}} \text{zoe} \xleftarrow{\text{knows}} \text{ada}$, but $(\text{sam}, \text{ada}) \notin paths_1(G_{ex})$.

2.2 Regular Path Queries

Fix a vocabulary \mathcal{L} . A *regular path query* (RPQ) is a regular expression R over the alphabet $\{\ell, \ell^- \mid \ell \in \mathcal{L}\}$, i.e., R is generated by the grammar

$$R ::= \epsilon \mid \ell \mid \ell^- \mid R \circ R \mid R \cup R \mid R^{i,j}$$

for $\ell \in \mathcal{L}$ and natural numbers i and j where $i \leq j$. Intuitively, “ ϵ ” is the identity transition, “ ℓ ” is forward navigation along an edge with that label, “ ℓ^- ” is backwards navigation, “ \circ ” is path composition, “ \cup ” is path disjunction (i.e., union of paths), and “ $R^{i,j}$ ” is bounded path recursion.

Given graph G over \mathcal{L} , the semantics of evaluating an RPQ R on G is a set $R(G)$ consisting of all pairs (a, b) in $paths(G)$ such that there exists a path from node a to node b in G whose label sequence $\ell_1 \dots \ell_n$ defines a word in the regular language specified by R .

As examples, we have in the graph G_{ex} of Figure 1 that:

$$\text{supervisor} \circ \text{worksFor}^-(G_{ex}) = \{(\text{kim}, \text{sue})\}$$

and

$$\begin{aligned} (\text{supervisor} \cup \text{worksFor} \cup \text{worksFor}^-)^{4,5}(G_{ex}) = \\ \{(\text{kim}, \text{kim}), (\text{kim}, \text{sue}), (\text{sue}, \text{kim}), (\text{sue}, \text{sue}), \\ (\text{ada}, \text{zoe}), (\text{ada}, \text{ada}), (\text{zoe}, \text{ada})\}. \end{aligned}$$

Note that we deviate from the traditional syntax of regular expressions by replacing Kleene star “ $*$ ” with bounded recursion. This is motivated by the following two observations. First, bounded recursion is supported (and encouraged) in practical graph query languages such as Neo4j’s Cypher.² Second, since we focus in this work on index construction and use, we are interested in query evaluation on a given graph. It is easy to establish that for any graph G there exists a natural number $n(G)$ such that for every RPQ R it is the case that $R^*(G) = R^{0, n(G)}(G)$.

²<http://neo4j.com/docs/stable/>, Section 8.8

3. INDEXES AND HISTOGRAMS

Given a graph G and a fixed $k > 0$, we now present our indexing and selectivity estimation approaches for paths in G localized to neighborhoods of size k .

3.1 k -path indexing

A *label path* is a sequence $\mathbf{p} = \ell_1 \dots \ell_n$, where $n > 0$ is the *length* of \mathbf{p} , and $\ell_i \in \{\ell, \ell^- \mid \ell \in \mathcal{L}\}$ for each $1 \leq i \leq n$.

Our index on G is based on an ordered dictionary (which can be implemented, for example, as a B+tree). In particular, we index $paths_k(G)$ using an ordered k -path index $I_{G,k}$ having search key $\langle \text{label path}, \text{sourceID}, \text{targetID} \rangle$. Specifically, for each label path \mathbf{p} of length at most k , and for each pair of nodes $(a, b) \in \mathbf{p}(G)$, we insert (\mathbf{p}, a, b) into $I_{G,k}$. Given a non-empty prefix p of a search key, $I_{G,k}$ returns an ordered list $I_{G,k}(p)$ of all matching entries.

EXAMPLE 3.1. In the graph of Figure 1, we have

$$\begin{aligned} I_{G,k}(\langle \text{knows} \cdot \text{knows} \cdot \text{worksFor} \rangle) = \\ \langle (\text{ada}, \text{tim}), (\text{jan}, \text{ada}), (\text{jan}, \text{jan}), (\text{jan}, \text{kim}), \\ (\text{joe}, \text{ada}), (\text{joe}, \text{jan}), (\text{joe}, \text{joe}), (\text{kim}, \text{joe}), \\ (\text{tim}, \text{jan}), (\text{tim}, \text{kim}), (\text{tim}, \text{tim}) \rangle, \end{aligned}$$

$$\begin{aligned} I_{G,k}(\langle \text{knows} \cdot \text{knows} \cdot \text{worksFor}, \text{jan} \rangle) = \\ \langle (\text{ada}), (\text{jan}), (\text{kim}) \rangle, \end{aligned}$$

$$I_{G,k}(\langle \text{knows} \cdot \text{knows} \cdot \text{worksFor}, \text{jan}, \text{ada} \rangle) = \langle () \rangle,$$

$$I_{G,k}(\langle \text{knows} \cdot \text{knows} \cdot \text{worksFor}, \text{jan}, \text{joe} \rangle) = \langle () \rangle.$$

We have developed a prototype k -path index implementation that leverages the B+ tree index support of PostgreSQL³. We translate RPQs into equivalent SQL statements over $I_{G,k}$ implemented as a relational table and backed by a B+tree (see [12] for full implementation details). In building on mature relational technologies, we are following an emerging trend in this direction [4, 7, 9] with practical benefits such as simplicity, ease of integration with and deployment within existing IT ecosystems, and leveraging field-proven technologies.

Notwithstanding the fact that we have described here an implementation of our proposed k -path indexing technique

³<http://www.postgresql.org>

using existing RDBMS technologies, other recent work [14] describes an implementation of a B+tree-based k -path index “from scratch”, focusing on issues such as index size, compression and performance, and undertaking a comparative performance study with the Neo4j graph DBMS over several real and synthetic datasets and query workloads. That evaluation too demonstrates the potential of our k -path indexing approach (showing speed-ups in query evaluation times ranging from 2 times to 8,000 times faster compared with Neo4j). Detailed performance comparison between these approaches to path indexing is an area of future work.

3.2 k -path histogram

For query plan generation over $I_{G,k}$, it is useful to have a data structure $sel_{G,k}$ which, given a label path \mathbf{p} of length at most k , returns an estimate of the *selectivity* of \mathbf{p} in G , i.e., the fraction of paths in $paths_k(G)$ which satisfy \mathbf{p} . As an example, we have in the graph G_{ex} of Figure 1 that $sel_{G_{ex},2}(\text{supervisor} \circ \text{knows}) \approx 0.02$, since only one of the 53 paths in $paths_2(G_{ex})$ is in $\text{supervisor} \circ \text{knows}(G_{ex})$.

There is a rich literature on statistics for query optimization [2]. Here, we adopt the well-established histogram data structure, since it is easy to deploy and extremely successful in practice. In particular, we implement $sel_{G,k}$ as an *equi-depth histogram*. The basic idea here is, given space to store cardinality information about B label path ranges, we keep track of the cardinality of label paths in the graph falling into B contiguous ranges, as induced by their lexicographic order (i.e., in the order maintained in $I_{G,k}$); the ranges are selected such that they each have roughly the same cardinality. We then estimate the cardinality of any given label path by dividing the cardinality of the range in which it occurs by the number of label paths in that range. As a simple example, suppose $k = 1$, $B = 2$, and we have edge labels \mathbf{a} , \mathbf{b} , and \mathbf{c} , with cardinalities 2, 4, and 6, resp. Then the first range covers \mathbf{a} and \mathbf{b} and the second range covers \mathbf{c} , with cardinalities 6 and 6, resp. Using this histogram, the estimated cardinality of \mathbf{a} is $\frac{6}{2} = 3$.

As with the path indexes, in our prototype implementation we store and access our histogram as a PostgreSQL table; see [12] for full implementation details.

4. QUERY EVALUATION WITH PATH INDEXES

The processing of a RPQ R proceeds in three steps: The **first step** is to replace each occurrence of bounded recursion in R as a union over its expansion. The result is a semantically equivalent query R' involving only edge labels or their inverses, compositions, and unions. In the **second step**, all unions in R' are “pulled up” to the top level of the query, resulting in a semantically equivalent query R'' consisting of a union of expressions each free of unions and bounded recursion, i.e., $R'' = R_1 \cup \dots \cup R_n$ where each R_i is a label path. In the **third step**, each disjunct R_i is processed in turn, with the aim of generating a physical execution plan for each R_i in which a merge-join is used whenever possible (to make the best use of the physical sort order of the index) and a hash-join is used otherwise.

As an illustrative example, consider the query $R = \mathbf{k} \circ (\mathbf{k} \circ \mathbf{w})^{2,4} \circ \mathbf{w}$, where \mathbf{k} and \mathbf{w} abbreviate **knows** and **worksFor**, resp. Query plan generation proceeds as follows, where for clarity of presentation we drop explicit use of the concatenate

operation \circ :

1. $(\mathbf{k}\mathbf{w})^{2,4}$ is expanded, giving

$$R' = \mathbf{k}(\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w} \cup \mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w} \cup \mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w})\mathbf{w}.$$

2. Nested unions are pulled up to the top level, giving

$$R'' = \mathbf{k}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{w} \cup \mathbf{k}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{w} \cup \mathbf{k}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{w}.$$

3. Finally, physical execution plans are generated for each of the disjuncts of R'' . In particular, suppose that $k = 3$; then processing each of the disjuncts proceeds as follows:

- $\mathbf{k}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{w}$ is processed, from left to right, generating the physical plan

$$I_{G,k}(\mathbf{w}^- \mathbf{k}^- \mathbf{k}^-) \bowtie I_{G,k}(\mathbf{k}\mathbf{w}\mathbf{w})$$

in which \bowtie is implemented as a merge join. Note the subexpression $\mathbf{k}\mathbf{k}\mathbf{w}$ has been inverted to obtain the correct sort order to perform a merge join.

- $\mathbf{k}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{w}$ is processed from left to right, generating the physical plan

$$[I_{G,k}(\mathbf{w}^- \mathbf{k}^- \mathbf{k}^-) \bowtie_1 I_{G,k}(\mathbf{k}\mathbf{w}\mathbf{k})] \bowtie_2 I_{G,k}(\mathbf{w}\mathbf{w})$$

in which \bowtie_1 is implemented as a merge join and \bowtie_2 as a hash join.

- $\mathbf{k}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{k}\mathbf{w}\mathbf{w}$ is processed from left to right, generating the physical plan

$$[(I_{G,k}(\mathbf{w}^- \mathbf{k}^- \mathbf{k}^-) \bowtie_1 I_{G,k}(\mathbf{k}\mathbf{w}\mathbf{k})) \bowtie_2 I_{G,k}(\mathbf{w}\mathbf{k}\mathbf{w})] \bowtie_3 I_{G,k}(\mathbf{w})$$

in which \bowtie_1 is implemented as a merge join and \bowtie_2 and \bowtie_3 as hash joins.

We term this evaluation strategy *semi-naive*. The complete physical plan is formed as a union of these three sub-plans.

The third step can be optimized by using the histogram $sel_{G,k}$, as follows. For each disjunct D of R''

1. if $|D| \leq k$, return $I_{G,k}(D)$.
2. Find the most selective k -path subquery D' of D (i.e., the k -path with smallest $sel_{G,k}$ value). There are $|D| - (k - 1)$ such subqueries to consider.
3. Let $D = D_{\text{left}} \circ D' \circ D_{\text{right}}$, and recur on D_{left} and D_{right} , to generate query plans for respective output streams *LEFT* and *RIGHT*.
4. Determine the cost of each of the following alternative query plans, and return the cheapest plan:
 - $[LEFT \bowtie I_{G,k}(D')] \bowtie RIGHT$,
 - $LEFT \bowtie [I_{G,k}(D') \bowtie RIGHT]$,
 - $[LEFT \bowtie I_{G,k}(D'^-)] \bowtie RIGHT$, or
 - $LEFT \bowtie [I_{G,k}(D'^-) \bowtie RIGHT]$.

We term this evaluation strategy *minSupport*.

Figure 2: Advogato query execution times (ms)

5. EMPIRICAL EVALUATION

We refer the reader to [12] for full details of an empirical evaluation of our system with respect to a broad spectrum of RPQs over four different real and synthetic datasets. In addition to the semi-naïve and minSupport evaluation methods described above, two other methods are investigated: *naïve*, in which k is fixed at 1 (so indexing is on edge labels, not path labels), which corresponds to automaton-based evaluation (approach 1, discussed in the Introduction); and *minJoin*, which is similar to minSupport but also aims to minimize the number of joins.

As an indicative subset of the empirical results obtained, the three graphs in Figure 2 show the run-times of 8 queries over the Advogato data set, for each of the four evaluation methods, with values of k ranging from 1 to 3. Advogato is a real-world social network having 6,541 nodes and 51,127 edges with $|\mathcal{L}| = 3$, where edges indicate varying degrees of trust between users in the network [11].⁴

We observe that the naïve method always performs worst, that the semi-naïve method is generally outperformed by minSupport and minJoin, and that the latter two perform similarly. This demonstrates the value of the lightweight histogram data structure for selectivity estimation. We also see that increasing the value of k generally improves the run-times for all methods (apart from naïve, where k is fixed at 1 throughout).

6. DEMONSTRATION OVERVIEW

We give participants a hands-on overview of the life of a regular path query, from its submission to our system, through parsing and optimization, to execution. We further demonstrate the speed-ups achieved by our approach compared with Datalog-based evaluation (approach (2), discussed in the Introduction), where our solution is on average 1200x faster on the Advogato queries [12].

Through these interactive activities, we hope to both demonstrate the promise of our approach to RPQ evaluation and to stimulate further broader discussion and study in the research community of engineering strategies for this challenging practical class of graph queries. A system demonstration is an excellent setting in which to accomplish these goals.

ABSTRACT

A large volume of Open Data is being generated on a continuous basis. Examples of this are the case of social, natural, and information systems such as World Wide Web and social networks. Most entities and objects in the Open Data are interconnected, forming a complex, semi-structured, and information-rich networks. In this sense, Linked Open Data has the potential to be similar to a federated database. Since Linked Open Data is based on W3C standards, it is possible to implement a federation infrastructure, however, the current SPARQL standard makes it challenging to analyze the Open Data in an explorative manner. Consequently, it will be hard to discover the hidden knowledge in the relationships among entities in Open Data sources. In this paper, we present Galaxy, a platform for explorative analysis of Open Data Sources. Galaxy facilitates the analysis of Open Data graphs based on simple abstractions, i.e. folders and paths, which enable an analyst to group related entities in the graph or find paths among entities. Galaxy uses Hadoop data processing platforms to store and retrieve large numbers of RDF triples and to support cost-effective and Web-scale processing of Semantic Web data through a Folder-Path enabled extension of SPARQL.

Keywords

Linked Data, Open Data Analytics, Querying Graphs

1. INTRODUCTION

Open Data sources may include any information that can be obtained without a privileged position. Examples include electronic and print media (e.g. RSS feeds from newspapers), social media (Twitter, Facebook, Instagram, YouTube), and blog sites (e.g. Tumblr, Wordpress). The production of knowledge from Open Data is seen by many organizations as an increasingly important capability that can complement

the traditional intelligence sources. In particular, most entities and objects in the Open Data are interconnected, forming a complex, semi-structured, and information-rich networks which can be modeled using graphs. In this sense, Linked Open Data has the potential to be similar to a federated database: combining these data sources offer a rich information resource for enterprise analysis.

Since Linked Open Data is based on W3C standards (e.g. RDF format and the SPARQL query language), it is possible to implement a federation infrastructure, however, the current SPARQL standard makes it challenging to analyze the Open Data in an explorative manner. Consequently, it will be hard to discover the hidden knowledge in the relationships among entities in Open Data sources. For example it is important to quickly form an intelligence picture from the Open Data sources around a topic of interest (such as country, person, organization or event), group related entities around that topic, find paths among entities, and use all these information for the follow-on analysis. There is a need for graph representation models and efficient approaches for expressing and executing these types of queries. In particular, manipulating, querying, and analyzing Linked Open Data graphs to discover new knowledge is of high interest.

In this paper, we present Galaxy, a platform for explorative analysis of Open Data Sources. Galaxy helps in facilitating the analysis of Open Data graphs based on simple abstractions, i.e. folders and paths (introduced in our earlier work [4]), which enables an analyst to group related entities in the graph or find paths among entities. A folder node contains a set of entities that are related to each other, i.e., the set of entities in a folder node is the result of a given query that requires grouping graph entities in a certain way. We define a path node for each query that results in a set of paths (i.e. transitive relationship between two entities which can be codified using regular expressions). Folder and Path nodes, can represent a network snapshot, i.e. a subgraph, from multiple perspectives and granularities. Folder and Path nodes can be timed [3]: Timed folder/path nodes can show their evolution for the time period that they represent. Galaxy uses Hadoop data processing platforms to store and retrieve large numbers of RDF triples and to support cost-effective and Web-scale processing of Semantic Web data through a Folder-Path enabled extension of SPARQL.

The rest of the paper is organized as follows. In Section 2, we present some key components of our system, while in Section 3 we describe our demonstration scenario.

2. SYSTEM OVERVIEW

Figure 1 represents the architecture of the Galaxy. The main components of the system include the Extracted Data Folder and the Graph Query Engine.

Extracted Data Folders. Open data are complex, unstructured and generated at a high rate, resulting in many challenges to ingest, store, index, and analyze such data efficiently. The notion of *extracted data folders* serves to enable the ingestion of data (from open data sources), and the persistence of this data in accordance with a particular defined schema. Machine learning techniques can be used to construct the schema for an open data source [5]. We assume that the expert analysts will construct the schema for each folder. Figure 4 illustrates the Twitter schema where the main entities include users, tweets, links, domains, and hashTags. Folders provide a federated data access infrastructure upon which the federated analysis will operate. We also envisage folders to support multiple layers of granularity (e.g., split or merge existing folders). Folders can also be combined to create higher-level virtual folders, called federated folders, using filter, project and join operators.

Graph Query Engine (SPARQL extension). Due to space restrictions, in this paper we highlight the main component of the query engine. However, we refer to our paper [2] for algorithmic and other details. Figure 2 presents the graph processing architecture which consists of the following components: graph loader, data mapping layer, query mapping layer, regular expression processor, time-aware controller, and OLAP (on-line analytical processing) controller.

Graph Loader. Input graph (e.g. Twitter extracted folder) can be in the form of RDF, N3, or XML. We developed a workload physical design by developing a loader algorithm. This algorithm is responsible for: (i) validating the input graph; and (ii) generating the triples, where two types of triples are recognized: attribute-edges (e.g., “Bob @age 35”) and relationship-edges (e.g., “Bob knows Fred”). We use the ‘@’ symbol for representing attribute edges and distinguishing them from the relationship edges.

Data Mapping Layer. This layer is responsible for creating: (i) object-store, which contains all objects in the input graph uniquely identified by an identifier. Each object contains an arbitrary list of attribute-edges describing its features; (ii) link-store, which contains all directed links between pairs of objects represented as relationship-edges; and (iii) data element mappings between semantic web technology (i.e. Resource Description Framework) and Hadoop file system. As a result, object-store and link-store will be stored in Hadoop cluster.

Query Mapping Layer. This layer is consist of a parser for parsing SPARQL like queries (based upon the syntax of Folder-Path extension [2, 3, 4] of SPARQL) and a SPARQL-to-PigLatin translation algorithm. In order to translate the SPARQL queries into Pig-Latin we follow a specific format in which data is read from the HDFS, a number of Pig-Latin operations (e.g., LOAD, SPLIT, JOIN, FILTER, GROUP, and STORE) are performed on the data, and then the resulting relation is written back to the file system. In particular, SPARQL graph pattern matching is dominated by join operations, and is unlikely to be efficiently processed. We use existing query optimization techniques [7, 8, 9] to generate the optimal query plan by reinterpreting certain join tree structures as grouping operations, i.e., to enable a greater degree of parallelism in join processing. In the

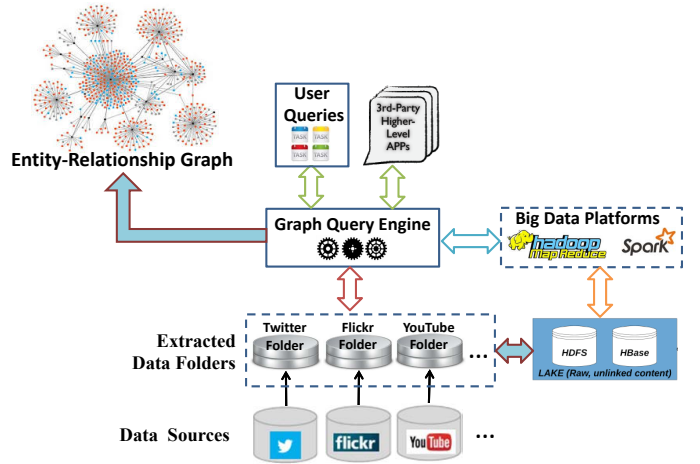

Figure 1: The Galaxy Architecture.

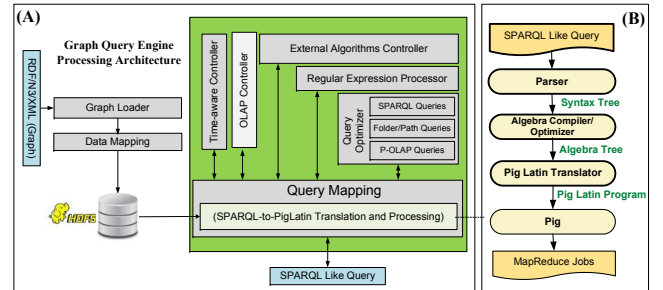

Figure 2: The Query Engine Architecture.

following, we illustrate an example for a sample mapping between SPARQL and Pig-Latin.

Example 1. DBLP¹ is an open source data for computer science bibliographical network. Adam, an OLAP analyst, is interested in partitioning the DBLP graph into a set of authors having same interests. Then he plans to apply a set of OLAP style operations (e.g., calculating authors ranking and contribution degree) on constructed partitions. Details about this example, including the SPARQL query can be found in [2]. Processing this query using Pig Latin’s query algebra, results in the query plan shown in Figure 3. The logical plan can be described as follows: (1) load the input dataset using the LOAD operator in Pig-Latin; (2) split the dataset, based on the partitioning condition, and create triple tables for related predicates. Next step is to filter the dataset into related authors, where the ‘interest’ triplestore will be needed for the partitioning phase and ‘publications’ and ‘citations’ triplestores will be needed to apply OLAP style operations on partitions; (3) filter the graph using the result of previous step, i.e., to support the triple syntax and weave the predicated to related partitions. Notice that, in the case of using JOIN operator in this step, the triple syntax will be no longer available; (4) group by the interest table on the object column to remove redundant values, e.g., cases where two or more authors, different subjects, having same interests; (5) evaluation of OLAP operations on graphs independently for each partition, providing a natu-

¹<http://dblp.uni-trier.de/db/>

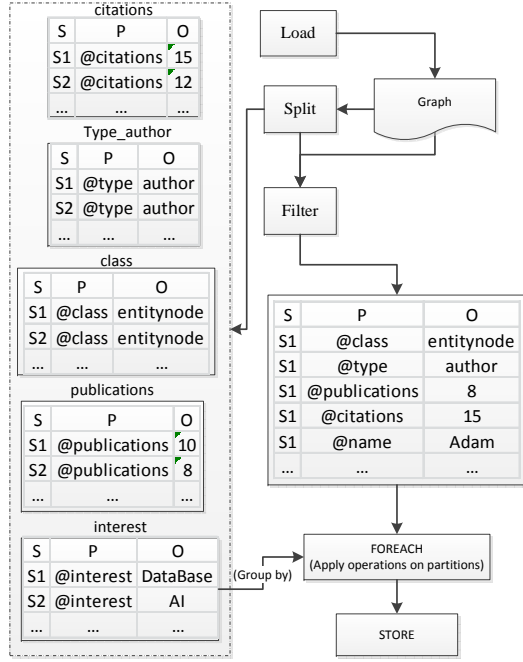

Figure 3: Query plan for the Example 1.

ral parallelization of execution; and (6) store the final result on Hadoop cluster using the STORE operator in Pig-Latin.

Regular Expression Processor. This component is responsible for parsing graph patterns. In particular, graph analysts can codify their knowledge into regular expressions that describe paths through the nodes and edges in the graph. The regular expression processor supports optional elements (?), loops (+, *), alternation (|), and grouping (...).

Time-aware Controller. RDF databases are not static and changes may apply to graph entities (i.e. nodes, edges, and folder/path nodes) over time. Time-aware controller is responsible for data changes and incremental graph loading. Moreover, it creates a monitoring code snippet and allocate it to a folder/path node in order to monitor its evolution and update its content over time.

GOLAP controller. This component is responsible for supporting on-line analytical processing on graphs, through partitioning graphs (using folder and path nodes) and allows evaluation of OLAP operations on graphs independently for each partition, providing a natural parallelization of execution, details can be found in [2].

External Algorithms Controller. This component is responsible to support applying existing graph mining algorithms (e.g. graph reachability and shortest path) to the open data graph, and store the result in a folder/path node for the follow on analysis. For example we developed interfaces to support various graph mining algorithms [1] such as Transitive Closure, GRIPP, Tree Cover, Chain Cover, Path-Tree Cover, and Shortest-Paths.

3. DEMONSTRATION SCENARIO

The demonstration scenario consists of three parts. First, we would like that the attendee appreciates the difficulties that one can encounter when dealing with open data sources.

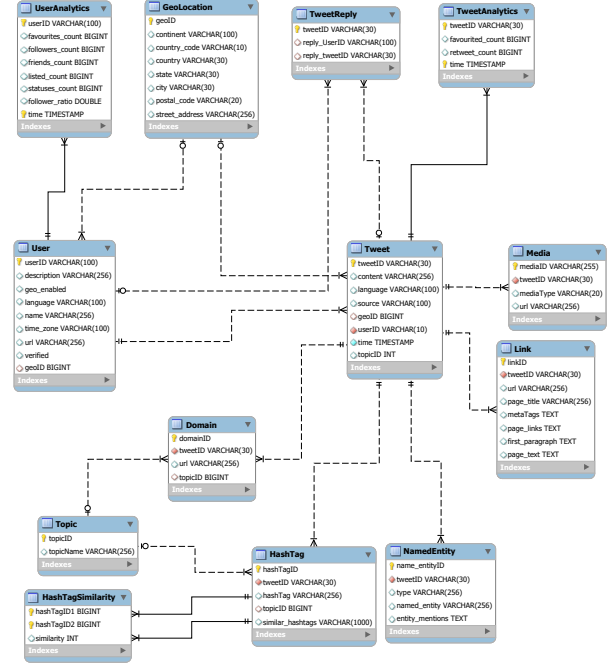

Figure 4: Twitter Extraction Folder Schema.

We start with a Twitter dump² and illustrate how we generate the Twitter extraction folder according to the generated Twitter schema (Figure 4). Next, we illustrate how we use the query language to construct content-based relationships among related entities. When talking about content we mainly deal with entity attributes, where we consider content-based relationships as correlation condition-based relationships. For example, a correlation condition in Twitter may enable grouping entities in different ways, e.g. Tweets coming from the same location or users from the same timezone, and store them in folder nodes. Figure 5 presents the set of related tweets whose location country is the same as Australia.

Next, we present to the attendee an interactive scenario where she would be able to generate the ‘influence graph’ among users in the Twitter open data through the following steps: (i) Using Folder Nodes, to form an intelligence picture from the Twitter data around a topic of interest (i.e. Twitter User) by grouping related entities around that topic and store them in folder nodes. Examples are, folders for users who: (a) belong to the same location, (b) tweet the same topics (we assume that we have a topic discovery algorithm), (c) use similar hashTags/links in their tweets; and (d) retweet similar tweets; (ii) Using Path Nodes to construct relationships among twitter constructed folders. For example a reachability algorithm will be used (in path node queries) to see if two different twitter users are reachable through a shared friend or a retweet path. As the result set of related patterns can be stored in path nodes for further analysis; (iii) Constructing relationships among open/federated data sources. We will provide the attendee with a set of folders constructed from other open data sources such as Wikidata and DBpedia. The attendee will use query templates

²<https://archive.org/details/archiveteam-twitter-stream-2012-02>

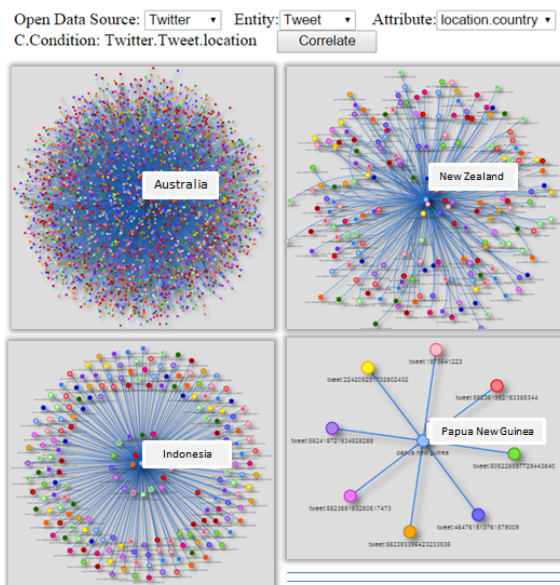

Figure 5: An example of partitioning the graph for the follow on analysis.

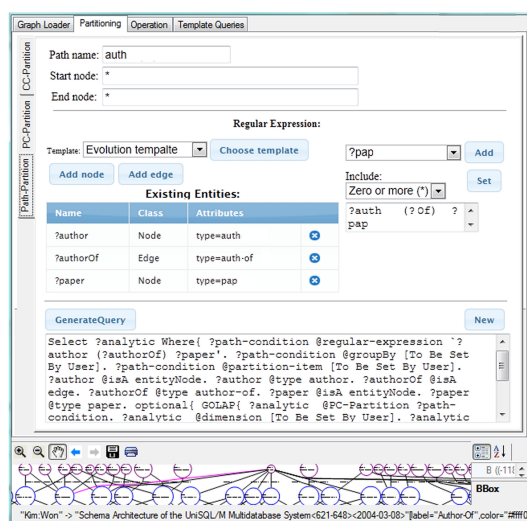

Figure 6: Screenshots of the front-end tool: assisting user to generate regular expressions.

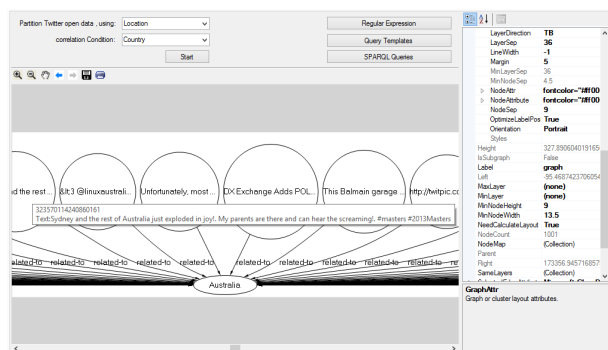

Figure 7: Screenshots of the front-end tool: assisting user to generate correlation conditions.

to discover similarity among different folders, e.g. a tweet in Twitter folder can be related to a topic in Wikidata folder; and (iv) Generating the ‘influence graph’ among users in Twitter. The attendee will use SPARQL like queries to further analyze the folder and path nodes and use the front-end tool to visualize the influence graph. In order to facilitate creating SPARQL queries, we provide a front-end tool for assisting users to create SPARQL queries in an easy way. Figures 6 and 7 illustrates screenshots of the front-end tool,

4. CONCLUSION AND FUTURE WORK

In this paper, we presented Galaxy, a platform for explorative analysis of Open Data Sources. Galaxy assists the analysts to quickly form an intelligence picture from the Open Data sources around a topic of interest, group related entities around that topic (folder nodes), find paths among entities (path nodes), and use all these information for the follow on analysis. Galaxy uses Hadoop data processing platforms to store and retrieve large numbers of RDF triples in Hadoop file system. As future work, we plan to make use of interactive graph exploration and visualization techniques which can help users to quickly identify the interesting parts of a graph.

5. ACKNOWLEDGEMENTS

ABSTRACT

Ontologies are the backbone of the Semantic Web and facilitate sharing, integration, and discovery of data. However, the number of existing ontologies is vastly growing, which makes it is problematic for software developers to decide which ontology is suitable for their application. Furthermore, often, only a small part of the ontology will be relevant for a certain application. In other cases, ontologies are so large, that they have to be split up in more manageable chunks to work with them. To this end, in this demo, we present *OAPT*, an ontology analysis and partitioning tool. First, before a candidate input ontology is partitioned, *OAPT* analyzes it to determine, if this ontology is worth to be considered using a predefined set of criteria that quantify the semantic richness of the ontology. Once the ontology is investigated, we apply a seeding-based partitioning algorithm to partition it into a set of modules. Through the demonstration of *OAPT* we introduce the tool's capabilities and highlight its effectiveness and usability.

Semantic Web, ontology, modularization, analysis

1. INTRODUCTION

Ontologies are the backbone of the Semantic Web. By making information understandable for machines [7] they enable integrating, searching, and sharing of information on the Web. The growing value of ontologies has resulted in the development of a large number of these. According to [3], at least 7000 ontologies exist on the Semantic Web, providing

*Department of Computer Engineering, Tanta University, Egypt

an unprecedented set of resources for developers of semantic applications. On the other hand, this large number of available ontologies makes it hard for software engineers to decide which ontology(ies) is (are) suitable for their needs. Even, if a developer settled on an ontology (or a set of ontologies), she is most often interested in a subset of concepts of the entire ontology, only. For example, the CHEBI ontology¹, contains 46,477 fully annotated concepts describing chemical entities of which not all will be relevant to a specific application. Also, it might be necessary to split up large ontologies like CHEBI in more manageable chunks before feeding them to ontology matching tools or other applications.

To cope with these challenges, in this demo paper, we present *OAPT*, a tool for analyzing and partitioning ontologies. The tool allows the user to interactively investigate a candidate input ontology based on a predefined set of quality criteria. This will help to build trust for sharing and reusing ontologies. Once an ontology has been analyzed, the partitioning algorithm can be applied to partition the ontology into a set of disjoint modules. Our method to examine the ontology quality is based on the consistency and richness of the input ontology. First, a suitable reasoner is applied to the ontology to validate its consistency. It is clear that the way an ontology is engineered is largely based on the domain for which it is designed and modeled. Therefore, a measure for the semantic richness of an ontology should consider different aspects and its potential for knowledge representation [9]. To this end, we then consider a set of structural, semantic, and syntactic metrics. The structural and syntactic criteria can be used to quantify the ontology design and its potential for knowledge representation, while the semantic-based criterion can be used to evaluate how instances are placed within the ontology.

To partition the analyzed ontology into a set of disjoint modules, we introduce a seeding-based clustering approach, called *SeeC_{Ont}*. In particular, input ontologies are parsed and represented as concept graphs. A *Ranker* function is then used to rank ontology concepts exploiting the concept graph features. The highest ranked concepts are finally selected as cluster seeds (cluster heads). Each of these constitutes the initial concept of a resulting module. To assign the remaining concepts to their proper modules, we introduce a membership function. This reduces the complexity of the comparisons by comparing concepts with only seeds instead of all other concepts. Please note that this partitioning method is independent of the concrete application or a concrete subset of concepts a user is interested in. Rather, it

¹<https://www.ebi.ac.uk/chebi/>

relies on intrinsic ontology characteristics only. This allows, e.g., precomputation of the modules.

The rest of the paper is organized as follows. In Section 2 we present an overview of the proposed system, while in Section 3 we describe our demonstration scenario. Due to space restrictions, in this paper we provide only a glimpse of the techniques employed by *OAPT*. However, we refer to our full research paper [1] for algorithmic details and for more elements of related work.

2. THE TOOL OVERVIEW

First, input ontologies are parsed using the Apache Jena² framework. Then, a concept graph is extracted. We define the *concept graph* $\mathcal{G} = (\mathcal{C}, \mathcal{R}, \mathcal{L})$ as a labeled directed graph. $\mathcal{C} = \{c_1, c_2, \dots, c_n\}$ is a finite set of nodes representing the concepts of the ontology. $\mathcal{R} = \{r_1, r_2, \dots, r_m\}$ denotes a finite set of directed edges representing various relationships between concepts in an ontology \mathcal{O} , such that $r_k \in \mathcal{R}$ represents a directed relation between two adjacent concepts $c_i, c_j \in \mathcal{C}$. \mathcal{L} is a finite set of labels of graph nodes and edges defining the properties of each entity, such as the names of concepts. $n(= |\mathcal{C}|)$ and m are the number of nodes (concepts) and edges (relationships) in \mathcal{G} , respectively.

After an input ontology has been parsed and represented as a concept graph, the *OAPT* tool analyzes the ontology based on a predefined set of criteria. If the user is satisfied with the result of the analysis, the ontology is then partitioned into a set of modules, as shown in Fig. 1.

2.1 Ontology analysis

In order to build trust for an ontology as a prerequisite for reuse and sharing, we evaluate and analyze the quality of ontologies. We start the analysis process by applying an OWL reasoner to make sure that the input ontology is consistent. As it is known that the way an ontology is engineered is specific to the domain for which it has been designed and modeled, the ontology design and its potential to represent knowledge should be examined. To this end, we then use the ontology richness as a metric for its quality. The richness of the ontology considers different aspects of ontologies and their potential for knowledge representation [9]. We categorize measures for the richness of an ontology into three categories: *structural*, *semantic*, and *syntactic*. We exemplarily present some implemented metrics for each type in detail:

- **Structural richness.** This dimension describes the topology of the concept hierarchy of an ontology. It includes several criteria, such as relationship, attribute, depth, and connection richness. The **Relationship richness, RR**, reflects the variability in the types of relations and the placement of these relations within the ontology. An ontology that contains numerous relation types other than class-subclass relations is richer than a taxonomy with just class-subclass relations. The relation richness (RR) of an ontology \mathcal{O} can be defined as: $RR(\mathcal{O}) = \frac{|R \setminus SC|}{|R|}$, where $|R|$ is the number of relationships in the ontology, and $|SC|$ is the number of sub-class relations. The value of the relation richness criterion is normalized between 0 and 1, where the value of 0 means that the ontology contains only sub-class relationships. Another criterion

that can be used to evaluate the structural richness of an ontology is the **connection richness, ConnR**. It indicates the number of connected components of the concept graph, i.e., the number of subgraphs linked to its root element. So, for calculating *ConnR* we determine the number of root classes, i.e., the children of the root node. $ConnR(\mathcal{O}) = \frac{1}{No.root.classes}$. This metric can help to avoid "islands" forming in a knowledge base as a result of extracting data from separate sources that do not have common knowledge.

- **Semantic & Syntactic richness.** These two dimensions describe the semantics and the descriptive information of the ontology. In this context, we make use of several metrics, such as class richness and readability [9]. The **Class Richness, CR**, is an instance-based criterion used to reflect how instances in an ontology are distributed across classes. The class richness (CR) criterion can be defined as follows: $CR(\mathcal{O}) = \frac{|\mathcal{C}^I|}{|\mathcal{C}|}$ where $|\mathcal{C}^I|$ is the number of classes that have instances. Another criterion that is important during the evaluation of the semantic richness of an ontology is the **descriptivity richness, DR**. This measure indicates availability of human-readable knowledge provided by an ontology. The descriptivity of an ontology can be defined as the number of concepts that have comments and/or labels: $DR(\mathcal{O}) = \frac{|\mathcal{C}'|}{|\mathcal{C}|}$ where $|\mathcal{C}'|$ is the number of concepts having comments and/or labels.

We combine these three dimensions to compute the total richness of an ontology using a simple weighted-sum approach. Therefore, the ontology richness (OR) criterion is defined as follows:

$$OR(\mathcal{O}) = w_1 \times StrR(\mathcal{O}) + w_2 \times SemR(\mathcal{O}) + w_3 \times SynR(\mathcal{O}) \quad (1)$$

where $StrR(\mathcal{O})$, $SemR(\mathcal{O})$, and $SynR(\mathcal{O})$ are the total structural, semantic, and syntactic richness of the ontology (\mathcal{O}), respectively. w_1, w_2, w_3 are weights that reflect the importance of each of the richness metrics, such that $\sum w_i = 1$. The normalized score is then listed for the user to decide whether to partition the ontology or to look for another one.

2.2 Ontology partitioning

Once the input ontology is inspected, the next step is to partition the concepts \mathcal{C} of the concept graph \mathcal{G} into a set of separate (disjoint) modules $\mathcal{M}_1, \mathcal{M}_2, \dots, \mathcal{M}_k$ such that the *cohesion* of concepts within modules is high, while the *coupling* across modules is low. To this end, we develop a seeding-based clustering algorithm. The steps of the algorithms are described in the following:

2.2.1 Determining the proper number of modules

Typically, the number of modules a given ontology should be split up in is determined by trial and error without using objective criteria [6]. In contrast, the *OAPT* tool provides two options to determine the number of modules. First, if the user has enough experience with the ontology to be partitioned, she can directly input the number of modules. Otherwise, the user asks the tool to suggest an "optimal" number of modules.

2.2.2 Ranking the concepts

²<https://jena.apache.org/>

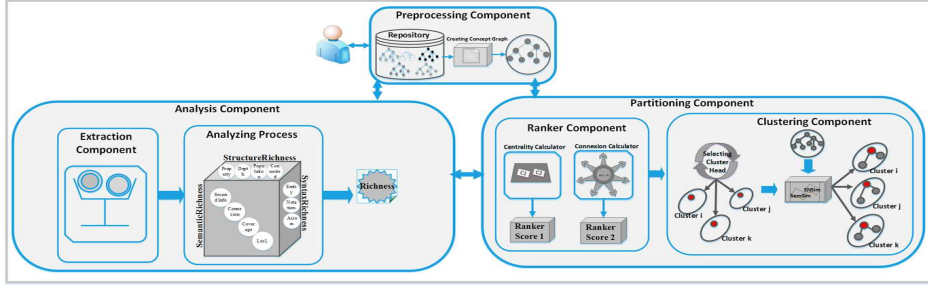

Figure 1: Tool overview

The seeding-based algorithm starts by selecting a set of nodes distinguished as *important nodes*. These nodes are then selected to be cluster heads, \mathcal{CH} . To quantify the role a node has within the concept graph, we introduce a new function, called *Ranker*. This function should be as simple as possible but effective. I.e. computing the *Ranker* function should not consume much time, however, correctly rank the concepts inside an ontology.

Ranker Function.

The importance of a node in a concept graph is determined by the properties of the node itself and its surroundings [5, 10]. This leads us to use graph-theoretic measures based on graph connections in the *Ranker* function. In the current software, we included two different implementations of the *Ranker* function. The first is based on the *centrality* measure of a concept, while the second depends on the context of the concept. To consider the effect of the concept itself through its edges, we use a set of centrality measures [4]. During the employment of the first *Ranker* function, we observed that it is an effective measure but requires a lot of time to rank concepts. This makes it unsuitable for partitioning large ontologies. Therefore, we propose another ranking function, which is based on the *connexion set* concept. The *connexion set* $\Psi(c_i, d)$ of a concept $c_i \in \mathcal{C}$ is defined as: $\Psi(c_i, d) = \{SubClass(c_i, d) \cup SuperClass(c_i, d)\}$, where $\Psi(c_i, d)$ is the set of all concepts within d levels that effect on c_i . $SubClass(c_i, d)$ is the set of children of c_i within d hierarchical levels, and $SuperClass(c_i, d)$ is the set of parents of c_i within d hierarchical levels. It is evident that the importance of a concept increases as it has a larger number of surrounding nodes.

2.2.3 Determining cluster heads.

Once having computed the importance of the concepts of a concept graph, the next step is to select which concepts represent cluster heads, \mathcal{CH} . If simply the nodes with the highest score are selected as the cluster heads, the distribution of cluster heads across the concept graph would be disregarded. To avoid this problem, the distance between two cluster heads is measured, and among the highest scored nodes, those with a minimum distance \mathcal{D} from each other are selected as the cluster heads.

2.2.4 Finalizing Clustering

The seeding-based algorithm creates one module per cluster head. Then, it places direct children in the corresponding cluster and finally, for the remaining nodes, a membership function is used to determine the cluster each node shall

be assigned to. The direct placement of children reduces the time complexity, since it reduces the number of comparisons by avoiding to compute the membership function for all concepts.

Membership Function.

Once having determined the cluster heads, (\mathcal{CH}), and having assigned direct children to their proper heads, the next step is to place the remaining concepts into the fitting cluster. To this end, we developed a membership function, *MemFun*. First, each concept is associated with a flag, \mathcal{F} , such that if \mathcal{F} of the concept c is false, it means c is not assigned to any cluster yet and thus, the membership function has to be called for the concept c . In addition, the \mathcal{F} flag can be set only once, i.e. each node can be placed in only one cluster so that there is no overlap between clusters. The membership function determines for each concept $c_i \in \mathcal{C}$ to which module $\mathcal{M}_i, i < \mathcal{K}$ it shall be assigned. For this, the similarity of c_i with all \mathcal{CH}_i is calculated and then c_i is placed in a cluster with the maximum similarity value. Using the proposed membership function, each concept is compared with the Cluster Heads only, instead of comparing it to all concepts as usually done (see e.g. [2, 8]). This reduces the complexity of the algorithm.

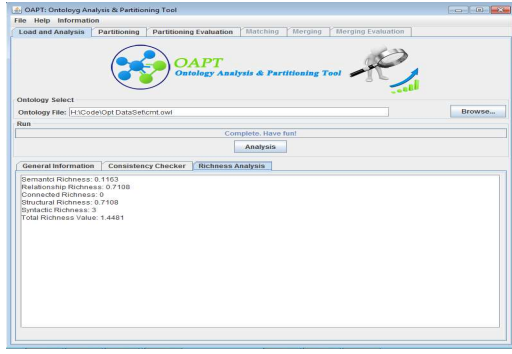

In order to compute the membership of a concept to a cluster head, a linear combination of structural and semantic similarity measures is calculated as follows:

$$MemFun(c_i, \mathcal{CH}_k) = \alpha \times SNSim(c_i, \mathcal{CH}_k) + (1 - \alpha) \times SemSim(c_i, \mathcal{CH}_k) \quad (2)$$

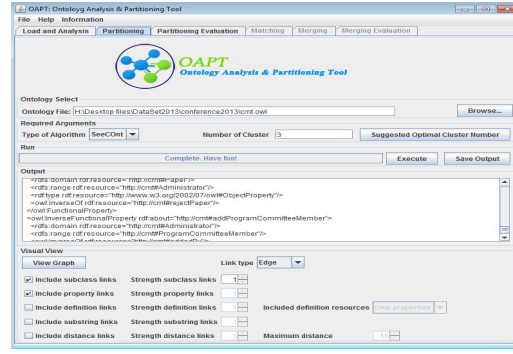

where α is a constant between 0 and 1 that reflects the importance of each similarity measure, *ShareNeighbors*(*SNSim*) and semantic similarity *SemSim* are two similarity measures that quantify the structural properties of the concept c_i , respectively. The *SNSim* measure considers the number of shared neighbors of c_i and \mathcal{CH}_k . The neighbors of a concept are the concept's direct children, the concept's parents, the concept's siblings and the concept itself. While the *SemSim* measure considers the semantic connection between a concept and a cluster head, which is based on the concept hierarchy.

2.2.5 Partitioning analysis

After having partitioned an ontology into a set of modules, the *OAPT* tool analyzes the quality of the partitioning output. This step aims at monitoring the quality of the partitioning process. We implemented a set of quality metrics such as size, cohesion, coupling, and connectivity. The module size is used to check the number of classes and number

(a) Ontology analysis

(b) Ontology partitioning

Figure 2: OAPT Screenshots

of relations within the module to validate if it is adequate.

3. DEMONSTRATION SCENARIO

In this demonstration, we will start by presenting the different features of the *OAPT* tool³ such as the process of analyzing an ontology (Figure 2a), partitioning the ontology, or sharing the partitioning quality (Figure 2b). The demonstration will consist of two main parts. First, we would like the user to appreciate the importance of the analysis phase. Second, we present the core of the *OAPT* tool.

Ontology analysis.

In this part, we aim at demonstrating the importance of the ontology analysis phase and how it largely affects the following steps. The user can select an ontology from the given repository and then start to study the effect of different evaluation criteria. The user starts with applying a single evaluation criterion and studies its effect on the semantic richness of an ontology. Then, the user attempts to combine different sets of the evaluation criteria to see why this set of metrics is needed.

Ontology partitioning.

In this part, we demonstrate the various steps of the ontology partitioning component. First, we allow the user to validate the importance of determining an optimal value for the number of modules. She starts with guessing a value for the number of modules an ontology should be partitioned into, and then she asks the tool to suggest such a number. Once the number of modules that an ontology should be partitioned into has been determined, the user can apply the *SeeCOnT* algorithm to get these modules. The set of the output modules as well as a set of evaluation metrics will be shown to the user to validate the quality of the partitioning algorithm.

4. CONCLUSIONS

In this demo, we show how *OAPT* can be used to investigate ontologies in a way that enables knowledge engineers to determine the quality of an ontology. Once an ontology is investigated, the tool can partition it into a set of disjoint modules. We developed and implemented a new seeding-based clustering approach. The tool has been evaluated and validated with ontologies from different domains which demonstrates the effectiveness and the usability of *OAPT*.

³<http://fusion.cs.uni-jena.de/fusion/activity/oapt/>

This will be demonstrated in the sample workload that we prepare for the demo. In our future work, we will complete the tool in order to support the developers in selecting which module(s) fulfill(s) his requirements. Furthermore, we plan to improve the ontology analysis phase by considering more measures and criteria and to improve also the partitioning phase by taking into account other partitioning techniques. Furthermore, we plan to visualize all these processes and steps to be more user-interactive.

ShapeExplorer: Querying and Exploring Shapes using Visual Knowledge

Tong Ge¹, Yafang Wang^{1*}, Gerard de Melo², Zengguang Hao¹, Andrei Sharf³, Baoquan Chen¹

ABSTRACT

With unprecedented amounts of multimodal data on the Internet, there is an increasing demand for systems with a more fine-grained understanding of visual data. ShapeExplorer is an interactive software tool based on a detailed analysis of images in terms of object shapes and parts. For instance, given an image of a donkey, the system may rely on previously acquired knowledge about zebras and dogs to automatically locate and label the head, legs, tail, and so on. Based on such semantic models, ShapeExplorer can then generate morphing animations, synthesize new shape contours, and support object part-based queries as well as clipart-based image retrieval.

Keywords

Shape Knowledge Harvesting, Shape Matching, Shape Segmentation, Shape Synthesis

1. INTRODUCTION

In recent years, we have seen an explosion in the availability of multimodal data on the Internet, driven mostly by the ubiquity of mobile devices and online sharing platforms. Despite great advances in tasks such as object detection and tracking and multimedia retrieval, we still lack systems that provide more fine-grained semantic analyses of visual data.

In their widely noted work, Deng et al. [4] introduced ImageNet, a hierarchical organization of visual knowledge in raw images, according to semantic categories and relations. We take a further step in this direction and utilize the semantics of individual parts, subparts, and their shapes to facilitate their interpretation and manipulation. We present ShapeExplorer, an interactive software tool that analyzes images of objects and locates and labels specific object parts. For instance, given an image of a donkey, it can draw on previously analyzed images of related objects, e.g. of zebras or even just of dogs, to infer the location and labels of likely parts such as the head, legs, tail, and so on. An analysis in terms of parts is motivated by extant evidence from cognitive research on human vision showing that shape parts play an

important role in the lower stages of object recognition [9]. Seeing a small part of an object often suffices for a human to be able to recognize the object, provided that the part is sufficiently unique [3, 2]. Still, fine-grained shape understanding remains a challenging problem in computer vision. It appears that richer data is necessary so that systems can be equipped with the required background knowledge.

Independently from the developments in computer vision, there has been considerable progress on automatically constructing knowledge bases (KB), utilizing textual information to extract relational facts and attributes. Examples include YAGO [10, 12], DBpedia [1], Freebase (www.freebase.com), ConceptNet [7], and WebChild [11]. Often, the backbone of such KBs is a taxonomy of entity types or of part-whole relationships (e.g., Head *isPartOf* Horse).

In our work, we have constructed a visual knowledge base called PartNet, for object parts and their shapes. PartNet semantically describes objects in terms of their classes, parts, and visual appearance. Unlike regular KBs, it gathers examples of the shape contours of objects and object parts.

Based on this, ShapeExplorer provides several higher-level operations, including (partial) shape querying, semantic morphing, shape synthesis, and part-based image retrieval using cliparts.

2. FRAMEWORK

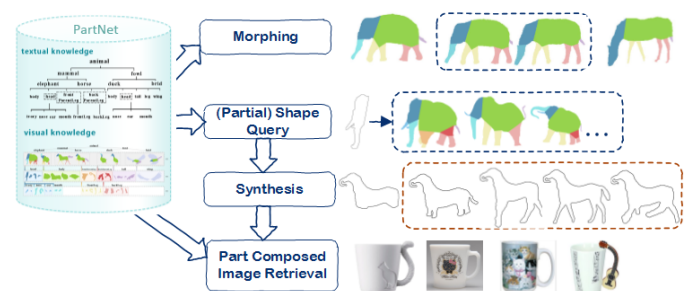

Figure 1: Flow diagram

Hierarchical Part Exploration. Figure 1 provides an overview of ShapeExplorer's operational flow. The system is based on the PartNet knowledge repository, which users can explore hierarchically. This knowledge is also used in several applications such as morphing and querying.

PartNet is organized according to taxonomic categories (animals, dinosaurs, home appliances, etc.), sub-categories

*Corresponding author: yafang.wang@sdu.edu.cn

(mammals, brontosaurus, chairs, etc.), and their part decompositions. At each level, the system presents corresponding shapes that the user may select and analyze. Internally, these are stored as subject-predicate-object triples, similar to regular knowledge bases, but including multimodal items.

There are two main user interfaces. Figure 3 presents a screenshot of the primary control center for part knowledge exploration. On the left side, the user can explore the knowledge in a convenient hierarchical tree based on categories (animals, home appliances, etc.), sub-categories (mammals, chairs, etc.), and their part decompositions. The right side of the screen serves as a working area. The user drags shapes into the bottom part of that area and can then select from several operations. These include an image analysis to infer the segmentation and labeling, which we describe below, as well as higher-level applications such as querying, morphing, and automated synthesis and completion (described in Section 3). Another user interface, shown in Figure 4, is used for part-based image retrieval. Users may compose a clipart-style query based on object parts and the system retrieves matching images from the database (see Section 3).

Image Analysis. ShapeExplorer’s image analysis is based on a joint inference procedure for joint classification, segmentation, and labeling, leveraging visual knowledge from previously analyzed images. In order to bootstrap this process in a particular domain, a small number of manually annotated seed images need to have been fed to the system initially. For those initial seeds, the user manually provides an image label, a segmentation, and part labels for the segments. The labels are chosen from the WordNet taxonomy [5]. For instance, the user could mark the image as portraying an *elephant*, and then the individual segments can be annotated with part labels such as *head*, *tail*, etc.

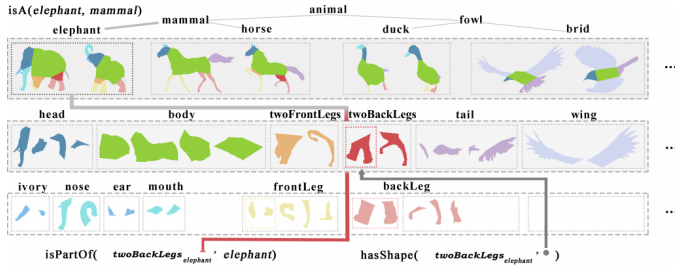

Figure 2: ShapeExplorer’s hierarchical organization

After that, one can progressively augment ShapeExplorer’s collected knowledge by adding new images, which the system analyzes using a transfer learning strategy. The system first generates a raw set of segmentation candidates, considering merely the image geometry using the short cut strategy [8]. It then matches the image with similar, previously seen ones using the inner-distance method [6], described in more detail later on in Section 3. From the top-3 matching images, we transfer additional candidate segmentations based on the contour alignments. The resulting set of candidate segmentations is pruned using semantic constraints.

Next, we determine label hypotheses for the image and for the parts based on the top-5 matching images in terms of the inner-distance method. For each cut/label candidate, we compute a confidence score based on the probability of the label within the top-5 matches and based on the cost

of the contour point alignment. Finally, we perform a joint optimization step, relying on an Integer Linear Program to maximize the sum of confidence scores for the chosen candidates subject to compatibility and cardinality constraints.

In Figure 2, we illustrate the kind of knowledge that ShapeExplorer collects. The general taxonomy comes from WordNet, while image representations are derived from the seeds and the subsequent joint inference procedure for new images.

Implementation Details. ShapeExplorer is implemented as a web application with a JavaScript-driven browser interface that users can access via their web browsers. The back-end is implemented in Java and includes the powerful PartNet shape part knowledge base as well as images indexed using Lire¹.

3. APPLICATIONS

Based on the core framework, ShapeExplorer implements algorithms for several higher-level applications.

3.1 (Partial) Shape Queries

Users may provide an input image with an unknown shape and then ShapeExplorer attempts to match it against known shapes, retrieving top-k matches from the repository. The input image may be partial (i.e., with occlusions or missing parts). Thus, Alg. 1 considers subsets of the parts of every shape class as possible candidates. This is restricted to parts that are adjacent and sufficiently large, in order to avoid a combinatorial explosion. We use the inner-distance method [6] for similarity computation, which we found to be efficient, rotation-invariant, and robust. Given two shapes A and B , described by their contour point sequences p_1, p_2, \dots, p_n and q_1, q_2, \dots, q_m , respectively, we use χ^2 statistics to compare point histograms, resulting in a cost value $c(p_i, q_j)$. Then we solve for the optimal matching between A and B , denoted as $\pi : (p_i, q_{\pi(i)})$ using dynamic programming. We compute the minimum cost value as $C(\pi) = \sum_{i=1}^n c(p_i, \pi(i))$ and the number of matching points as $M(\pi) = \sum_{i=1}^n \delta(i)$, where $\delta(i) = 1$ if $\pi(i) \neq \emptyset$, and 0 otherwise. Finally, given a best matching shape, we define a segment cut, denoted as $\text{cut}_A(p_i, p_j)$, as the 2D line connecting contour points p_i, p_j in A . We use the computed shape matching π to map $\text{cut}_A(p_i, p_j)$ onto the input shape B as $\text{cut}_B(q_{\pi(i)}, q_{\pi(j)})$. Thus knowledge from existing images is transferred onto new ones to classify them and annotate their parts.

Algorithm 1 (Partial) Shape Querying

Input: connected input part and shape database, candidate object classes $\mathcal{C} = \{c_0, c_1, \dots, c_{n_C}\}$, number of results k
Output: top-k matching shapes

```

1: for each class  $c_i \in \mathcal{C}$  do
2:   for each part  $p_j$  of  $c_i$  do
3:      $\text{partialShape}[] \leftarrow$  set of relevant combinations of parts of  $p_j$ 
4:     for each part  $ps_z \in \text{partialShape}[]$  do
5:        $\text{cost}[ps_z] \leftarrow$  matching cost  $\mathcal{C}(\pi(\text{part}, ps_z))$ 
6:  $\text{shape}[] \leftarrow$  ranking of shapes in  $\text{cost}[]$  according to cost values
7: return top-k entries in  $\text{shape}[]$ 

```

In Figure 3, the user selects an elephant head (blue) and a horse body (green) and synthesizes them together in the bottom right input region. This new shape is converted into a simple contour and given as input to ShapeExplorer.

¹<http://www.lire-project.net/>

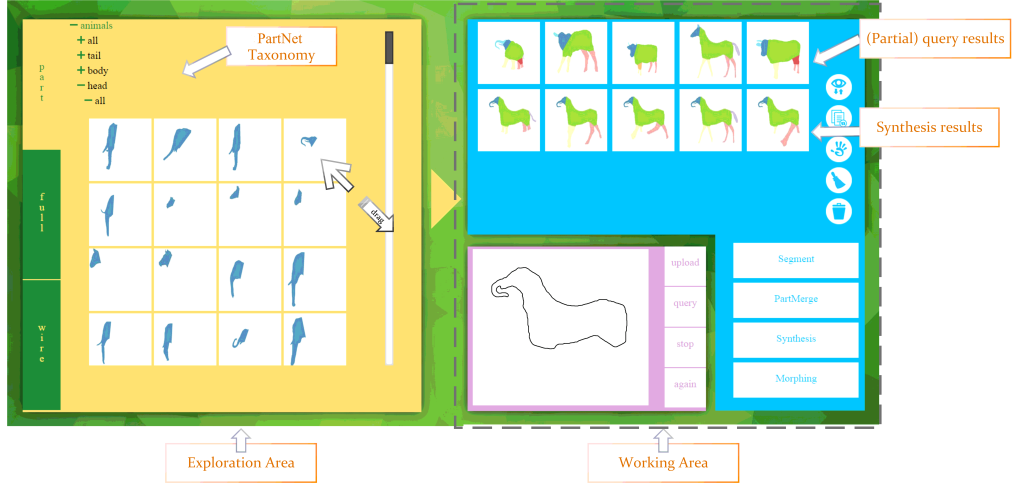

Figure 3: Screenshot for part knowledge exploration

Figure 4: Screenshot for part-based clipart image retrieval

In partial query mode, the top-5 most similar results with respect to their partial similarity are shown in the top row on the right. These can be used to retrieve images with objects showing similar shapes.

3.2 Semantic Morphing

Given two images, ShapeExplorer can automatically perform a semantic form of morphing by classifying and performing a conformal joint segmentation of the two images. Alg. 2 first produces a segmentation of the two images into the same meaningful parts. This task is accomplished by searching for the lowest common cuts in the part hierarchies (e.g., a joint segmentation of a horse and elephant will return heads without the unique trunk of the elephant).

Algorithm 2 Part Based Morphing

Input: $shape_1$ and $shape_2$, part labels $\mathcal{L} = \{l_0, l_1, \dots, l_n\}$

Output: morphing animation sequence

```

1:  $part_1[] \leftarrow shapeSegmentation(shape_1)$ 
2:  $part_2[] \leftarrow shapeSegmentation(shape_2)$ 
3: align  $part_2[]$  to  $part_1[]$  using common parts
4: for each label  $l_i \in \mathcal{L}$  do
5:    $point_1[l_i][] \leftarrow samplePoints(part_1[l_i])$ 
6:    $point_2[l_i][] \leftarrow samplePoints(part_2[l_i])$ 
7: return  $morphing(shape_1, shape_2, point_1[], point_2[])$ 

```

Having a full part correspondence between the two shapes, our system generates a morphing sequence which gradually interpolates from one to the other. See the morphing sequence in Figure 1 for an example of morphing from elephant to horse. This is accomplished by performing a per-part morphing while maintaining connectivity between adjacent parts during the deformation.

The morphing algorithm generates animations by smoothly interpolating transitions between corresponding parts in each shape (see morphing sequence in Figure 1). During the animation, users may pause and resume it to review intermediate frames, which can also serve as new inputs for querying and synthesis operations. Additionally, the user may select the intermediate frames as new inputs, which may further be queried, synthesized, and used to retrieve images.

3.3 Shape Synthesis and Completion

In shape synthesis mode, ShapeExplorer starts with a new user-provided partial shape and then uses best matching shapes from the repository to synthesize the missing parts so as to obtain a complete image.

Given an unknown shape, Alg. 3 first finds the top-1 best matching shape in the repository using the (Partial) Shape Query method. The segmentation and labels of the matching

shape are transferred to the input image. Then, missing parts in the input shape with respect to the matched shape are detected. We synthesize the missing parts by transferring them from the matched shape onto the input image. Specifically, we subtract from the retrieved shape the parts in common with the input one and gracefully translate, scale, and rotate the shape and its parts so that they fit to their adjacent ones in the unknown one. Please note that *body* might have many part-cut labels, such as head, leg and tail. Therefore, line 6 means whether p_i and p_j have matching part-cut labels. For example, head can match body.

Algorithm 3 Shape Synthesis

Input: query *shape*, shape database

Output: new shape

```

1:  $rParts[] \leftarrow$  parts of top-1 partial query result for shape (Alg. 1)
2:  $parts[] \leftarrow$  labeled segmentation of shape via Alg. 1
3:  $mParts[] \leftarrow rParts[] - parts[]$ 
4: for each part  $p_i \in mParts[]$  do
5:   for each part  $p_j \in parts[]$  do
6:     if  $label(p_i)$  matches  $label(p_j)$  then
7:       transfer from  $p_i$  to  $p_j$  in shape
8: return shape

```

In Figure 3, the user selects an elephant head (blue) and a horse body (green) and synthesizes them together in the bottom right input region. Synthesis results are displayed in the second row of the results region in the work area. These results can be used for retrieving similar images.

3.4 Clipart-based Image Retrieval

Another option is to perform image retrieval from a large image repository by composing a clipart-like query using parts or sketches. Our multimodal retrieval interface is composed of four components (see Figure 4): a control panel on the left, a text query field on the top, the working canvas in the middle, and the retrieval results on the right. Figure 5 illustrates the workflow of the part-based clipart image retrieval system. Users can issue textual queries to retrieve parts of interest from the PartNet knowledge repository. They can explore the results and drag parts of interest into the working area so as to craft a query image. This query image may be composed of parts stemming from different objects in the repository. Users also are able to modify the composition by drawing sketches using a pencil tool in conjunction with a color selection interface. This can be used to add additional items to the image, or to modify the original colors and textures of the parts coming from PartNet. An eraser tool is also provided for cleaning.

Figure 5: Part-based clipart image retrieval

Finally, the query image is used to retrieve similar images from the database. In the example in Figure 4, the user seeks to find images of cups with cat tails as handles. With standard image retrieval tools, it is hard to find such images unless they have sufficient textual metadata. With ShapeExplorer, the user can first issue a query for the word “cup” to find the cup body in the PartNet repository. This is then

dragged from the results area onto the canvas. Similarly, the user finds the body and legs of a cat in PartNet and incorporates them into the query canvas. In order to ensure that the handle looks like a cat tail, the user can pick the color brown via the color selection interface and use the pencil tool to sketch a brown handle. This results in a sort of clipart image that can be used to retrieve matching real images from the database. For image matching, ShapeExplorer relies on a set of image features, combining JCD (Joint Composite Descriptor) and edge histograms. Thus, we can find cups with cat-like handles. Figure 4 shows the top-3 results, and the user may scroll to obtain further images.

4. CONCLUSION

In this paper, we have presented ShapeExplorer, a system aimed at fine-grained analyses of images in terms of object parts that captures multimodal knowledge in more detail than previous work. We see that explicit semantic representations of the parts enable several novel applications, including novel forms of querying, semantics-driven morphing, and synthesis.

1. INTRODUCTION

The Personal Cloud paradigm emerges as a decentralized and privacy preserving solution to manage personal documents under users' control. It can be seen as an alternative to the current Web model, which centralizes the complete digital life of millions of individuals in data silos, and increases frustration generated by the weak control of the individuals on the way their personal data are shared, used and disseminated. The home cloud is the most emblematic form of Personal Cloud. It can be thought of as a dedicated box connected to the user's internet gateway, equipped with storage, computing and communication facilities [11], running a personal server and acquiring data from multiple sources [3]. This personal server is in charge of organizing the personal dataspace in a document database style to ease its management and to protect it against loss, theft and abusive use. Many startups (e.g., OwnCloud, CozyCloud, etc.) and research projects (e.g., PlugDB at Inria or OpenPDS at MIT) investigate this direction.

To make the vision of the Personal Cloud reality, two important challenges related to data management have to be considered. First, leaving the data management control into the user's hands pushes the security issues to the user's computing platform as well. Hence, besides the management of collections of personal documents of any type, the personal cloud takes the security and privacy in charge. This requires protecting personal documents and their metadata by means of encryption and evaluation of access control rules. This challenge is paramount considering that the Personal Cloud paradigm puts a significant part of the digital life of the individual in the user's hands.

The second challenge is rooted in the high level of decentralization of the Personal Cloud, i.e., each user owns her personal cloud (see Figure 1). Indeed, this user-centric architecture must not hinder the development of global data services of great interest for the individuals, the companies and the community, which is also required to meet a viable business model. Hence, as in a centralized setting, certain applications require crossing data from multiple individual Personal Clouds. This is the case of any application developed for communities of users sharing a similar interest. For example, within a community of patients suffering from the same pathologies, each participating user may provide her own set of information such that distributed searches may help to identify within the community the most relevant documents related to current treatments or symptoms, or more generally, help users to share and benefit from each other experiences. Clearly, this must be performed without exposing the privacy of the participating users.

This demonstration tackles precisely these two challenges. Our approach relies on a secure hardware based co-server, called *secure token* hereafter, which provides a search engine interface to users and applications to manage the documents with high security and privacy guarantees. This search engine, described in

detail in [5], manages the encryption/decryption of documents, answers local searches and enforces access control rules on the fly with good performance. In this demonstration, we extend this previous work to provide a secure distributed search engine, such that applications can query the documents stored in a large number of Personal Clouds. Any global search has to be accomplished while preserving the participants' privacy, i.e., no further information beside the computation result can be learned by any participant or a third party. This property is key to encourage users to participate in global computations.

The implementation of a secure distributed search engine is however challenging. Considering a top-k search where the score of each document is evaluated by a *tf-idf* metric and answering global searches over a (large) community of users require (1) to compute some global values (i.e., the total number of shared documents and the inverse frequency of the query terms in all these documents), (2) to evaluate the score of each document accessible for the query according to these global values, and then (3) to identify the *k* documents with the highest scores among the set of participants.

Although users may accept to contribute to a given community of interest by granting a right to search over a subset of their own personal documents, the risk that any compromised participant gains access to the complete collection of documents must be avoided. This can be achieved by minimizing the amount of information exposed during query evaluation. While the final result of each query (i.e., the *k* most relevant documents) can be published to the community, neither the intermediate computations nor the complete set of local documents eligible for a given query should be revealed.

Computing a result without revealing input data can be done (1) by outsourcing the data on a trusted party, but we consider this option as not satisfactory in personal cloud context where no trusted entity clearly appears in the scenario, (2) by using Secure-Multi-Party (SMC) cryptographic techniques, but these techniques cannot currently meet both query generality and scalability objectives [10] or (3) by relying on privacy preserving distributed query computation techniques (see Section 3).

Our approach capitalizes on the tamper resistant hardware available on each personal cloud to form a global secure decentralized data platform. No plaintext data will be exposed outside of the secure elements except the final result to be published. The risk of data disclosure thus only depends on the possibility of the secure elements of certain participants to be compromised, i.e., the secure token has been tampered with and the decryption keys it contains may become accessible to malicious participants. Although these attacks are highly difficult and costly to conduct, they cannot be totally ignored. It is therefore mandatory to quantify the impact of such an attack and to propose computation strategies minimizing it. We then introduce privacy metrics linked to the amount of intermediate personal data made accessible to the secure infrastructure during the computation and show how it can be minimized.

The aim of this demonstration is to show that practical and efficient solutions can be devised to evaluate distributed searches within large communities of Personal Cloud users with a very limited privacy risk for the participants. More precisely, we

demonstrate that “gossip” based computations [8] (1) can provide accurate search results with good performance and scalability (i.e., large communities of users, with thousands to millions of personal clouds) and (2) can drastically minimize the risk of privacy violation even if compromised participants are involved in the computation.

2. ARCHITECTURE AND SCENARIOS

Let us consider the Secure Personal Cloud Platform of Alice as pictured in Figure 1. The main component is a home cloud data system gathering personal data from multiple sources (employer, banks, hospitals, commercial web sites, etc.) and devices (smart meters, quantified-self devices, smartphones, cameras, etc.). The Personal Cloud can be implemented by any type of computing platform with storage facilities such as a set-top box or a plug computer. This data system is complemented by a secure co-server which can be hosted by any type of tamper-resistant devices flourishing today, e.g., Mobile Security Card (produced by Giesecke & Devrient), Personal Portable Security Device (produced by Gemalto and Lexar), Multimedia SIM card [4] or Secure Portable Token [5]. Whatever its commercial name and form factor, a tamper-resistant device embeds a secure microcontroller (e.g., a smart card chip) connected to a large NAND Flash memory (e.g., an SD card) and can communicate with a host through a USB, Bluetooth or Ethernet port. Open hardware secure tokens are also provided (e.g., by the Versailles Science Lab, <http://tinyurl.com/UVSQ-Lab>), and can be built by any electronic manufacturer.

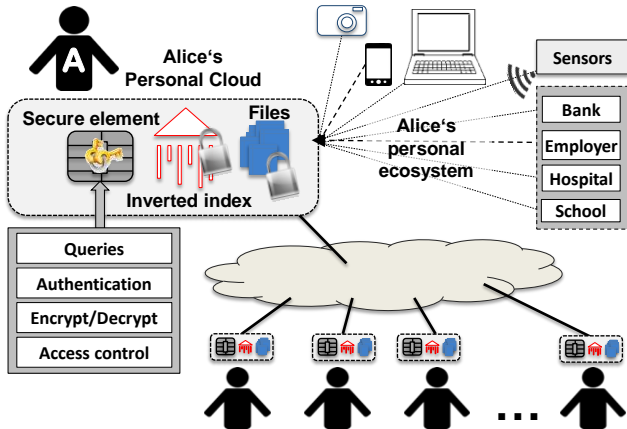

Figure 1: Secure Personal Cloud architecture

Alice participates here to a community of patients. Each secure token acts as a participant in a secure distributed search allowing users and applications to express full-text search queries over document collections stored within the community. The token being the root of security, it is in charge of data access control, encryption/decryption and metadata maintenance, that is the insertion, update and deletion of documents in the full-text search index. Each secure token locally stores an index of the user’s documents build on the documents content and including a set of access control terms associated with these documents. It also stores cryptographic keys used to protect the documents, stored encrypted locally or remotely on external cloud storage. Each user grants access to the documents by specifying access control rules (conjunction and disjunction of access control terms). The secure tokens collaboratively compute the result of top- k information retrieval queries issued by users or applications by only considering the documents matching the access control rules on each personal cloud.

The documents can be any form of files (pictures, text files, pdf files, mails, data streams produced by sensors, etc.) associated to a set of terms. The terms are extracted from the file content and

from metadata describing it (e.g., name, type, date, creator, words, visterms, tags set by the user herself). A query issued by a user or an application can be any form of term search expression, with a ranking function (e.g., *tf-idf* [15]) identifying the top- k most relevant documents (see Section 3). Only the documents granted to the user/application must appear in the query result. Hence, such a search engine can be used locally to query any documents entering a user dataspace, in the same spirit as a Google desktop or Spotlight augmented with access control capabilities.

A distributed search can be initiated by any member of the community to retrieve the most relevant documents for the query within the community. Each member within the community can contribute to the query by granting access to her own documents.

The question is how to pool these dataspace without the assistance of a central server. The objective indeed is to avoid centralizing sensitive information that may be at risk in case the server is compromised. We consider the existence of a network infrastructure enabling direct information exchange between any pair of personal clouds taking part in a distributed search query. We also assume that each participant owns a public/private key pair. Within a community, all participants exchange their public key at the time of registration. This could be achieved using traditional PKI or GPG techniques.

3. TECHNICAL CHALLENGES

Search engine requirements. To identify the top- k most relevant documents in a given collection for a certain query, a ranking function is used to score each document. For this demonstration, we use the classical *tf-idf* function:

$$tf-idf(d) = \sum_{t \in Q} f_{d,t} \cdot \log \left(\frac{N}{F_t} \right)$$

where $f_{d,t}$ is the occurrence number of term t in the document d , N is the total number of indexed documents and F_t is the number of documents that contain t . For a local query (which searches into single personal cloud) N and F_t are local values (i.e. the local number of indexed documents and the local number of documents that contain the term t). To evaluate a global search, the scores computed in the different personal clouds must be comparable. This requires computing beforehand the global values of N and F_t to be used in the previous formula. Then, the local top- k scores have to be exchanged and compared to find the global result. To this end each participant has to transmit their data to others.

Security constraints. The secure tokens are the unique source of trust in the architecture. They are endowed with a tamper resistant element (secure microcontroller) which prevents physical attacks and also its owner from having access to the secret data it contains and manipulates. Hence, even the holder of the secure token cannot spy intermediate data manipulated by his token during a computation (similar with a banking card holder that has no access to the cryptographic secret stored in his card and cannot spy its data processing). However, despite its high level of security, we cannot exclude the possibility of having a small percentage of hacked tokens (e.g., as a result of a sophisticated attack from the token owner). Such an attack would lead the personal cloud owner to have access to the cryptographic material stored inside her secure token. From this, she can potentially decrypt any encrypted information sent during the computation to her personal cloud. One objective of this demonstration is to evaluate the risk taken by the participants of a community to have their personal data unexpectedly exposed in this case. This risk analysis is essential since the hardware is left into users hands. Breaking a set of secure tokens should not put the personal documents of the whole community at risk. To evaluate that risk, we measure (1) for a given set of (potentially compromised) secure tokens, the amount of intermediate results and documents exposed during the evaluation of a distributed search query, and (2) for a given set of (not compromised) participants, the amount

of her own information transmitted to remote secure tokens and the number of secure tokens to which this information is disseminated. The first metric gives an estimate of the benefit of an attack for the attackers. The security being evaluated as a ratio between the cost of the attack and its benefit, the lower the value is, the better the security is. The second metric estimates the impact of the information leak for an honest participant. Our objective is to keep both metrics as low as possible, and never favor a solution which puts the complete dataset at risk in case of successful attacks.

State of the art solutions. Distributed query processing and the top-k queries are well investigated topics. Although, to our knowledge, decentralized secure computation of top-k queries on a population of secure elements has not been investigated yet, several previous proposals are related to our work. A first approach to solve the problem is to rely on a super peer (i.e., a central manager or a designated peer used as a coordinator) as proposed in [6, 12, 13, 14]. However, these solutions do not comply with our security requirement since the complete dataset becomes at risk if the super peer is compromised. Other existing approaches [1, 7] propose to organize the peers as a tree to process the queries. However, tree architectures are very sensitive to peers failures. In addition, the peers participating in the tree potentially gather a lot of branches and can thus be the transit point of a large amount of data, leading to large privacy breaches if compromised. Other solutions found in the literature use gossip protocols, which are highly suitable for fully decentralized architectures. In [6], a gossip protocol is used to broadcast top-k queries only to the peers who have similar interests as the querier, which is very interesting in our context if transposed to "trusted peers" and is part of our future works. However, the solution proposed in [6] assumes that the querier can see all the intermediate results coming from the participants, which would not be acceptable in our context. In Chiaroscuro [2], participating devices collaborate using gossip style computations to achieve privacy thanks to encryption and differential privacy. But this solution is dedicated to perform clustering operations on time series. A recent proposal [13] addresses the problem of computing SQL aggregate queries over an asymmetric architecture composed of potentially large populations of secure tokens and a central server. However, the focus is to prevent data inferences while delegating operations to the central server. Also, the secure tokens share the same secret key, which incurs the risk of exposing the complete dataset if one secure token is hacked.

4. DESIGN OF THE SOLUTION

Our solution to perform the distributed search relies on three main phases described as follows. In Phases 1 and 3, gossip computations algorithms [8] are used to respectively compute a sum and a top-k using of gossip computation algorithms.

Phase 1: computation of global N and F_r . The query is broadcasted to the participants. The secure token of each participant computes locally its own contribution to the global N and F_r , considering only the documents compliant with its active access control rules. The local contributions are then aggregated in order to compute the global values for N and F_r , according to the push-sum algorithm proposed in [8]. The precision on the approximate values obtained on each participant for N and F_r can be controlled by the number of gossip exchange rounds which remains reasonable even for a large number of participants:

$$nb_round = O(\log(n) - \log(\epsilon) - \log(\delta))$$

where nb_round is the number of rounds necessary in a network of n participants to be obtained with a probability at least $1 - \delta$ a result with an error under ϵ . At the end of this step, each participant has an approximate value of the global N and F_r values.

Phase 2: local computations of the top-k. Based on these global values, each secure token computes locally the global scores for

the documents compliant with its active access control rules and produces a local top-k.

Phase 3: computation of the global top-k. A new phase of gossip communication starts during which secure tokens exchange their top-k. At each round, each secure token receives k tuples (cloud_id, doc_id, score) from another peer and selects the k highest scores within the union of the received tuples and the local tuples. Then, it chooses randomly the next peer to which it sends its current local result. In this way, the tokens refine their local results at each round of the protocol. After a given number of rounds [8], all the tokens share a set of local results that are close to the exact global result. Due to the random characteristic of gossip protocols, the final result is only an approximation of the exact result (i.e., the one which would have been obtained on a centralized union of all the authorized documents in all participating personal clouds). The present demonstration will show that the results are good and that the improvement of the result accuracy is fast in number of rounds.

To enforce the security of the protocol and meet the privacy requirement, an asymmetric encryption/decryption system is used. Each token owns a private/public key pair. We assume in the demonstration that every participant has at disposal the complete list of public keys of all the participants. During the gossip communication phases tokens randomly choose a public key in the list, encrypt their message to transmit it to the corresponding secure token which decrypts the message with its private key. A token can thus be sure that its message can only be read by the chosen recipient, which limits the data exposure risk.

5. DEMONSTRATION

In this section, we present our prototype platform and describe the demonstration scenario covering the security and the performance of the proposed solution for distributed search in the secure Personal Cloud architecture.

5.1. Platform

Hardware Platform. The demonstration platform is an instance of the architecture depicted in Figure 1. A laptop is used as the communication infrastructure, and 20 secure tokens (see Figure 2) are used as participants. Each token is running the distributed search algorithm based on gossip computations as presented in the previous section, and evaluates the local access control rules. The local searches are performed using a previous prototype [11]. The secure tokens are equipped with a 32 bit RISC MCU clocked at 120 MHz with 128 KB of static RAM and 1MB of NOR Flash (to store the code of the distributed search engine). The MCU is connected to a smartcard chip hosting the cryptographic material and to a μ SD card which stores the inverted index use by the embedded search engine. The PC which connects to all tokens via a USB port plays the role of the network infrastructure, controls the communications between tokens, and shows exchanged data and results it receives from tokens.

Figure 2: Secure Tokens used in the demonstration.

Graphical User Interface. The GUI is used to control the system and evaluate our privacy metrics. Any participant can issue a global search query and retrieve the relevant files. The demonstration interface compares the efficiency, performance and privacy offered by our distributed search algorithm with a secure

solution where all the secure tokens would share the same encryption key (in the spirit of [13]) and with tree based approaches inspired by [1]. The accuracy of the search is compared with a central search computed over the union of the document databases stored in the participating personal clouds (using traditional precision and recall metrics). To evaluate the privacy level of our computation technique, the GUI also shows the probability of data disclosure to the attackers and the number of external documents that an attacker could read. To this end, the interface enables choosing certain participants to be considered as being corrupted.

Dataset. We use the Pseudo-desktop collection [9] as the baseline dataset of the demonstration. It includes more than 27000 documents (representing emails, photos, pdf, docs, and ppts). We randomly spread the documents among the tokens. We also use a synthetic dataset to show the scalability of the approach with more documents in each personal cloud.

5.2. Scenario

The first goal of this demonstration is to present the performance of the distributed search. Each participant has set her own access control rules. One of them issues a query (set of terms) and chooses the expected error rate. The number of iterations in the gossip phases is then fixed according to this error rate. The result (an approximate top- k obtained by each participant) is compared to the exact one, which is computed by the PC on the union of the authorized documents. Query times, average score error, precision and recall are presented and compared. The demonstration shows that good performance can be achieved even for low error rates. The average score error is given by the difference between the scores obtained in the approximate results for each token and the exact score obtained with a centralized search. The recall (respectively, precision) is given by the ratio between the number of documents present in both the approximate result and the exact result, and the number of results (respectively, the number of documents in the exact result with a score greater than the minimum in the approximate result).

The second goal of this demonstration is to focus on the privacy properties of gossip computations. The attendees choose some personal clouds as being corrupted before running the query. First, the interface will show the ratio between the number of distinct couples (cloud_id, doc_id, score) computed by each token which are exposed to the attackers, and the total number of couples (cloud_id, doc_id, score) in the local top- k computed during the query. Second, for each participant considered as honest, the interface plots the ratio between the number of couples which do not appear in the result and have been transmitted (directly or transitively) to one of the attackers during the execution, and the number couples which have been computed locally (typically k).

These two metrics obtained with our search algorithm will be compared to those obtained using alternatives representative of state of the art solutions: (1) a tree based evaluation, where the data flow between the participants is modeled as a tree structure (inspired by [1]) and (2) a secure query execution where all secure tokens would share a same secret key to evaluate the query (inspired by [13]).

5.3. Demonstration results

In terms of performance, the execution query time with our proposal is larger compared to a centralized database. This is obvious since our system requires a number of gossip iterations. However, the execution time is reasonable even on large databases and with large numbers of participants (obtained by simulation in the demonstration). In terms of precision, the average score error is less than 10% and the precision lies between 0.6 and 0.9 with a relatively low number of iterations. These values show that our proposal can be used in practice. In terms of privacy and security, our proposal shows much better results than existing approaches. Typically, honest users involved in the

computation disclose few couples (cloud_id, doc_id, score) to the attackers. Considering 10% of attackers, the probability to expose a couple to an attacker is around 20% in our experiments. Our technique could be improved by choosing in the first gossip steps only users considered as trusted by the participant. This would decrease this number drastically (this is part of our future works). And for an attacker, the benefit of an attack is very small since only a very tiny proportion of the intermediate results can be obtained.

6. CONCLUSION

The emerging Personal Cloud paradigm holds the promise of a Privacy-by-Design storage and computing platform where personal data remains under the individual's control while being shared by valuable applications. In this demonstration, we present a distributed secure search engine with the objective to provide a high level of security founded on the introduction of low cost secure tokens in the architecture. This architecture minimizes the loss of privacy risks even if some participants are compromised, i.e., could bypass the tamper resistance of the token. While many personal cloud platforms are flourishing, riding the wave of repeated scandals blemishing the typical centralized management of personal data, none of them provides such a tangible source of trust to the individuals. We hope that the platform demonstrated here, which enable both local application and distributed ones, emphasizes the interest of studying new database techniques based on secure hardware for the database community.

Type-aware Web-search

Michael Gubanov

ABSTRACT

Keyword-search engines (e.g. Web-search) usually can be outperformed by a specialized system optimized for a specific domain, type of data, or queries [8, 2, 12, 5, 11, 9]. For example, Halevy et. al. in [13] demonstrate how a specialized Google Fusion Tables spatial search can outperform the general-purpose Google Web-search on *bike trails search* in San Francisco Bay Area. At the same time, Web content providers usually exhibit a specific focus for their postings. For example, information at <http://www.csail.mit.edu> is devoted to Computer Science research and education, *Hannah Montana* is mostly tweeting about music, and the same is true for most sources.

This paper describes the work in progress on a new Type-aware Web-search system that uses topical focus of information sources to process a large class of queries better than a regular Web search-engine. It leverages semantic profiles similar to [10, 6, 7] and a new Type-aware Locality-Sensitive Hashing (TLSH) scheme to accomplish it.

1. INTRODUCTION

Figure 1 illustrates search-results from one of the Web search engines for query *Frozen in Phoenix* where a user is trying to find a theater to watch a movie. You can see the search-results are not the best (about ice cream and frozen yogurt). It happened, because the generic Web-search engine employs simple term matching of the query with the Web pages, and did not take into account type information, which can be done to get more relevant results. Table 1 illustrates the Web-search results of a *type-aware* search-engine described here for queries *Careers of People with Ph.D.* You can see, it returns precisely what the user has been asking for in these queries. A regular Web-search engine would return career-pages of companies and recruiting agencies, resulting from term matching to *careers*.

Table 1: Type-aware Search Results

2. ARCHITECTURE

The crawled Web pages are processed by a Natural Language Processing domain-dependent parser, which emits the entity data along with the text fragments they came from and saves the result into a large-scale storage (see Figure 2 for a schematic). Both a large-scale semi-structured sharded storage engine as well as a parallel relational engine are used.

The earlier work in [10] introduces *semantic profiles* intended to capture the semantics of an information source and store it in a compact and reusable manner. It summarizes and accumulates all *types* of entities from the source. For example, the newspaper *New York Times* often publishes about **companies**, **products**, and **organizations**; *The Finance* usually tweets about **dividends** and **products**; *The Oregonian* publishes about **sports**, **holidays**, **music**, and hence their profiles are comprised of these types. These profiles are calculated and saved for each source. Due to space limitations, interested readers are referred to [10] for more details on profile construction.

Next, the hashing routines treat each profile as a vector and assign it to one of the hash tables. Similarly, the incoming query is represented a vector, the query processing module computes the set of relevant hash tables for a query, the relevance score of the documents from these hash tables

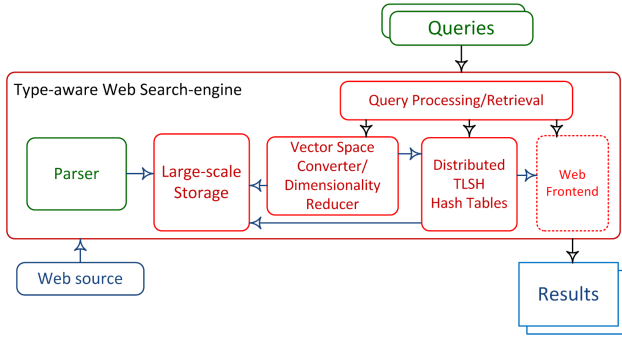

Figure 2: Architecture

and the query is computed, and finally the documents are ranked by this relevance score and output to the user.

3. TYPE-AWARE WEB-SEARCH

Type-aware Locality Sensitive Hashing: Locality-Sensitive Hashing (LSH) [14] is an algorithm that enables searching for near neighbors in a high-dimensional vector space S^n with dimensionality n . Formally, given a query $q \in S^n$, return the nearest neighbors of q within certain radius R . LSH performance crucially depends on a family of hash functions F that it uses to map the input vectors to its internal data structures. In order for the algorithm to perform well, F usually has to reduce the dimensionality of the original vector space still satisfying the *locality-sensitive* requirements on the reduced vector space. F is considered to be *locality-sensitive* if collision of two vectors v_1 and v_2 under a random choice of a hash function from F depends only on the distance between v_1 and v_2 . Refer to [3] for an overview of locality-sensitive hash-function families.

Here, a new two-tier family of hash functions Ψ is described and used. First, it maps the original vector space V of *terms* into a vector space of *types* - T , hence reduces dimensionality (there are much less types than terms). Second, k random unit vectors $u \in T$ are generated, which defines a family of hash-functions $h \in \Psi$ as follows $h(v) = \text{sign}(u \cdot v / \|v\|) : u, v \in T$. Refer to [4] for a proof of its locality-sensitivity. Angular distance measure is used here for this vector space.

Query Processing: The queries and Web documents are represented as vectors in a high-dimensional vector space S^n with dimensionality n (number of types). To return vectors (Web documents) within radius R of the query q the algorithm concatenates k hash functions $h_i \in \Psi$ described above into a composite hash function $h_c(v) = h_1(v), \dots, h_k(v)$, hence creating a family of hash functions $h_c \in \Phi$.

Next, for query q it computes all functions from h_c and considers the documents only from the corresponding hash tables. It returns all vectors v from those hash tables that are within angular distance R from q . The evaluation below justifies that using this semantic hashing/retrieval algorithm outperforms a generic Web-search engine by relevance of search-results.

Relevance Evaluation: Here, relevance gain of TLSH hashing/retrieval scheme compared to a general purpose Web-search engine for “type-containing” queries (i.e. containing a Named-entity) is quantitatively evaluated. An experiment

was conducted to calculate NDCG (Normalized Discounted Cumulative Gain) [1] on a static set of queries with respect to a general purpose Web-search engine, which provides quantitative insight into their performance difference. NDCG is one of the standard widely used search relevance measures, which is employed by major search engines and, similarly to F-measure, measures both precision and recall of retrieval. NDCG is well suited for search evaluation, because it rewards relevant results in the top positions more than those ranked lower. Due to space limitations, interested readers are referred to [1] for details about NDCG computation. Total NDCG gain over all queries turned out to be very large $> 6\%$. Usually for two industrial Web-search engines NDCG difference more than 4% is considered to be significant.

Indexing and Querying A Large Database of Typed Intervals

Jianqiu Xu¹, Hua Lu², Bin Yao³

ABSTRACT

Assume that a database stores a set of intervals associated with types and weights. Typed intervals enrich the data representation and support applications involving different kinds of intervals. Given a query time and type, the system reports k intervals that intersect the time, contain the type and have the largest weight. We develop a new structure to manage typed intervals based on the standard interval tree and propose efficient query algorithms. Experiments with synthetic datasets are conducted to verify the performance advantage of our solution over alternative methods.

1. INTRODUCTION

In this paper, we study top- k queries on typed intervals. Assume that a database stores a set of tuples, each of which defines three attributes: an interval with start and end points, a type and a weight. Given a query time and type, the system reports k tuples fulfilling the conditions: (i) intersect the query time; (ii) contain the type; and (iii) have the maximum weight, i.e., return k intervals with maximum weights among all fulfilling conditions (i) and (ii).

To help understand the problem, Figure 1 shows a running example. In traffic monitoring systems, the database stores the number of vehicles appearing in a district over time. There are different kinds of vehicles: {*Taxi*, *Bus*, *Truck*, *Private Car*}. Each tuple records a time interval, the vehicle type and the count. A top- k query is “return the district with the largest number of buses at the time 8.5”, and the system returns o_3 . The following objects $\{o_3, o_5, o_8, o_{10}\}$ intersect the query time, but only o_3 and o_5 fulfill the type condition.

In the literature, queries on interval data have been studied with operators such as intersecting [3], stabbing [1] and top- k on keyword intervals [5]. However, they do not consider intervals associated with types and therefore do not support applications involving different types of intervals, e.g., various genome intervals in genomic datasets and different versions of data items.

Figure 1: Typed Intervals

Edelsbrunner’s interval tree [2] is a popular structure for reporting intervals intersecting a given query. In principle, an interval tree is a binary tree that serves as the *primary* structure. Each node in the tree maintains two lists (*secondary* structure) of sorted intervals. One can directly employ the two-list structure to manage typed intervals, but the method is not optimal. Since the standard interval tree does not support intervals with types, a linear scanning is performed in each accessed node to find intervals that intersect the time and contain the type, even some of them are not equal to the query type. Another problem is, too many intervals are visited. In fact, the query only needs k intervals.

We propose a new structure to replace the sorted lists in each node to maintain typed intervals. Given a node storing a set of intervals, the new method is able to determine part (even all) of the intervals intersecting the query time without accessing the data. An index is built on managing types, leading to quickly finding intervals with a particular type. Employing the new structure, much less intervals are accessed to report k results. We carry out the experimental evaluation to demonstrate the performance of our method by using synthetic datasets.

2. THE SOLUTION

In each node, we replace two lists by a new structure for interval management. The idea is, we partition the interval space into a set of equal-length slots, each of which has a unique id and defines a subspace. We use two tables in which one maintains intervals *containing* the relevant slots and the other maintains intervals *intersecting* the slots, named as *full* and *partial* tables, respectively. Each row in the tables corresponds to a slot and stores a list of interval ids.

Figure 2: Slot representation based on interval tree

Figure 2 depicts the binary tree built on intervals and the slot representation for the root node. The new secondary structure includes the center point p and two child pointers lp, rp . These items are the same as the traditional structure [2]. Next, min and max are lower and upper endpoints of all intervals at this node. To perform the partition, the number of slots is defined, denoted by g . In the example, four slots are created for the root node. Intervals located in each slot are first sorted on type and then on weight. The type index is a list of items and each item records the type and the start position of intervals with that type. For example, the index for the third slot in the full table will be $\{(Taxi, 0), (Bus, 1)\}$ because o_8 is the first interval in the slot and o_3 is the second interval.

To answer the query, we perform a binary search on the tree. Given a node, we first determine the corresponding slot and then access the full and/or partial tables. Intervals in the full table do not have to be tested on the intersection condition. We use the type index to find intervals having the query type and return the first k intervals. For intervals in the partial table, we find those fulfilling the type condition and then iteratively test each on the intersection condition. Intervals from the two tables are inserted into a min-heap with the size k . We keep updating the min-heap until the searching procedure is terminated. Apparently, the better the performance is, the more intervals are in the full table. This depends on the slot number defined to partition the space.

3. EXPERIMENTAL EVALUATION

We use synthetic datasets in the preliminary evaluation: $\{S1(1M), S2(5M), S3(10M), S4(20M), S5(50M)\}$. The start point of an interval is randomly chosen within the domain $[1, 100000]$, and the length is a random value between 1 and 1000. Let T be the number of types and we set $T = 100$ in the experiment. The weight is randomly selected as an integer from $[1, 500]$.

Three competitive algorithms are developed in the evaluation. One extends the standard interval tree by integrating a boolean bit string representing whether there are intervals

with certain types in the node. The secondary structure in each node is defined to be $2 \cdot T'$ ($T' \leq T$) lists. Each list stores intervals with the same type. The second algorithm uses a relational interval tree [4] in which the bit string is also integrated. The last method employs a 2D R-tree. The three algorithms are named by *Ext-I-tree*, *RI-tree*, and *R-tree*, respectively, and our method is named *Slot*.

Figure 3: scaling the data size

Figure 4: synthetic dataset, $S5$

We perform the evaluation by scaling the number of data intervals and the number of returned intervals k . The CPU time and I/O accesses are reported in Figure 3 and Figure 4. The results demonstrate that our method significantly outperforms other methods, e.g., 3-6 times faster than *R-tree*, 2-10 times faster than *Ext-I-tree*. Since the CPU time is only several milliseconds, a small deviation may lead to a sharp slope of the curve, e.g., in Figure 3(a). The I/O variation in Figure 4(b) is attributed to the randomness of the generated queries.

ABSTRACT

Rankings are a widely used techniques to condense a potentially large amount of information into a concise form. However, rankings are dynamic and undergo changes, thus need to be maintained, which can be a tedious and expensive task. Given a ranking τ that got updated to τ' , we aim at identifying those rankings σ that are very likely to have changed as well, as they are close in distance to the original ranking τ . We do so by modeling the expected change in form of a hypothetical ranking σ' and mark σ to require a refresh if the expected change is above a threshold. We do this for the Footrule distance and demonstrate through a preliminary evaluation the potential of our approach.

1. INTRODUCTION

We focus on the task of maintaining a set of crowdsourced entity rankings. One important characteristic of crowdsourced rankings is that although they share the same entities, they conform to different constraints, thus, a change in one ranking does not imply the same change in another ranking. We propose a framework that uses the similarity between the rankings, to reason about the degree of change in a set of rankings due to an update in one ranking. Since the distance between two rankings resembles not only structural but semantic similarity as well, it is reasonable to assume that once a ranking changes, it is more likely that similar rankings change, rather than dissimilar ones. Specifically for top-k rankings that only report on a (usually short) subset of items, if two rankings are similar, they need to share also a fraction of items. If ranking τ changes, this means that items that are present in τ changed, respectively their features. Such changes might or might not propagate to a ranking σ that is in distance λ to τ —the likelihood of such a propagation is what we aim at quantifying in this work.

When considering rankings created over some objective (measurable) scoring function, like wealth in USD, the update of the rankings can be done by maintaining one global ranking, and directly updating all rankings affected by an update. However, keeping a global ranking in the case of

crowdsourced rankings, where there is no measurable scoring function, but instead entities are ranked by some user perceived quality, like popularity, is not only expensive, but also unintuitive, as there is no ground truth.

1.1 Problem Statement

As **input** we are given a set \mathcal{T} of top-k rankings τ . Each ranking τ has a domain \mathcal{D}_τ —the items it ranks. We further know the Footrule distance between each pair of rankings in \mathcal{T} . We define an **update** $u_\tau(i, j)$ **to a ranking** τ **as a swap of two items** $i, j \in \mathcal{D}_\tau$. A size of an update $u_\tau(i, j)$, for brevity denoted simply as $|u_\tau|$, is the difference between the positions of the swapped items, $|\tau(i) - \tau(j)|$. We denote with τ' the ranking τ after applying an update $u_\tau(i, j)$.

For a given update u over a ranking τ , the task is to compute the likelihood that u affects other rankings $\sigma \in \mathcal{T}, \sigma \neq \tau$ such that $F(\sigma, \sigma')$ is larger than some user defined threshold θ . In that case, σ is marked to be refreshed (e.g., crowdsourced) to bring it up to date. If we believe a ranking is not affected by a change but in fact it is, we suffer loss in **recall**, the ranking is not refreshed and our database \mathcal{T} is getting stale. If we, however, believe it is affected and it is not, we suffer loss in **precision**, which leads to wasting cost to refresh a ranking when it is not required to do so. For an overview to methods for comparing top-k rankings, see [1].

2. APPROACH

Algorithm 1 shows the procedure for determining (allegedly) affected rankings. As input the algorithm takes a specific update, a set of rankings, where the Footrule distance between all pairs is known, and a threshold θ . First, we compute the maximum distance, d_{max} that would likely result in the updated items i, j being present in both rankings τ and σ , i.e., $i, j \in \mathcal{D}_\tau \cap \mathcal{D}_\sigma \Rightarrow F(\tau, \sigma) \leq d_{max}$ with some probability p . We explain how this bound can be computed below. The next step is computing the expected change according to the distance. For this purpose, in a pre-processing step for each possible distance, for a given k , we compute an average difference between the positions of the items in two rankings τ and σ , such that $F(\tau, \sigma) = \lambda$. We call this average displacement (see Section 2.1) and it does not depend on the actual rankings in \mathcal{T} . Using the average displacements, we compute the expected change, according to the actual update. If the change is larger than a user specified threshold θ , we retrieve all distances and output all rankings within the retrieved distance to the changed ranking.

When we have a sequence of updates, we can simply accumulate the change. Note that an update over several items can also be considered as a sequence of updates of two items.

2.1 Computing the Expected Change

Since we do not know the positions, if any, of the affected items in the rankings, the first step toward quantifying the expected change in a ranking is reasoning about the most

```

Algorithm 1: Algorithm for determining all the rankings in \mathcal{T} affected by a change u_τ according to their distance.

likely position of the affected items, when the distance λ between the rankings is known. To do this we first define a displacement of an item i in two rankings τ and σ :

DEFINITION 1. Displacement of an item: For two rankings τ and σ , $\tau \neq \sigma$, we define a displacement of an item i , denoted with μ_i , $i \in D_\tau \cap D_\sigma$, as the difference of the position of the item in the two rankings, i.e., $\mu_i = |\sigma(i) - \tau(i)|$. In the case when $i \in D_\tau \setminus D_\sigma$, $\mu_i = k + 1 - \tau(i)$ or vice versa.

The Footrule distance between two rankings τ and σ is in fact the sum over the displacements of the items in $D_\tau \cup D_\sigma$. We can compute the most likely position of the affected items, i, j in σ as $E[\sigma(i)] = \tau(i) + E[\mu]$ and $E[\sigma(j)] = \tau(j) + E[\mu]$, where $E[\mu]$ is the average displacement between the items in two rankings within distance λ of each other.

To compute the average displacement $E[\mu]$ for a given Footrule distance λ we need to compute all the displacements that contribute to that distance. The naive way to do this is to generate all top- k rankings for a given k , compute the distances between all combinations of rankings, and compute the *average item displacements* for every distance. However, this is computationally very expensive, as generating all the rankings of size k has a complexity in $O(k!)$.

One key observation that allows us to more efficiently compute the sample space is the fact that the Footrule distance is a sum over non-negative integers, where each integer is a displacement of an item. In number theory and combinatorics, an unordered collection of positive integers whose sum is n is called a partition of n . Several efficient algorithms for generating all the partitions for a number, working in constant amortized time, have been proposed. Thus, we could use one of those algorithms to generate all the partitions for the distance λ . The resulting set of partitions could be used to compute the average displacement $E[\mu]$. Note that not all partitions of λ should be used in computing $E[\mu]$. The details of how exactly $E[\mu]$ can be computed we leave out of this paper due to lack of space. Considering an update $u_\tau(i, j)$ of τ , one can compute the expected change $E[F(\sigma, \sigma')]$ as:

$$E[F(\sigma, \sigma')] = (1 - \lambda) \times (2 \times |E[\sigma(i)] - E[\sigma(j)]|)$$

where λ is the distance between τ and σ . The reasoning is that since these are the only two items that changed in σ' with respect to σ , the change can be computed as $(2 \times |E[\sigma(i)] - E[\sigma(j)]|)$. However, since σ is only similar to τ , we do not want to fully propagate the change. Thus, we multiply the change by $1 - \lambda$ (we normalize λ , thus $0 \leq \lambda \leq 1$).

The above formula only covers the case when we assume that the affected items belong to the domains of both rankings. However, since we are working with top- k rankings it can happen that the updated items in τ cannot be found in σ at all. To eliminate the rankings that are so dissimilar to the updated ranking, and thus it is very unlikely that they changed, we define a maximum distance bound d_{max} . This bound is computed using the probability of not finding both updated items i and j in σ , $P(i, j \notin D_\tau \cap D_\sigma) = \frac{\binom{2 * (k - w)}{2}}{\binom{2 * k - w}{2}}$, where w is the overlap between the rank-

	$\theta = 0.1$		$\theta = 0.15$

Our approach	0.58	0.6	0.59	0.41
Baseline	0.12	1	0.08	1

Table 1: Experimental results: Precision and Recall

ings. Since we only know the distance between the rankings, we can compute the maximum overlap that two rankings can have within a distance λ as $w_{max} = \lceil \frac{1}{2} \times (-1 + \sqrt{1 - 4 \times \lambda + 4 \times k + 4 \times k^2}) \rceil + 1$ and then plug this value into the above probability estimation formula.

3. EXPERIMENTS

We have implemented the described algorithm in Java 8. We created one synthetic dataset by first creating a small set of base rankings, by randomly choosing at least ρ from k items, where k is the size of the rankings, and then randomly choosing the remaining $k - \rho$ items. All the other rankings are created by swapping a random number of items from the base rankings. The dataset contains 500 rankings with size $k = 10$. We compared our approach with the baseline approach—retrieving all rankings that have at least one item in common with the affected ranking. For the experiments, we randomly selected one ranking from the dataset, randomly selected a pair of items from this ranking, and then swapped their places. We then used our method and the baseline to find the affected rankings in the dataset.

Table 1 reports the average precision and recall for the two approaches over 100 trials. We report on results for two values of the threshold θ , 0.1 and 0.15. To compute d_{max} , we set $P(i, j \notin D_\tau \cap D_\sigma)$ to 0.9. Note that the recall of the baseline is always 1 since the relevant rankings must have at least one item in common with the changed ranking. We can see that with our approach we can achieve high precisions (much higher than the baseline) while still maintaining relatively high recall.

4. RELATED WORK

Research around crowdsourcing information usually addresses the problem of reducing the cost, while still retaining high quality results. Guo et al. [3] address the problem of finding the highest ranked object using the least number of questions, from a set of objects, in a crowdsourcing database system. Wang et al. [5] use transitive relations to reduce the number of questions asked to the crowd for the case of crowdsourced joins. Gruenheid and Kossmann [2] investigate the cost and quality trade-offs of different algorithms in a crowdsourcing environments. Polychronopoulos et al. [4] propose an algorithm for creating top- k lists using the crowd. The idea behind the algorithm is to create a high agreement top- k list for a low latency and monetary cost, by adaptively choosing the number of tasks posed to the crowd. To the best of our knowledge, there has not been any work that focuses on maintaining a set of crowdsourced rankings.

ABSTRACT

Phase change memory (PCM) as a newly developed storage medium has many attractive properties such as non-volatility, byte addressability, high density and low energy consumption. Thus, PCM can be used to build non-volatile main memory databases. However, PCM's long write latency and high write energy bring challenges to PCM-based memory systems. In this paper, we propose an improvement over the B+-tree for PCM. Particularly, we consider the read/write tendency of leaf nodes. For write-intensive leaf nodes, we use an overflow-node technique to reduce PCM writes, while for read-intensive ones, we adjust the tree structure to remove overflow nodes to improve read performance. Our experimental results suggest that our proposal outperforms the traditional B+-tree and the overflow B+-tree.

B+-tree; Index; PCM

1. INTRODUCTION

The increasing needs for large energy-efficient main memory call for new types of memories, such as phase change memory (PCM). PCM is byte-addressable and supports random access. Compared with DRAM, PCM is non-volatile and is expected to have higher storage density in the future [1, 2]. However, two problems make it difficult to replace DRAM in current computer systems. First, the write latency of PCM is about 6 to 10 times slower than that of DRAM. Second, PCM cells have limited write endurance [3].

Therefore, a more practical way to utilize PCM in memory architecture is to use both PCM and DRAM to construct hybrid memory architecture [2]. In such hybrid memory architecture, the high density and non-volatility of PCM makes it possible to build non-volatile main-memory databases. However, due to the special properties of PCM, many existing database algorithms such as indexing have to be revised to take advantage of PCM.

In this paper, we focus on the indexing issue in PCM/DRAM-based hybrid memory systems. We aim to improve the traditional B+-tree to make use of PCM and DRAM efficiently. Specifically, we improve the traditional B+-tree in two aspects. First, we use an overflowing mechanism [4, 5] to reduce write operations to PCM, where each leaf node in the B+-tree is allowed to have several overflow nodes to keep newly inserted records when the leaf node is full. Thus, we can reduce the split operations on the index and consequently reduce writes

and lengthen the lifetime of PCM. Second, we propose to predict the read/write tendency of index requests, based on which we use different ways to process index requests. Particularly, we use the overflowing scheme for write-intensive requests, but adopt a tree-adjusting operation to remove overflow nodes so as to improve read performance. We conduct experiments to evaluate our proposal and make comparison with the traditional B+-tree and the overflow B+-tree. The results suggest the efficiency of our proposal.

2. CB+-TREE

The structure of the CB+-tree is similar with the B+-tree, except that each leaf node can have a few overflow nodes. A leaf node without overflow nodes is called a *tra*, while a leaf node containing overflow nodes is called an *ovf*.

All the data stored in leaf nodes of CB+-tree is the same as that in the B+-tree. Nodes of the CB+-tree are ordered, thus binary search is allowed. Every node of the CB+-tree consists of a set of $\langle \text{key}, \text{value} \rangle$ pairs and some auxiliary information. The auxiliary information includes *num_keys*, *is_leaf*, *parent*, and *brother*. Here, *num_keys* denotes the number of $\langle \text{key}, \text{value} \rangle$ pairs, *is_leaf* indicates whether the node is a leaf node, and *parent* and *brother* denote the parent and the brother of the node, respectively.

In the CB+-tree, when an *ovf* leaf node has a read tendency, we remove it from the overflow chain and make it be a new *tra*. With this mechanism, we can reduce the number of overflow nodes and therefore improve read performance. As shown in Fig. 1, the leaf nodes LN1, LN2 are *tra* and LN3 is an *ovf*. If LN3 is required to be changed into a *tra*, we remove LN3 from its overflow chain and change it into a *tra*. Other *ovf* in the original overflow chain remain unchanged. Consequently, the overflow chain is changed into two segments, as shown in the right part of Fig. 1.

Figure 1. Structure adjustment of the CB+-tree.

The key issue in the CB+-tree is how to predict the read/write tendency (\mathcal{T}) of a leaf node. Formally, \mathcal{T} is calculated by (1). Here, $ratio_t$ and $ratio_c$ are total and recent proportion of writes to all accesses on a leaf node, respectively.

$$\mathcal{T} = ratio_t * \delta + ratio_c * (1 - \delta), s.t. \delta \in [0, 1]. \quad (1)$$

We make use of a sliding window to record k latest read/write requests for a leaf node, and further get the value of $ratio_c$. Generally, a node is considered to be write-intensive when \mathcal{T} is higher than 0.7, and be read-intensive when \mathcal{T} is lower than 0.3. The read/write tendency prediction scheme works when \mathcal{T} is in 0.3-0.5 for an *ovf* and in 0.5-0.7 for a *tra*.

We perform the prediction by using the polynomial fit technique according to the recent access information in the sliding window. In addition, we do not trigger the prediction when the \mathcal{T} of an *ovf* drops a little below 0.7 immediately, but wait for some time to collect more information about the access pattern. This strategy is also applied to the change of the parameter *tra*.

3. EVALUATION

To observe the performance benefits of the proposed CB+-tree, we implemented three algorithms: the traditional B+-tree, the OB+-tree[4] and the CB+-tree, and we run them on a computer with Ubuntu 14.04, a CPU of AMD Athlon II X2, 4GB RAM, and 1 TB Seagate hard disk. In addition, we used DRAM to simulate PCM by artificially increasing write latency.

We used the TPC-C¹ workload to generate the traces in the experiments. When running the TPC-C workload, 10 warehouses and 100 clients are configured. The TPC-C workload contains eight index files built on eight tables, and the size of the tables is approximately 1 GB. We used BenchmarkSQL² to generate the TPC-C workload running on the open-source PostgreSQL, and collect page requests on the eight tables at the same time. We first performed insertions on the tables to get index insertions. Consequently, we performed 5.4 million insertions requests and the original B+-tree index file is about 135 MB. Then, we prepared a trace containing about 3.8 million index requests including 74.2 % searches, 23.8 % insertions, and 1% deletions.

Figure 2. PCM read counts with different buffer sizes.

Figure 3. PCM write counts with different buffer sizes.

We first measure the read and write count of cache lines. Figures 2 and 3 show the read and write counts when varying the buffer size of each index. As shown in Fig. 2, the B+-tree has the least read count under all settings, because it does not involve any overflow nodes. However, as shown in Fig. 3, the B+-tree introduces more PCM write operations, which will shorten the lifetime of PCM and worsen the overall time performance. The OB+-tree has the highest read count because each leaf node in the OB+-tree is likely to contain a long chain of overflow nodes, which introduces more read operations. On the other side, the proposed CB+-tree has much less read operations compared with the OB+-tree, because it uses read/write tendency to dynamically remove overflow nodes.

Note that our index has a little more PCM writes than the OB+-tree. This is due to the read/write-tendency-based adjustment of the index structure. Figure 4 shows the run time of each index, which is normalized according to the run time of the B+-tree, i.e., the run time of the B+-tree is always set to 1. It indicates that the CB+-tree outperforms the B+-tree and the OB+-tree in terms of overall run time. As a result, the CB+-tree is able to balance the read and write costs, yielding a better indexing mechanism for PCM-based memory systems.

Figure 4. Run Time (normalized w.r.t. B+-tree).

4. CONCLUSIONS

PCM has been regarded as a new kind of future memories. In this paper, we proposed an efficient tree indexing approach called CB+-tree that is an improved version of the traditional B+-tree. We used the overflow-node design to reduce writes to PCM, and thus the endurance of PCM can be improved. We also proposed to predict the read/write tendency of index requests, based on which we performed necessary adjustment on the tree index to reduce additional read operations caused by overflow nodes. The comparative experimental results including read/write count and run time, show the efficiency and superiority of our proposal.

ABSTRACT

This work proposes and evaluates a novel approach to determine interesting category for ranked lists using ν -SVM. We identify three characteristics (features), entropy, unlikability, and peculiarity and show how to train a classifier on these features using a set of Wikipedia tables. The learned model is evaluated by relevance assessments obtained through a user study, reflecting the correctness of our approach.

1. INTRODUCTION

Understanding and exploring information is becoming more and more complex due to the dramatic growth of data. Scale, dynamics, and (schema) heterogeneity advocate for solely automated means, by which users can sit back and explore data already put in meaningful and interesting categories. In this work, we specifically look at ranked lists, a concise form of data summarization, that can be found in nearly all domains as virtually everything can be ranked, if not by measurable means then by crowdsourcing rankings. Given a ranked list, for instance, the list of tallest building in the world, we consider the task to decide which dimension is worth being used as a constraint to specialize the query. In database terminology, we are interested in determining OLAP-cube dimensions for the drill-down operation, but consider the case of data beyond a well understood database schema. Specifically, our approach is using statistical measures that can be computed from any table, no knowledge about the semantics of the schema or human input is required. Getting back to the above example, a list of tallest buildings by continent or country appears interesting, while a list of the tallest buildings that are 31 stories tall might be less important to be investigated, if at all. The key idea behind this work is to assume that it is feasible to train a classifier based on training data obtained from Web tables, such as tables in Wikipedia, assuming that the presence or absence of a table can act as in indicator of general interest or disinterest of humans in such a table.

1.1 Problem Statement, Setup, and Key Idea

Consider a set of rankings-style tables \mathcal{R} , where $r \in \mathcal{R}$ is a ranking table with its attributes \mathcal{A} . A subset of \mathcal{A} is of

*This work has been supported by the German Research Foundation (DFG) under grant MI 1794/1-1.

numeric type, denoted as \mathcal{N} . We divide \mathcal{A} in three kinds of attributes: (i) the subject of ranking denoted as a_s which represents the set of entities, (ii) the criterion of the ranking, denoted as a_{cr} , based on which the ranking order of subject entities are made and (iii) the remaining attribute considered as categorical attribute denoted as a_c . Hence, the ranking table r is written as $r = (a_s, a_{cr}, a_{c1}, a_{c2} \dots)$.

Each attribute $a \in \mathcal{A}$ is associated with a set \mathcal{V}_a of possible values. Following the previous example, assigning a constraint on an attribute, for instance, $a_{c1} = \text{'Canada'}$ where $\text{'Canada'} \in \mathcal{V}_{a_{c1}}$ and c_1 denotes the country a building is placed in, specifies the ranking of the tallest buildings in Canada. That is, $(a_{c1}, \text{'Canada'})$ becomes the category for r_{new} .

Let \mathcal{I} be the complete set of interesting categorical attribute. Our objective is to create a classifier \mathcal{C} that can tell whether using a non-numeric categorical attribute as a constraint to a table would lead to an interesting "new" table or not, i.e.,

$$\mathcal{C}(a_c) = \begin{cases} \text{interesting,} & \text{if } a_c \in \mathcal{I} \text{ and } a_c \notin \mathcal{N} \\ \text{not interesting,} & \text{otherwise} \end{cases} \quad (1)$$

In this work, we opt for a classification-based approach using ν -SVM as our classifier. Hence, we first need to determine training data \mathcal{T} of interesting categorical attributes, and we do so by harnessing a set of Wikipedia tables \mathcal{R} . **Based on our assumption, categorical attributes for a specific subject are considered interesting iff we find at least one ranking in Wikipedia that is created by imposing a constraints over that categorical attributes.** Formally, $(a_s, a_c) \in \mathcal{T}$ iff $\exists r, r_{new} \in \mathcal{R}$. Note that the interestingness of a category is bound to the entity type (i.e., class of the subjects), which satisfied by the condition: $r.a_s = r_{new}.a_s$. Then, we learn the model using SVM on the training data and verify how accurate we can predict interesting category for ranking by evaluating it on held-out test data and by relevance assessments obtained from a user study.

2. WORKING MODEL

Creation of Training Data: Algorithm 1 retrieves interesting and non-interesting categorical attributes for a specific ranking subject (i.e., (a_s, a_c)). The constraints of a ranking table is parsed from the title/caption of the table or the title of the Wikipedia page by using propositions from the English dictionary, presented by the function in line 6 in Algorithm 1.

Learning Interesting Categories: In this work, we use the *soft-margin classifier* ν -SVM [4] to learn the interesting characteristics of categorical attributes. ν -SVM suits best for our purpose as it can detect outliers while learning. According to our intuition, conciseness and diversity of a categorical value of ranking entity is important to capture

Algorithm 1 Generating Training Samples

```

4:   nonInteresting  $\leftarrow$  empty list(subject, attribute)
5:   for  $\mathcal{T} \in \text{wikitable}$ s do
6:      $\mathcal{T}.a_s, \mathcal{T}.cons \leftarrow \text{parse\_cons}(\mathcal{T}.title)$ 
7:     constraintsmap[( $\mathcal{T}$ ).cons]  $\leftarrow$  ( $\mathcal{T}.cons, \mathcal{T}.a_s$ )
8:   for  $\mathcal{T} \in \text{wikitable}$ s do
9:     [ $\mathcal{T}.a_c, \mathcal{V}_{A_c}$ ]  $\leftarrow \text{parse}(\mathcal{T}.table)$ 
10:    for  $a_c \in \mathcal{T}.A_c \setminus \mathcal{N}$  do
11:      for  $x \in \mathcal{V}_{A_c}$  do
12:        subjectList  $\leftarrow$  constraintsmap.contains[x]
13:        if  $\mathcal{T}.a_s \in \text{subjectList}$  then
14:          interesting  $\leftarrow$  ( $\mathcal{T}.a_s, a_c$ )
15:          break;
16:        else
17:          noninteresting  $\leftarrow$  ( $\mathcal{T}.a_s, a_c$ )
18:  return interesting, noninteresting

```

human interests. Hence, we use the following three measures as features to feed our learning model.

Shannon Entropy reflects the uncertainty of information content of a discrete random variable. Here, we treat a categorical attribute $a_c \in \mathcal{A} \setminus \mathcal{N}$ as a random variable, where \mathcal{V}_{a_c} is the set of possible values that a_c can hold. Shannon entropy is calculated by $H(a_c) = -\sum_{x \in \mathcal{V}_{a_c}} P(x) \log_2 P(x)$, where $P(x) = \text{count}(x)/|\mathcal{T}|$, $|\mathcal{T}|$ is the size of the ranking table. The normalized entropy is calculated as $\hat{H}(a_c) = \frac{-\sum_{x \in \mathcal{V}_{a_c}} P(x) \log_2 P(x)}{\log_2 |\mathcal{T}|}$, $x \in \mathcal{V}_{a_c}$.

Unlikeability is a diversity measures for categorical attribute that measures how often the observation of random variables differs from one another [2], calculated as $U(X) = 1 - \sum_{x \in \mathcal{V}_{a_c}} P(x)^2$.

Peculiarity is another diversity measure for categorical value used here to measure the peculiarity which is defined by the probability that a randomly chosen categorical value has not been seen previously [2]. It is defined by $D(X) = 1 - \sum_{x \in \mathcal{V}_{a_c}} \frac{\text{count}(x)(\text{count}(x)-1)}{|\mathcal{T}|(|\mathcal{T}|-1)}$.

All three measures are normalized to $[0, 1]$, the values towards 1 indicate few or only one distinct categorical value of the ranking entity and a value towards 0 represents a large (maximum) diversity.

Thus, it is clear that a categorical attribute of an interesting ranking should have more tendency toward having a feature-value near the mid-range of $[0, 1]$, i.e., around 0.5. In contrast, uninteresting ranking would have a tendency toward having a feature value closer to 0 or close to 1.

Clearly, the range of values is responsible for the classification of interestingness measures. Hence, we use the Radial Basis Function (RBF) kernel to map our data space to the dot product space needed for SVM.

3. EXPERIMENTS

Setup: We use the LIBSVM [1] tool to learn the models. 2,744 non-interesting and 158 interesting samples are extracted using Algorithm 1 from 2,045 ranking tables out of Wikipedia. 25% of samples are chosen randomly from each class, and also merged for testing purpose denotes as **TestPos** and **TestNeg**, and **Total**. The remaining non-interesting samples are divided into 10 smaller chunks and merged with the remaining interesting samples to create 10 training files, each containing 323 samples. We learn the respective model for all these files and chose the best performing one, denoted as **M** with accuracy of 80.11% for **Total**. According to our testing samples, the accuracy is a fraction of the correctly classified samples. For our training data, a feasible solution for SVM is found where $0 \leq \nu \leq 0.73$ and

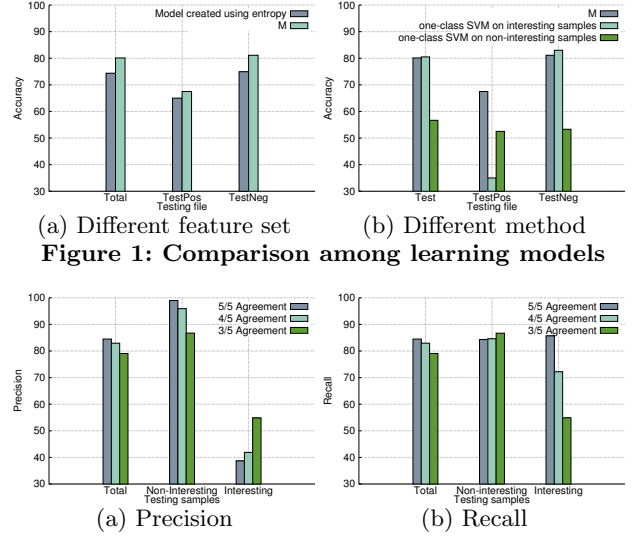

Figure 1: Comparison among learning models

the optimal $\nu = 0.51$. Here, we also present the evaluation of a user study on test set of 130 randomly selected samples of (a_s, a_c) , i.e., classification tasks. We gathered five user relevance assessments per classification task. The accuracy of model **M** is evaluated by using ground truth that is built for different agreement levels of users.

Validation of Models on Test Data: In Figure 1(a), we can see that the accuracy increases at least 5% for all testing files except **TestPos** (2.5%) while using all three features together in learning. As our training data is unbalanced, a common option is to use the simpler one-class SVM model. However, Figure 1(b) shows that the model **M** is a better classifier than the model possible to create from an one-class SVM. **M** is also more robust as it classifies samples from each class better than the other two models.

Results Based on User Study: Figure 2 is showing precision and recall achieved by **M** with varying agreement level of user. We see that for a user agreement of 5/5 the highest accuracy is reached. That is, considering the tasks with 5/5 user agreement as ground truth of the test data, our model correctly identify more than 80% of the test cases (Figure 2). We use Fleiss Kappa to determine the reliability of user agreements. The 5/5 user agreement has a Kappa score 0.28, which denotes fair agreement according to a commonly cited interpretation of Kappa values [3]. Also, the 95% confidence interval for Kappa has range between 0.24–0.32 for the collected user data. These values significantly differ from 0 and, thus, prove the statistical significance of 5/5 agreement level for our user-study.

4. CONCLUSION

From the experimental evaluation, we can conclude that our model of classifying category to capture the interesting ranking performs very well. We also saw that all three features together create a better classification model than the commonly used entropy measure.

ABSTRACT

NoSQL databases provide new opportunities by enabling elastic scaling, fault tolerance, high availability and schema flexibility. Despite these benefits, their limitations in the flexibility of query mechanisms impose a real barrier for any application that has not predetermined access use-cases. One of the main reasons for this bottleneck is that NoSQL databases do not support joins. In this poster we present a solution that efficiently supports joins over such databases. More specifically, we present a query optimization and execution module placed on top of Cassandra clusters that is able to efficiently combine information stored in different column-families. Our preliminary evaluation demonstrates the feasibility of our solution and the advantages gained when compared to a recent commercial solution by DataStax. To the best of our knowledge our approach is the first and the only available open source solution allowing joins over NoSQL Cassandra databases.

1. INTRODUCTION

During the latest years, the explosive growth of data and the emerging requirements for big data management solutions led to the development of NoSQL databases. Among the reasons for the rapid adoption of NoSQL databases is that they scale across a large number of servers by horizontal partitioning of data items, they are fault tolerant and achieve high write throughput, low read latencies and schema flexibility. To achieve all these benefits, the main idea is that you have to denormalize your data model and avoid costly operations in order to speed up the database engine. As such, the NoSQL databases were initially designed to support only single-table queries and explicitly excluded the support for join operations allowing applications to implement such tasks. However, modern applications increasingly require the efficient combination of information from multiple tables and column-families.

To this direction the first approaches are starting to emerge for operators similar to join, based on Map-Reduce such as rank-join queries [1] and set-similarity joins [2]. Rank-join queries try to find the most relevant documents for two or more keywords whereas set-similarity joins are those that try to find similar pairs of records instead of exact ones. However, both these approaches execute joins at the application level using Map-Reduce implementations and the joins implemented do not focus on an exact matching of the joined tuples. This emerging need has also been recently recognized by DataStax, the biggest vendor of Cassandra NoSQL commercial products which recently introduced a commercial join-capable ODBC driver. The company claims that Cassandra can

now perform joins just as well as relational database management systems. However, no results were presented nor the specific join implementation algorithms and optimization techniques..

To fill these gaps, in this poster we present a naïve, yet efficient query optimization and execution module enabling joins over Cassandra NoSQL databases surpassing DataStax's commercial solution and highlighting the differences between NoSQL and relational solutions.

2. PRELIMINARIES

Cassandra is a NoSQL database developed by the Apache Software Foundation. It uses a hybrid model between key-value and column-oriented database. The structure of the database is defined by super-columns and column-families. In this paper the term column-family and table will be used interchangeably although they are not exactly the same.

All stored data can be easily manipulated using the Cassandra Query Language (CQL) which is based on the widely used SQL. CQL can be thought of as an SQL fragment with the following restrictions over the classical SQL:

- *R1.* Joins are now allowed.
- *R2.* You cannot project the value of a column without selecting first the key of the column. Every select query requires that you restrict all partition keys. Select queries restricting a clustering key have to restrict all the previous clustering keys in order. Queries that don't restrict all partition keys and any possibly required clustering keys, can run only if they can query secondary indices. To be allowed to run a query including more than two secondary indices, Cassandra requires that "*allow filtering*" is used in the query to show that you really want to do it. All Cassandra queries that require this run extremely slow and Cassandra's recommendation is to avoid running them. Tables can be stored sorted by clustering keys. This is the only case in which you are allowed to run range queries and *order by* clauses.
- *R3.* Unlike the projection in a CQL SELECT, there is no guarantee that the results will contain all of the columns specified because Cassandra is schema-optional. An error does not occur if you request non-existent columns.
- *R4.* Nested queries are not allowed, there is no "OR" operator and queries that select all rows of a table are extremely slow.

CQL statements change data, look up data, store data or change the way data is stored. A select CQL expression selects one or more records from Cassandra column family and returns a result-set of rows. Similarly to SQL each row consists of a row key and a collection of columns corresponding to the query.

3. QUERY OPTIMIZER & EXECUTION

Our query optimization and execution module can be placed on top of any Cassandra cluster and is composed of the following components, shown in Fig. 1:

a) *Rewriter*: The rewriter accepts the CQL query containing joins and creates the queries for accessing each individual column-family/table. For example assuming that $Q0$ is issued by the user, this module produces as output $Q1$ and $Q2$ as shown in Fig. 1.

b) *Planner*: This component plans the execution of the individual queries as constructed by the rewriter. First it identifies the available indices on the queried column-families and tries to comply with $R2$. For example, if the queries don't restrict all partition keys they can only run if there are available secondary indices on these keys. To satisfy this restriction the planner automatically generates secondary indices on the required fields. In our running example, a secondary index will be automatically generated to the *producedBy.movieID* column.

Figure 1. Components of the optimization & execution module

Besides trying to comply with all Cassandra restrictions the planner identifies which join algorithms should be used for executing the various joins by comparing the cost of left-deep trees. Currently two join algorithms have been implemented: a) a variation of Index-Nested Loops taking advantage of the existing indexes and additionally allowing joins over collection sets – indexed collections of elements (maps, sets and lists) supported after the Cassandra version 2.1; b) the sort-merge join allowing the join to be implemented in one pass over the data when the joined relations are indexed. When joining two column-families, if only one of them has an index on the joined field, the optimizer reads all rows from the non-indexed one and then uses the index for searching the indexed column-family. On the other hand when both column-families are sorted on the join column, the Sort-Merge join algorithm would be faster and is preferred by the optimizer.

c) *Combiner*: This component executes the queries, calculates the join using the selected algorithm and returns the results to the users.

4. EVALUATION & CONCLUSION

All algorithms reported in this paper were implemented as a Java API named CassandraJoins. The API is going to be released soon under an open-source license. To perform a preliminary evaluation of our implementation we used a single Cassandra DataStax Community Server 2.1.5 x64 node running on a system with an I5 Intel Processor, 8GB of RAM on a Samsung SSD 850 EVO. We compared our approach with the Simba-DataStax ODBC 0.7 driver and with a MySQL Server CE 5.6.24. The execution time reported in each case is the average of 50 runs of each query execution.

The first series of experiments we performed tries to join two tables with a join on the indexed field. When we have indices on the joined field the CassandraJoins optimizer is using the Index-Nested Loops join algorithm whereas, when the input relations are sorted, the optimizer uses sort-merge join. We cannot identify the specific algorithm used by Simba-DataStax - the source code is not publicly available. The results are shown in Fig. 2 for different input and

output sizes. We can observe that CassandraJoins is by far more efficient than the Simba-DataStax implementation in all cases. For example, when joining column-families with 2×10^5 rows each and the result is of the same size our approach needs 166 secs whereas Simba-DataStax ODBC driver needs 1087 secs. Obviously, when the selectivity of the query is increased the execution time is decreased. This is reasonable since Cassandra is known to be extremely slow when a query needs to retrieve all rows of a table, whereas it is extremely fast when only a small subset of the rows is selected. In addition, in all cases the implementation of Index-Nested Loops in a relational database (MySQL) is more efficient as shown in the third column of the graphs, whereas when the selectivity of the queries is high, our results are similar. However, we have to note that Cassandra scales linearly in a multi-node environment and we expect that our implementation will have even better results than MySQL when more nodes are used. Finally, to demonstrate the advantages of our implementation compared to a MySQL Database, we performed another experiment trying to join two column-families using collection indices. Since MySQL does not support collection indices the dataset has to be modelled using an additional indexed table. On the other hand Simba-DataStax does not support joins on collections. The results depicted in the last graph show that using CassandraJoins we need 0,01 sec whereas using MySQL we need 0,64 sec.

Figure 2. Results of preliminary evaluation on a single node

To the best of our knowledge our implementation is the only available non-commercial solution implementing joins over Cassandra databases. Our experiments demonstrate the advantages of our solution and confirm that our algorithms run efficiently and effectively. In all cases, we achieved better execution times than the commercial Simba-DataStax Driver currently available and our results are comparable to the execution times achieved in the relational database world. We have to note that our experiments were performed in an environment that favors relational databases (single node cluster). Surprisingly, our implementation is more efficient than relational databases when collection indices are used. The next step is to evaluate our implementation in a multi-node cluster with more data, to integrate our algorithms directly in the CQL language and to implement additional join methods.

ABSTRACT

State of the art RDF stores often rely on exhaustive indexing and sequential (self-)joins for SPARQL query processing. However, query execution is dependent on, and often limited by the underlying storage and indexing schemes. Even though RDF can give birth to datasets with loosely defined schemas, it is common for an emerging structure to be present in the data. In this paper we introduce a novel indexing scheme, called Double Chain Star (DCS), that takes advantage of the inherent structure that is often found in RDF datasets by extending the notion of Characteristic Sets to cater for chain-star joins. DCS essentially reduces pairs of chain-star patterns that typically involve multiple self-joins, to mere index scans. We perform preliminary experiments and show promising results in comparison with Jena TDB and RDF-3X.

Categories and Subject Descriptors

H.2.8 [Information Systems Applications]: Database Management—*Database Applications*

Keywords

RDF, SPARQL, Query Processing, Query Optimization, Performance

1. INTRODUCTION

RDF and SPARQL are W3C recommendations for representing and querying graph data in the Data Web. There exists a rich body of literature for storing and querying RDF, however, many of these do not take advantage of the data's inherent structure in order to accelerate query processing. SPARQL optimizers depend on traditional methods for providing good query plans, including the use of data statistics and cardinality estimation for ordering triple patterns. The assumption of data independence imposes a risk of propagating errors in the planning process, especially in joins that reside deeper in the query plan. This can result in the creation of plans with large intermediate results between joins.

In this paper, we discuss a novel indexing scheme that aims to decrease the effects of bad estimates by quickly filtering triples that collectively participate in multiple joins, in one single scan. We extend the notion of Characteristic Sets, that typically represents the inherent structure of nodes in an RDF dataset, in order to characterize subject-object joins instead of single subject nodes. We call this *Extended Characteristic Sets* (ECS), and we discuss how ECS can be used for the construction of an inverted index, named *Double Chain-star*, that maps ECS's to collections of triples.

2. RELATED WORK

RDF stores often rely on the mapping of triples to relational settings, such as a single table with three columns representing subjects, predicates and objects (SPO) [2], or sets of *property tables* that are used for grouping instances of the same classes [7]. Other approaches include indexing of various SPO permutations. For example, RDF-3X [5] and Hexastore [6] make use of exhaustive indexing which includes all six permutations of subject-predicate-object, while exclusively relying on the indexes for the actual storage. Virtuoso [3] uses a large table for triples (quads), and a combination of full and partial indexes.

Characteristic Sets have been introduced as a way to provide better estimations for join cardinalities [4], and implemented in the RDF-3X high performance triple store. Brodt et al [1] discuss how an SPO index can be used to identify Characteristic Sets (CS) and use them for fast retrieval of star-shaped queries. We propose an extension of CS as a means to store and index triples, and enable scan-based answering of chain-star queries.

3. EXTENDED CHARACTERISTIC SETS

By definition, a Characteristic Set of a subject node s contains all properties p_i that appear in triples with s as subject. More formally, given a collection of triples D , and a node s , the Characteristic Set $S_c(s)$ of s , as given by [4], is:

$$S_c(s) = \{p \mid \exists o : (s, p, o) \in D\}$$

and the set of all S_c for a dataset D is:

$$S_c(D) = \{S_c(s) \mid \exists p, o : (s, p, o) \in D\}$$

The upper bound for $|S_c(D)|$ is $|D|$, but the existence of an inherent structure in RDF data makes the distinct set of Characteristic Sets that appear in real-world data small [4]. We introduce the *Extended Characteristic Set* ECS, as the

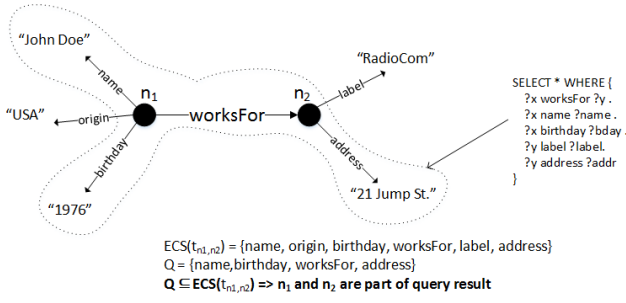

Figure 1: Double chain-star graph consisting of a star-shaped graph around n_1 and a star-shaped graph around n_2 .

union of the properties that appear in the subject t_s and the object t_o of a triple t , i.e. the union of the Characteristic Sets of t_s and t_o :

$$E_c(t) = \{p_1 \cup p_2 \mid \exists o_1 : (t_s, p_1, o_1) \in D \text{ and } \exists o_2 : (t_o, p_2, o_2) \in D\}$$

or simply:

$$E_c(t) = \{S_c(t_s) \cup S_c(t_o)\}$$

The set of all ECS in D is given by:

$$E_c(D) = \{E_c(t) \mid \exists p : (t_s, p, t_o) \in D\}$$

Essentially, $E_c(t)$ helps to quickly identify the largest super-set of graph patterns that contain *double chain-stars* consisting of a star pattern around t_s , a star pattern around t_o , and a subject-object join between t_s and t_o , with t_s being the subject and t_o the object in a common triple. An example double chain-star graph pattern is shown in Figure 1, where nodes n_1 and n_2 are present in the same triple t_{n_1, n_2} as subject and object respectively, and descriptive star patterns are present for each of the two nodes. A Characteristic Set $S_c(s)$ is also an *ECS*, meaning that *leaf* star patterns are also parts of the ECS space. Preliminary experiments have shown $|E_c(D)|$ to be low, specifically for LUBM100 with $\sim 15m$ triples, this number is 109, for 27 distinct CSs.

4. THE DOUBLE CHAIN-STAR INDEX

The Extended Characteristic Sets of a given dataset can act as filters for collections of triples that fulfil a certain query pattern, reducing costly subject-object joins to mere index scans. For this to be feasible, we propose the Double Chain-Star (DCS) index, which is essentially an inverted index that maps collections of triples to ECSs. A triple t is mapped to an ECS if the ECS contains properties that appear in triples of either the subject, or the object of t , and t cannot belong to more than one ECS. Because $ECS(t)$ contains all properties (outgoing edges) from nodes t_s and t_o , it also contains all subsets of properties for these two nodes. Therefore, we can check if an incoming query pattern q is a subset of $ECS(t)$, in which case the nodes of $ECS(t)$ are potential candidates for evaluating q . Physically, each *ECS* can be represented as a bit vector, where each bit represents a property in an (ordered) set of properties P appearing in D . Assuming a dictionary of properties and their position in P , an incoming query q can be split to a set of chain-star sub-queries q_1, q_2, \dots, q_n , and each q_i in q will be represented as a bit vector that instantiates the bits corresponding to the properties in q_i . Therefore, if $q_i \subseteq ECS(t)$, the triples

Table 1: Query execution runtime in seconds.

	Jena	RDF-3X	DCS
LUBM10	248.66	8.24	0.56
LUBM100	timeout	timeout	29.58

mapped to $ECS(t)$ effectively contribute to the evaluation of q_i . An example can be seen in Figure 1. The properties need to maintain their interesting order throughout sequential updates, which is left as future work. Patterns where a subject is joined with more than one objects with their own star-shaped graphs, are subject to cost estimation, in order to determine the order in which the DCS index should be accessed.

We implemented a naive version on top of Jena TDB, with the DCS index kept in-memory, and compared with Jena TDB (default stats-based optimizer) and RDF-3X, measuring wall-clock time (time out after 6 hours), for LUBM10 and LUBM100. For a *DISTINCT ** query with three double chain-star patterns, DCS outperforms the rest by orders of magnitude. For LUBM100 the other two approaches failed to answer completely, while ours needed a few seconds. The results can be seen in Table 1.

5. CONCLUSIONS AND FUTURE WORK

In this paper, we introduce the notion of *Extended Characteristic Sets* and propose the DCS indexing scheme, an inverted index for fast retrieval of double chain-star patterns that are present in many types of queries. Through these structures, we intend to reduce the time spent in sequential (self-)joins of stars forming around subject-object joins into mere index scans, and provide an implementation for storing and querying RDF data that provides faster query answering even for complex types of queries.

ABSTRACT

Entity resolution aims to identify descriptions of the same entity within or across knowledge bases. In this work, we present the Minoan ER platform for resolving entities described by linked data in the Web (e.g., in RDF). To reduce the required number of comparisons, Minoan ER performs blocking to place similar descriptions into blocks and executes comparisons to identify matches only between descriptions within the same block. Moreover, it explores in a pay-as-you-go fashion any intermediate results of matching to obtain similarity evidence of entity neighbors and discover new candidate description pairs for resolution.

1. DESCRIPTION

Over the past decade, numerous knowledge bases (KBs) have been built to power large-scale knowledge sharing, but also an entity-centric Web search, mixing both structured data and text querying. These KBs offer comprehensive, machine-readable descriptions of a large variety of real-world entities (e.g., persons, places, products, events) published on the Web as Linked Data (LD). Although KBs (e.g., DBpedia, Freebase) may be derived from the same data source (e.g., a Wikipedia entry), they may provide multiple, non-identical descriptions of the same real-world entities. This is mainly due to the different information extraction tools and curation policies employed by KBs, resulting to complementary and sometimes conflicting entity descriptions. Entity resolution (ER) aims to identify descriptions that refer to the same real-world entity appearing either within or across KBs [2, 3]. Compared to data warehouses, the new ER challenges stem from the openness of the Web of data in describing entities by an unbounded number of KBs, the semantic and structural diversity of the descriptions provided across domains even for the same real-world entities, as well as the autonomy of KBs in terms of adopted processes for creating and curating entity descriptions. In particular:

- The number of KBs (aka RDF datasets) in the Linking Open Data (LOD) cloud has roughly tripled between

2011 and 2014 (from 295 to 1014), while KBs inter-linking dropped by 30%. The main reason is that with more KBs available, it becomes more difficult for data publishers to identify relations between the data they publish and the data already published. Thus, the majority of KBs are sparsely linked, while their popularity in links is heavily skewed. Sparsely interlinked KBs appear in the periphery of the LOD cloud (e.g., Open Food Facts, Bio2RDF), while heavily interlinked ones lie at the center (e.g., DBpedia, GeoNames). Encyclopaedic KBs, such as DBpedia, or widely used geo-referencing KBs, such as GeoNames, are interlinked with the largest number of KBs [6].

- The descriptions contained in these KBs present a high degree of semantic and structural diversity, even for the same entity types. Despite the Linked Data principles, multiple names (e.g., URIs) can be used to refer to the same real-world entity. The majority (58.24%) of the 649 vocabularies currently used by KBs are proprietary, i.e., they are used by only one KB, while diverse sets of properties are commonly used to describe the entities both in terms of types and number of occurrences even in the same KB. Only YAGO contains 350K different types of entities, while Google's Knowledge Graph contains 35K properties, used to describe 600M entities.

The two core ER problems, namely how can we (a) effectively compute similarity of entity descriptions and (b) efficiently resolve sets of entities within or across sources, are challenged by the large scale (both in terms of the number of sources and entity descriptions), the high diversity (both in terms of number of entity types and properties) and the importance of relationships among entity descriptions (not committing to a particular schema defined in advance). In particular, in addition to *highly similar* descriptions that feature many common tokens in values of semantically related attributes, typically met in the center of the LOD cloud and heavily interlinked mostly using owl:sameAs predicates, we are encountering *somehow similar* descriptions with significantly fewer common tokens in attributes not always semantically related, that appear usually in the periphery of the LOD cloud and are sparsely interlinked with various kinds of predicates. Plainly, the coming up of highly and somehow similar semi-structured entity descriptions requires solutions that go beyond those applicable to duplicate detection. A promising area of research in this respect is cross-domain similarity search and mining [8, 7], aiming to exploit similarity of objects described by different modalities (i.e., text,

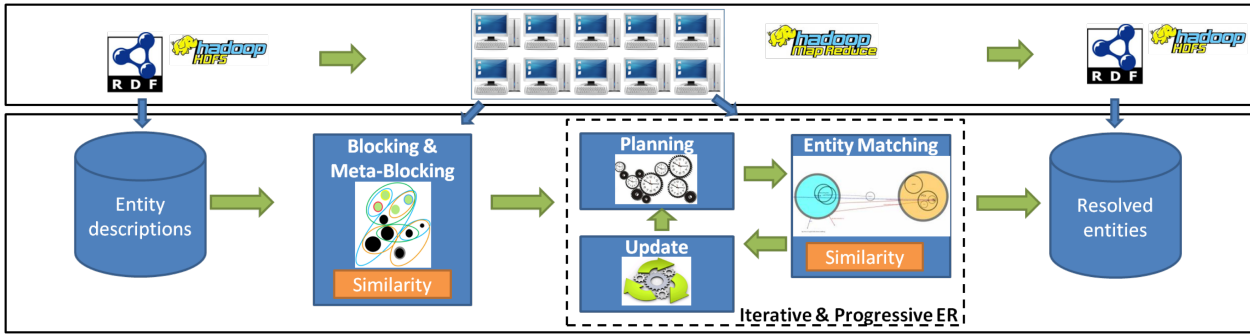

Figure 1: The Minoan ER Framework.

image) and contexts (i.e., facets) and support research by analogy. Such techniques could be also beneficial for matching highly heterogeneous entity descriptions and thus support ER at the Web scale.

We present in this poster the Minoan ER platform for resolving entities described by linked data in the Web (e.g., in RDF). Figure 1 illustrates the general steps involved in our process.

Blocking and Meta-blocking in Minoan ER: We use *blocking* as a pre-processing step for ER to reduce the number of required comparisons. Specifically, blocking places similar entity descriptions into blocks, leaving to the entity matching algorithm the comparisons only between descriptions within the same block.

Typically, token-based blocking algorithms place highly similar descriptions (having many common tokens) in many common blocks; intuitively, the more common blocks two descriptions share, the more likely it is that they match. This leads to many repeated comparisons between the same pairs of descriptions. To overcome this problem, we accompany blocking with *meta-blocking*, which prunes such repeated comparisons. Moreover, meta-blocking aims at discarding comparisons between descriptions that share few common blocks and are thus less likely to match. In Minoan ER, to support a Web-scale resolution of heterogeneous and loosely structured entities across domains, we use algorithms for blocking and meta-blocking that disregard strong assumptions about knowledge of the data schema and rely on a minimal number of assumptions about how entities match (e.g., when they feature a common token in their descriptions or URIs) within or across sources. For doing so, we exploit the parallel processing power of a computer cluster via Hadoop MapReduce, as presented in [5, 4].

Progressive Entity Matching in Minoan ER: Blocking approaches in the Web of data, especially when handling somehow similar descriptions appearing in the periphery of the LOD cloud, may miss highly heterogeneous matching descriptions featuring few common tokens [5]. To overcome that, we focus on exploiting the partial matching results as a similarity evidence for their neighbor (i.e., linked) descriptions. Since this inherently iterative process entails an additional overhead, we are interested in maximizing its benefit, given a computational cost budget. So, we need to estimate which part of the graph is the most promising to explore in the next iteration, in a *progressive* way.

In this respect, Minoan ER focuses on extending the typical ER workflow with a *scheduling phase*, which is responsible for selecting which pairs of descriptions, that have re-

sulted from blocking, will be compared in the entity matching phase and in what order. The goal of this new phase is to favor more promising comparisons, i.e., those that are more likely to increase the targeted benefit. This way, those comparisons are executed before less promising ones and thus, higher benefit is provided early on in the process. The *update phase* propagates the results of matching, such that a new scheduling phase will promote the comparison of pairs that were influenced by the previous matches. This iterative process continues until the cost budget is consumed.

In contrast to existing works in progressive relational ER (e.g., [1]), which consider the quantity of entity pairs resolved, as the benefit of ER, we explore different aspects of data quality, improved through ER. In particular, we are interested in characterizing the quality of the resolved pairs, with respect to the number of descriptions resolved, corresponding to the same real-world entity (targeting attribute completeness), the number of real-world entities resolved (targeting entity coverage), and the number of real-world entity graphs resolved (targeting relationship completeness).

ABSTRACT

Next generation sequencing (NGS) and the recent development of efficient algorithms for genomic analysis are contributing to the understanding of human genetic variation and thus to personalized medicine. Among those genomic analysis, disease-causal gene analysis that finds genes relevant to specific diseases has received much attention. In this paper, we present our work on extending the PostgreSQL open source relational database management system (RDBMS) to efficiently handle genomic analysis. We introduced a new genome data type and a genome type aggregation function that drastically improved the performance of a typical query for disease-causal gene analysis by a factor of 50 to 360.

1. INTRODUCTION

Human beings have a sequence of three billions deoxyribonucleic acid (DNA) molecules which contains some millions of variants called “gene variants” that cause individual variations. Each individual has personal types of gene variants called “genotypes” which are combinations of nucleotide derived from chromosome dipoles. Figure 1 illustrates an example of genotypes. Individual 0 has genotype ‘C/C’ at gene variant 0, and genotype ‘T/C’ at gene variant 1. On the other hand, individual 1 has genotype ‘A/C’ at gene variant 0, and ‘T/T’ at gene variant 1.

Figure 1: Chromosome dipoles of two individuals

The improvement of processing performance and the reduction of running cost of NGS, and the recent development of efficient algorithms for genomic analysis have resulted in an enormous increase in the amount of data of gene variants like SNP (single nucleotide polymorphism) and INDEL (insertion-deletion polymorphism). These gene variants are leveraged in a variety of studies such as cohort study, inheritance history study and disease-causal gene study. Disease-causal gene study aims to find the genes relevant to specific diseases and clarify the reasons of these diseases. The typical processing in such a study is to first filter the

individuals by some patient clinical condition (e.g. case-control), and then, find the genes whose frequency of its genotype is different between the filtered group and the rest. Normally the genetic data is delivered in flat-files (VCF [4]), and the patient information data, for instance, demographic information as gender/race/age, clinical information, and lifestyle information, are usually stored/managed in RDBMS. Recently, some studies integrate the genetic data and the patient data to be managed in RDBMS [1] [2]. Although the RDBMS approach improves the data manageability and usability, the improvement of the procedure and performance of the analysis processing in finding out the genes of interest remains a big challenge because of the very huge amount of gene variants.

In this paper, we present our work on extending the PostgreSQL [3] open RDBMS with a new data type and a new aggregation function called “genome type” and “genome type aggregation function”, respectively. Some preliminary examination shows that our approach is promising and can improve the execution time of disease causal gene analysis processing by a factor of 50 to 360.

2. Conventional Methods

2.1 Database Schema

Figure 2: Conventional database schema

Figure 2 shows the database schema composed of tables that contain the N gene variants ($GV_0 \dots GV_{N-1}$) with the associated genotype for each individual. Note that since there is a limit on the number of columns a table can contain, in this case M , there are N/M tables ($T_0 \dots T_{N/M-1}$) to store all the M gene variants of the individuals. Figure 1 shows also a clinical table (T_c) with information related to n diseases ($D_0 \dots D_{n-1}$) for each individual. Other tables containing information about the patients (lifestyle, demographics, etc.) can also be necessary to properly describe the individuals.

2.2 Naïve Method

A naïve method counts the number of occurrence of each genotype for all the gene variants of patients with a specified disease. SQL 1 shows the SQL statement that calculates the distribution of genotype of a gene variant (GV_0) for patients who have a specified disease (D_0). This query is executed N times (i.e. for each $GV_0 \dots GV_{N-1}$). It takes 1,530ms on PostgreSQL to execute the above query on 150,000 individuals for each gene variant GV_i . For

```
SELECT count(T0.GV0) FROM T0, Tc
GROUP BY T0.GV0
WHERE T0.ID = Tc.ID and Tc.D0 = 'Yes'
```

SQL 1: SQL for naïve method

the usual case of 3,000,000 gene variants, it would take more than 50 days. There are two major reasons for such a long execution time. One is the huge number of gene variants N and thus, the huge number of corresponding SQL queries that have to be processed. The other is the long processing time of the query for the join between T_i and T_c . Note that in real cases the query could contain more joins to include lifestyle and demographics that are usually stored in other tables.

2.3 External Count Method

In order to decrease the number of queries and join operations, a method composed of an SQL that first retrieves all the genotypes of the gene variants for the individuals with a specified disease, and then an external application that counts the number of each genotype using the result of the query, is analyzed.

```
SELECT T0.GV0, T0.GV1, ...T0.GVM-1 FROM T0, Tc
WHERE T0.ID = Tc.ID and Tc.D0 = 'Yes';
```

SQL 2: Pseudo SQL for external count method

SQL 2 shows the SQL statement that retrieves the genotypes of gene variants ($GV_0..GV_{M-1}$) on Table T_0 for the patients with disease D_0 . Note that a similar query is executed N/M times, i.e., for all gene variants tables $T_{0..TN/M-1}$. The result of the SQL queries is input into an external program that counts the distribution of each genotype for all gene variants. It still takes about 5,500s, including both the PostgreSQL processing and the external processing, for the case of 1,000 individuals and 3,000,000 variants. This method still has two problems. First, since there is a limit on the number of columns a table can contain, many tables are necessary to store millions of variants and thus, the costly join processing of those tables with clinical and other tables cannot be avoided. Second, external processing causes a huge amount of data flow from the RDBMS to external application and thus, a high cost transfer time is necessary.

3. Proposed Method

In order to solve these problems, we proposed a method that integrates all the genotypes of the gene variations in a single table, making possible an efficient counting of the genotypes. We created a special database type and a special aggregation function called “genome type” and “genome aggregation function”, respectively.

Gene variants table T_{GV}		Clinical table T_c	
ID	GT	ID	D ₀ , D ₁ , ..., D _n
0	A/A,T/T,.....,C/A	0	Yes No No
1	A/C,T/T,.....,G/C	1	No No Yes
⋮	GV ₀ GV ₁ GV _{N-1}	⋮	

Figure 3: Proposed database schema

Figure 3 illustrates the gene variants table (T_{GV}) with the genome type (GT) column that packs all genotypes of all gene variants for each individual, enabling an efficient storing and scanning of the genotype data for its aggregation. SQL 3 shows the SQL statement with the proposed genome type aggregation function `fjgeno_count()`. Since all the genotypes of the gene variations are contained in GT, the genome aggregation function can efficiently count up through all genotypes of each individual at once. And only

```
SELECT fjgeno_count(TGV.GT) FROM T0
WHERE TGV.ID = Tc.ID and Tc.D0 = 'Yes';
```

SQL 3: SQL for proposed method

a single execution of the join processing with other tables as the clinical table T_c is necessary.

4. Evaluation

We implemented our proposed method on PostgreSQL, and compared its performance with the conventional methods presented in Section 3. We used the machine whose CPU is Xeon CPU E5-2680 0 @2.70GHz x2 and memory is DDR3 128GB.

Figure 4: Execution time for the three methods

Figure 4 shows the execution time per gene variant for the case of 1,000 individuals for the naïve, the external count, and our proposed method, when varying the number of gene variants packed in GT. For the naïve method, the execution time per variant is 13ms, and for the external method is 1.86ms. On the other hand, the execution time for our method improves when increasing the number of packed variants, and it is reduced to 0.035ms which represents an improvement factor of about 50 to 360 over the conventional methods.

5. Conclusion

We proposed a new database type and new aggregation function as extensions to PostgreSQL for genomic analysis. Our preliminary evaluation showed that it can greatly improve the processing time of a typical query in medical genomics study. We are now working on further performance improvements for the genome aggregation function using dictionary and vectorization techniques, which we plan to report in detail in a future paper.

The Best Bang for Your Buckg

When SQL Debugging and Data Provenance Go Hand in Hand

Benjamin Dietrich Tobias Müller Torsten Grust

Universität Tübingen
Tübingen, Germany

[b.dietrich, to.mueller, torsten.grust]@uni-tuebingen.de

ABSTRACT

We report on our ongoing effort to develop *observational debuggers* for SQL. This debugging paradigm—in which the evaluation of selected subexpressions may be “spied on”—fits the nature of query languages, but may lead to observations whose size can overwhelm users. Here, we tackle this challenge with the help of *data provenance analysis*. The analysis identifies exactly those input rows that are material in producing suspect query outputs. Running the debugger on such a minimized input will exclusively yield observations that are indeed relevant in understanding the bug.

1. SPYING ON SQL EVALUATION

SQL queries are prone to bugs much like code written in conventional programming languages. The present work investigates debugging paradigms that fit the declarative nature of SQL and, in particular, shield users from low-level internals (like execution plans, for example). We argue that *observational debugging* [5], an idea rooted in the logic and functional programming communities, is one such paradigm: users *mark* the “suspect” subexpressions—ranging from simple arithmetics to entire subquery blocks—of a buggy SQL query to *observe* their value at runtime. Seeing the difference between the expected and observed evaluation of a subexpression has turned out to be an effective tool in uncovering subtle SQL bugs [3].

A sample debugging scenario is depicted in Figure 1. Tables *cities* and *roads* jointly model a road network in which only selected cities host fueling stations (label  in Figure 1(a), 0/1 in column *fuel* of table *cities*). Which cities can we reach from *Alton* if our car has a maximum range of 100 km before it needs to be refueled? An attempt to answer this question is the recursive SQL query of Figure 3. The query emits table *hops*(*city*, *range*) in which a row $\langle c, r \rangle$ indicates that we can reach city *c* with a residual range of *r* (see Figure 2). The result looks suspicious, though: we are

(a) Simple road network with travel distances and fueling stations (). Which cities can we reach from Alton?

cities	
city	fuel
Alton	1
Brigg	0
Corby	0
Hedon	0
Lewes	1
Magor	0
Neath	0
Olney	0

(b) Table cities.

roads		
here	dist	there
Alton	40	Brigg
Brigg	30	Corby
Hedon	40	Lewes
Lewes	80	Neath
Lewes	70	Magor
Magor	110	Olney
Neath	80	Olney

(c) Table roads.

Figure 1: A debugging scenario: a relational model of cities and their connecting roads, parts of the instance hidden behind . (Disregard the provenance labels  and  until you reach Section 2.)

able to reach *Olney* although the city is farther from the last fueling station (in *Lewes*) than our maximum reach.

Pursuing the observational debugging paradigm, users mark parts of the buggy query ( in Figure 3) to learn about the evaluation of selected subexpressions. Markings typically start out large and then gradually zoom in on query details until the source of the bug can be observed directly. In keeping with the relational data model, the debugger presents observations in tabular form (Figure 4). Given the particular markings ① to ④ of Figure 3, one row in the observation table shows our current location (column ②) and the range available (possibly after refueling, column ④) before we travel *r.dist* kilometers (column ③)

city	range
Alton	0
Brigg	60
...	...
Magor	90
Neath	80
Magor	50
Olney	0
Neath	40

Figure 2: Final (but incorrect) hops table. The \neq identifies one questionable output: we did not expect to reach *Olney*.

```

1 WITH RECURSIVE hops(city, range) AS (
2   VALUES ('Alton', 0)
3   UNION ALL
4   SELECT r.there AS city,
5         h.range + c.fuel * 100 - r.dist AS range
6   FROM   cities AS c, roads AS r, hops AS h
7   WHERE  h.city = c.city
8         AND h.city = r.here
9         AND h.range + c.fuel * 100 >= r.dist
10 )
11 SELECT *
12 FROM   hops;

```

Figure 3: Users place markings (Ⓜ) to observe the evaluation of suspect SQL subexpressions.

to reach the next city (column Ⓜ). At recursion depths 9 and 10 we observe suspicious ranges which exceed the maximum of 100 (see the 160 km range marked by ⚡, for example). This suggests that the query’s range computation is to blame (see [2] for the complete story behind the hunt for the bug of Figure 3).

2. MAKE EVERY OBSERVATION COUNT

Observations may be sizeable, however, and it can be a true challenge to spot enlightening details like ⚡ in Figure 4. The sheer size of the input tables as well as the marking of subexpressions that are *evaluated before* aggregates or filters reduce data volume may lead to huge observations that do not reveal much. Indeed, in Figure 4 the lion’s share of our observations hides behind the ellipses (⋮), the majority of which contribute nothing to the understanding of the bug.

It is here where we propose to join two strands of work that have evolved independently until now. We build on a variant of *data provenance analysis* [1, 4] as follows:

- (1) In the query *output*, users identify one or more suspect cells or rows (see Figure 2 where we use the mouse to identify the questionable city *Olney*).
- (2) Provenance analysis infers those *input* table cells that are material in computing the value *Olney* (*where provenance*, cells labeled Ⓜ in Figure 1(a)) as well as all rows that were inspected to decide that *Olney* is part of the query’s result (*why provenance*, label Ⓜ).

recursion depth	hops AS h city range	SELECT... city range	r.dist	h.range...
0	Alton 0	Alton 0		
⋮	⋮	⋮	⋮	⋮
9	Iford 30 Lewes 60 Lewes 60 Magor 40 Magor 50 Neath 30 Neath 40	Lewes 20 Magor 90 Neath 80	110 70 80	130 160 160 ⚡ 160
10	Lewes 20 Lewes 20 Magor 90 Neath 80	Magor 50 Neath 40 Olney 0	70 80 80	120 120 80
11	Magor 50 Olney 0 Neath 40			

Figure 4: Excerpt of observations made by markings Ⓜ to Ⓜ.

- (3) Remove unlabeled input rows and run the observational debugger on the minimized database instance.

This input minimization will, in general, lead to significantly smaller observations: in the road network scenario, any city or road that does not lie on the path from *Alton* to *Olney* will be removed (see Figure 5 which features a mere 12 rows and hides nothing). Most importantly, the reduced input will still trigger the bug and *any* observation made will be relevant in identifying the bug’s cause—in a sense, after minimization the query will focus on producing the buggy output. We claim that this focus is just what is needed to effectively debug data-intensive computations.

Hand in Hand: Debugging and Provenance Analysis. The practical relevance of this research hinges on the ability to embrace expressive SQL dialects—featuring language constructs like correlation, grouping, window functions, recursion, as well as built-in and user-defined SQL functions. It is these rich queries that are potential sources of obscure bugs.

Our recent work on the efficient value-less interpretation of programs [4] provides a means to derive *where*- and *why*-provenance for such real-world SQL dialects. We are under-way to connect this analysis with the *Habitat* observational debugger for SQL [2] and are positive to be able to make a significant step towards truly declarative and scalable query debugging.

ABSTRACT

Biomedical ontologies play an important role for information extraction in the biomedical domain. We present a workflow for updating automatically biomedical ontologies, composed of four steps. We detail two contributions concerning the concept extraction and semantic linkage of extracted terminology.

1. INTRODUCTION

Biomedical big data raises a major issue: the analysis of large volumes of heterogeneous data. Ontologies, i.e. conceptual models of the reality, can play a crucial role in biomedical fields for automating data processing, querying, and integration of heterogeneous data. Few semi-automatic methodologies to build ontologies have been proposed in recent years. Semi-automatic construction/enrichment of ontologies are mostly achieved using natural language processing (NLP) [1] techniques to assess text corpus. However, besides the existence of various English tools, there are considerably fewer ontologies and tools available in French and Spanish. This shortcoming is out of line with the huge amount of biomedical data produced for several languages, especially in the clinical world. This paper proposes a workflow to enrich biomedical ontologies or terminologies from texts, addressing the lexical/syntactic and semantic complexity of this process. The lexical/syntactic complexity involves the extraction of biomedical complex terms from a specialized text corpus. The semantic complexity is related to concept induction and semantic linkage of new terms. Our methodology has been applied for English, French, and Spanish.

2. PROPOSED APPROACH

Our approach consists of four steps: (I) Term Extraction, (II) Polysemy Detection, (III) Sense Induction, and (IV) Semantic Linkage. The lexical/complexity complexity is tackled by (I), and the semantic complexity is addressed by (II), (III), and (IV).

(I) Term Extraction: We use BIOTEX¹, our application to extract biomedical terms from documents from text databases (e.g.

¹<http://tubo.lirmm.fr/biotex/>

PubMed). This application implements some measures presented in [4] allowing to extract terms that might be added to a biomedical ontology, we called them “candidate terms”.

(II) Polysemy Detection: This step seeks to predict if candidate terms are polysemic. We proposed new features based on statistical measures to characterize our text corpus. They are extracted directly from texts and from a graph itself induced from the text corpus. We used several machine learning algorithms to determine if a term is polysemic or not. Totally, 23 features were proposed, 11 direct and 12 from the induced graph. Their effectiveness showed an F-measure of 98%.

(III) Term Sense Induction: The objective of this step, is to induce the multiple or unique sense(s) (concept) of polysemic and not polysemic candidate terms. The senses are extracted according to the context of terms. For this, we execute two tasks. First, (a) *Number of senses prediction*: This task is performed only for the candidate terms predicted as polysemic in the previous step. Then, (b) *Clustering for concept induction*: This task executes a clustering algorithm taking as input the predicted k , then for each cluster it selects the most important features, which represent the induced concept. Note that $k = 1$ when the candidate term is not polysemic.

The prediction of the sense number of a term falls directly in clustering-based issues. In clustering tasks, one of the most difficult problems is to determine the number of clusters k , which is a basic input parameter for most clustering algorithms. In the biomedical domain, according to the statistics on UMLS (see Table 1), polysemic terms trend to be linked to only 2 and 5 senses (i.e. 2 and 5 clusters). Therefore, as we aim at identifying the possible senses for a new biomedical candidate term, we will limit the number of senses between 2 and 5. Table 1 shows the details of polysemic terms statistics in UMLS and MeSH for English, French, and Spanish. The English version of UMLS contains about 9 919 000 distinct terms of which about 54 257 are polysemic. It means that approximately for 200 biomedical terms there exists just 1 polysemic term.

# of Senses k	UMLS			MeSH		
	EN	FR	ES	EN	FR	ES
2	54 257	1 292	10 906	178	11	0
3	7 770	36	414	1	0	0
4	1 842	1	56	0	0	0
5+	1 677	1	18	0	0	0

Table 1: Details of Polysemic Terms in UMLS and MeSH.

To evaluate the clustering solutions, there exist two kinds of quality indexes [2]: external and internal. External indexes use pre-labelled data sets with “known” cluster configurations. Internal indexes are used to evaluate the “goodness” of a cluster configuration without any priory knowledge of the clusters, in our case, we propose to focus on internal indexes. We use the following measures: (i) the intra-cluster similarity (*ISIM*), and (ii) the inter-cluster

similarity (*ESIM*), in order to create new indexes. They focus on choosing the minimum or maximum value. That allows to have an idea if the reached clusters are homogeneous. New internal indexes are described in Table 2. **Notation:** $|S_i|$ is the number of objects assigned to the i_{th} cluster.

1) Average of ISIM: represented as a_k , is the average of the <i>ISIM</i> value of each cluster of a solution clustering with number of clusters = k . $max(a_k) = max\left(\frac{\sum_{i=1}^k ISIM_i}{k}\right)$
2) Average of ESIM: represented as b_k , is the average of the <i>ESIM</i> value of each cluster of a solution clustering with number of clusters = k . $min(b_k) = min\left(\frac{\sum_{i=1}^k ESIM_i}{k}\right)$
3) Average of the difference between ISIM and ESIM: represented as c_k , is the average of the difference between <i>ISIM</i> and <i>ESIM</i> multiplied by the number of objects in such cluster $ S_i $. $max(c_k) = max\left(\frac{1}{k} \sum_{i=1}^k S_i \times (ISIM_i - ESIM_i)\right)$
4) Division between the ISIM sum and ESIM sum: represented as e_k , is the division between the sum of <i>ISIM</i> multiplied by the number of objects in such cluster $ S_i $, and the sum of <i>ESIM</i> multiplied by the number of objects in such cluster. $max(e_k) = max\left(\frac{\sum_{i=1}^k S_i \times ISIM_i}{\sum_{i=1}^k S_i \times ESIM_i}\right)$
5) Global objective function divided by the logarithm: represented as f_k , is the division between the value of the average of <i>ISIM</i> and the logarithm of k to base 10. $max(f_k) = max\left(\frac{\frac{\sum_{i=1}^k ISIM_i}{k}}{\log_{10}(k)}\right)$

Table 2: New Internal Indexes.

For this purpose, we represented our text corpus of two different manners: (i) bag-of-words representation, and (ii) graph representation. We used clustering algorithms and computed the new internal indexes.

(IV) **Semantic Linkage:** This step aims to add a candidate term in an existing biomedical ontology, i.e., how to find the correct position in the ontology. (1) Creation of term co-occurrence graph with terms extracted in (I), selecting only the MeSH neighborhood of a candidate term, then (2) we evaluate the semantic similarity of the candidate term with: (i) its MeSH neighbors, and, (ii) the fathers/sons of those neighbors in MeSH ontology. The semantic linkage is based essentially on a context similarity using the cosine measure between the new biomedical candidate term and those appearing in an ontology. At the end, a list of terms is proposed where the new biomedical candidate term could be positioned.

3. DATA AND RESULTS

In this section, we report experiments done to evaluate the performance of our proposal for (ii) prediction of sense number, and (ii) semantic linkage.

(i) **Prediction of Sense Number:** We will describe the text database used and the experiments in the following paragraphs.

Text corpus: MSH WSD² [3], which is composed of 203 polysemic entities in English, linked to a number of concepts (2,3,4,5). This data set is well-known in Word Sense Disambiguation literature applied to the biomedical domain.

Results: We use five well-known clustering algorithms implemented in the CLUTO³ software, such as: *rb*, *rbr*, *direct*, *agglo*, *graph*. In general, bag-of-words and graph representations obtain similar accuracy values. For these two cases, the maximum value is 93.1% obtained by $max(f_k)$ index (See Table 2). Which means that for 100 terms, our approach can determine correctly the number of concepts of 93 terms.

(ii) **Semantic Linkage:** *Text corpus:* We collect 60 MeSH terms that have been added between 2009 and 2015, for instance the term “*corneal injuries*”. Each MeSH term will represent a “*biomedical candidate term*”. Then, we retrieve the context of these terms using PubMed, this context is composed of 333 073 311 tokens. Then, we create a co-occurrence graph per term from the retrieved context.

²<http://wsd.nlm.nih.gov/>

³<http://glaros.dtc.umn.edu/gkhome/cluto/cluto/overview>

Results: We use cosine similarity between contexts and we propose 10 positions to add candidate terms in the MeSH ontology. For instance, we take the term “*corneal injuries*” added in MeSH between 2009 and 2015. Its synonyms in MeSH are *corneal injury*, *corneal damage*, and *corneal trauma*. Its fathers are *corneal diseases* and *eye injuries*. Then, we apply our methodology to locate “*corneal injuries*” in MeSH. Table 3 shows the first 10 best propositions done by our methodology. From our 10 propositions, 5 are correct, i.e. we found the correct synonyms and fathers of “*corneal injuries*” in MeSH version 2015 (yellow rows).

N°	Where	Cosine	N°	Where	Cosine
1	<i>corneal injury</i>	0.4251	6	<i>eye injuries</i>	0.3681
2	<i>corneal damage</i>	0.4181	7	<i>amniotic membrane</i>	0.3639
3	<i>chemical burns</i>	0.4081	8	<i>re-epithelialization</i>	0.3588
4	<i>corneal diseases</i>	0.3696	9	<i>corneal trauma</i>	0.3582
5	<i>corneal ulcer</i>	0.3689	10	<i>wound</i>	0.3472

Table 3: Propositions about where to add the term *corneal injuries*.

Table 4 shows the precision of the number of terms which have at least 1 correct proposition with our methodology for the *Top 1*, *Top 2*, *Top 5* and *Top 10* propositions; taking into account the paradigmatic relations, i.e. synonyms, hyperonyms (fathers), and hyponyms (sons). For instance, the yellow cell shows that there exist at least 1 correct proposition (i.e. existent in MeSH ontology) for the 36 of the 60 terms (i.e. 40%).

<i>Top 1</i>	<i>Top 2</i>	<i>Top 5</i>	<i>Top 10</i>
0.333	0.400	0.500	0.583

Table 4: Precision of the number of terms which have at least 1 correct proposition with our methodology.

4. CONCLUSIONS AND FUTURE WORK

In this paper, we present an entire workflow to enrich biomedical ontologies. We focus on the last two steps of the global process. We presented new internal indexes to predict the number of clusters (number of senses) for a new biomedical candidate term. They are based on the clustering task by using bag-of-words and graph approaches. Another contribution is to find the right position in an already established ontology for new biomedical terms associated with their senses. We extracted the possible relations for a term. Those were based only on the similarity context, using the cosine measure between contexts.

A perspective of this work is to extract the type of relations. This could be performed with the linguistic patterns (e.g. the verbs used between two terms) and the associated contexts.

ABSTRACT

Mining dynamic influence in evolving entities, which provides insights into the interaction and causal relations among entities, is an important and fundamental data mining task. Meanwhile, nowadays pervasive sensors in a variety of contexts give rise to the development of many distributed real-time computation systems intended for massive time series streams. In this paper, we focus on mining dynamic influence from time series data generated by entities via such a distributed real-time computation system. The proposed D²InfMiner framework encompasses a statistical lead-lag correlation based influence detection module and an on-line model for dynamic influence inference. We implement D²InfMiner framework based on Apache Storm.

Keywords

Time series, Influence mining, Distributed data processing

1. INTRODUCTION

For our contemporary interconnected and dynamic changing world, dynamic influence in evolving entities described by time series is fundamental knowledge that helps people understand the behaviours of involved entities. For instance, as massive powerful and various sensors are becoming prevalent in our daily life (e.g., mobile phones, sensor networks, smart meters and etc.), influence among the time series generated by these sensors reflects the real-time status of the carriers and their interactions. Moreover, such quickly and continuously increasing amount of real-time data leads to the development of many distributed real-time computation systems [1], analogous to MapReduce ecosystem designed for large-scale static data.

This paper aims at addressing the problem of mining evolving entity influence based on such a new emerging distributed real-time computation paradigm (DisMineInflu problem). DisMineInflu problem is of great value to various applications such as event/anomaly

detection, trend prediction, casualty analysis and so on. For instance, for data-driven event detection in performance monitoring of data centres, when an event is detected from the performance time series (e.g., network I/O) w.r.t. a certain server, using our proposed dynamic influence mining framework, operators can quickly identify from large-scale of servers which one(s) are highly probable to be affected by this event in a certain time and then respond in advance. It is also especially applicable in the financial markets and social data analysis [5–7].

Specifically, our proposed distributed data mining framework should be able to tackle the following challenges. Contrary to static influence mining, since new arriving observations of time series from evolving entities are continuously distributed into different computing nodes of a cluster, mining dynamic influence via the distributed real-time computation system requires a computation and communication efficient solution. Otherwise the system would encounter bottlenecks, which lead the influence detection to lag further and further over time and report stale results [1]. Another challenge lies in modeling the dynamic influence through time series. Since the evolving data could be quite volatile during some periods or events [8], the proposed framework should entail a statistical model responsible for providing stable influence inference. How to efficiently on-line maintain this model to capture the dynamic nature of influence is also non-trivial.

Contributions: This paper is the first work that proposes a truly distributed and real-time solution for DisMineInflu problem. The approach in [6] assumes that the underlying influence relationships are static. [5, 7, 8] focus on mining influence in a centralized way and do not consider the data communication overhead in the distributed environment as well as correlations among time series of entities. Overall, this paper makes the following concrete contributions: we formally define the problem of continuously mine dynamic influence from time series yielded by evolving entities based on a distributed real-time computation system (DisMineInflu problem). The D²InfMiner framework is proposed to optimize both communication and computation cost as well as providing statistical inference of influence for DisMineInflu problem. We implement D²InfMiner framework based on Apache Storm.

2. PROBLEM DEFINITIONS

In this section, we formulate the DisMineInflu problem.

2.1 Distributed Real-time Computation Engine

In a typical cluster of a distributed real-time computation engine [1], *Topology* is a job submitted to the cluster, which is a program-described directed acyclic graph (DAG). The vertexes are user-defined processing elements denoted by *boxes* and the communication between boxes is dictated by the edges in the topology.

A topology is executed to continuously process tuples. Each box has a user specified number of *tasks* denoted by *parallelism* of the box and such tasks are executed in parallel to process the tuples sent to this box. *Shuffling function* is a function between two boxes, which determines to which task of the connected box a tuple from the preceding box should be sent.

Figure 1: The topology of dynamic influence mining in a distributed real-time computation system

We use n to denote the total number of entities continuously feeding time series streams to the cluster. For an entity i ($1 \leq i \leq n$), let s_i denote the sequence of discrete real-valued observations $s_{i,t}$ (t represents a time instant) of this entity's attribute. The sliding window of length h ending at time instant t of entity i is denoted by $s_i^t = (s_{i,t-h+1}, \dots, s_{i,t})$ and $s_i^t \in \mathbb{R}^h$.

2.2 Problem Statement

In this paper, we utilize statistical lead-lag correlations, namely Pearson correlation and Spearman correlation to measure the influence between time series of entities [4, 8].

DEFINITION 2.1 (LEAD-LAG CORRELATIONS). Define a generic correlation function for sliding windows $s_i^{t_1}$ and $s_j^{t_2}$ of time series of two entities i and j as $\text{corre}(s_i^{t_1}, s_j^{t_2}) = \frac{(s_i^{t_1} - \mu(s_i^{t_1})\mathbb{1}) \cdot (s_j^{t_2} - \mu(s_j^{t_2})\mathbb{1})}{(h-1)\sigma(s_i^{t_1})\sigma(s_j^{t_2})}$

where $\mathbb{1}$ is all one vector ($\mathbb{1} \in \mathbb{R}^h$), $\sigma(s_i^{t_1})$ and $\mu(s_i^{t_1})$ are the sample standard deviation and mean of the elements in $s_i^{t_1}$, respectively [4]. Assume $t_1 < t_2$ and $\text{corre}(s_i^{t_1}, s_j^{t_2})$ measures the correlation between time series i and j with lag $\tau = t_2 - t_1$.

Pearson correlation coefficient $\rho_{i,j}^{t_1,\tau}$, which evaluates the lagged linear relationship, is defined as follows [4]: $\rho_{i,j}^{t_1,\tau} = \text{corre}(s_i^{t_1}, s_j^{t_2})$

Spearman correlation $\xi_{i,j}^{t_1,\tau}$, which measures the strength of lagged monotonic relationship is defined as: $\xi_{i,j}^{t_1,\tau} = \text{corre}(\mathbf{r}_i^{t_1}, \mathbf{r}_j^{t_2})$, where the entries of $\mathbf{r}_i^{t_1}$ are the ranks of the corresponding entries in original $s_i^{t_1}$ [4].

For a certain application, users can choose either Pearson or Spearman correlation to measure the influence in evolving entities as defined below:

DEFINITION 2.2 (CORRELATION BASED INFLUENCE). Given an application-specific correlation threshold ϵ , for the time series of entities i and j ($1 \leq i, j \leq n$), entity i has influence on entity j at time t_1 with lag τ if $\rho_{i,j}^{t_1,\tau}$ (or $\xi_{i,j}^{t_1,\tau}$) is significantly above ϵ .

Intuitively, correlation based influence evaluates to what extent entity j will have a correlated trend with i in time ℓ [3, 8]. For simplicity, we call it influence in the rest of paper.

Now the DisMineInflu problem is formulated as:

DEFINITION 2.3 (DISMINEINFLU PROBLEM). Assume n time-series streams collected from corresponding n entities are continuously arriving and distributed to different nodes of a distributed real-time computation system. DisMineInflu problem requires to mine the following information for each entity:

(1) continuously report the entities on which it has influence within a maximum lag ℓ ;

(2) on-line maintain a statistical model over the detected dynamic influence such that the probability that certain entities will be impacted within maximum lag ℓ can be inferred.

The maximum lag ℓ represents the temporal range of users' interest to model the dynamic influence and also indicates how far in advance users want to predict the future based on detected influence. In real applications, due to the dynamic nature of evolving entities and observational errors, the yielded time series often embraces volatile or sudden changed influence [7, 8]. The statistical model built on the real-time detected influence from sub-problem (1) enables to discover significant and stable influence in entities. It can also serve for event and anomaly detection [2], influence prediction and so on [5, 7, 8].

3. DISTRIBUTED DYNAMIC INFLUENCE MINER

Figure 2: Illustration of key components in the topology

In this section, we briefly describe the proposed D²InfMiner framework whose topology is shown in Figure 1. Box_pre is in charge of maintaining sliding windows and preparing the tuples for PAS-shuffling. Box_influ collects the data sent by PAS-shuffling and calculates the qualified lead-lag correlations based on hypercube computation pruning. Refer [3] for details of Box_pre, Box_influ and PAS-shuffling. Then Box_model builds a beta-distribution based Bayesian approach to estimate the probability of entity i 's influence on entity j at certain time instances. Figure 2 depicts some details of D²InfMiner framework.

ABSTRACT

KIWI is a SQL-on-Hadoop system enabling batch and interactive analytics for big data. In database systems, materialized views, stored pre-computed results for queries, are one of the most commonly used techniques to improve the query processing speed. However, the key challenge in using materialized views is maintaining their freshness as base data changes. This paper introduces a new approach for accelerating OLAP query processing using query workload statistics and *query column sets* instead of materialized views. We present an architecture of SQL-on-Hadoop system using query column sets of original tables in database. The experimental results demonstrate that our system can provide improved performance by 1.77x on average in terms of TPC-H query processing.

Keywords

Column Sets; SQL-on-Hadoop; OLAP; Big Data Analytics

1. INTRODUCTION

Data warehouse (DW) on Hadoop has rapidly gained popularity and is now being used intensively by *business intelligence* (BI) users in enterprises as well as scientific institutions. SQL-on-Hadoop (SoH) is a class of "Big Data" analytics systems that combine established SQL-style querying with Hadoop-based data warehouse [4]. Most of the Online Analytical Processing (OLAP) query workloads in BI applications are long-running batch workloads that are read-mostly and run repeatedly [1]. *Materialized views* are widely used to facilitate fast queries on large datasets. However, one of the most challenging aspects of using materialized views is maintaining their freshness as base data changes.

Sampling refers to the commonly used technique of evaluating the queries from a small random sample of the original database [1, 3]. Typical OLAP query processing approaches exploit two sampling methods to construct the samples, such as, *horizontal* sampling (or row sampling) and *vertical* sampling (or column sampling) [2]. Given a table T with r rows R_1, \dots, R_n and c columns C_1, \dots, C_m , in horizontal sampling, let $S_h = \{R_i, R_{i+1}, \dots, R_{i+l}\}$, where $i \leq i+l \leq r$, denote a *row set* that consists of l rows in T . In vertical sampling, let $S_v = \{C_j, C_{j+1}, \dots, C_{j+k}\}$, where

$j \leq j+k \leq c$, denote a *column set* that consists of k columns in T . A query q often need to scan fully or partially all data items in a row set or a column set S_q of T . If data items in S_q have been materialized, for q , need to scan only materialized items instead of full table T . In case of column sampling, because the number of columns in S_q is often much smaller than c , scanning would be done much faster. In our work, we select vertical sampling method to accelerate OLAP query processing on large-scale dataset.

KIWI¹ is the proposed SoH system, which runs on hundreds of machines in existing Hadoop cluster. The ultimate goal of our work is to provide a SoH system, which can support interactive analytics as well as deep (batch) analytics. *Sweet KIWI* is a statistics-driven query processing engine in order to support deep analytics at scale.

Main contributions: The contributions of our work can be summarized as follows.

- *Dual-Mode Analytics:* The proposed SoH system supports *interactive* analytics as well as MapReduce-based *batch* processing in the unified KIWI architecture.
- *Statistics-Driven OLAP Acceleration:* We introduce a OLAP query acceleration method using query column sets to support deep analytics at scale.

2. SYSTEM OVERVIEW

This section focuses on the overall architecture for query processing engine using query column set and describes two main components in the proposed system architecture.

Query Workload Analyzer: One common assumption about query workloads is that future queries will be similar to historical queries [2]. This component is responsible for analyzing a set of historical query workloads to classify the frequently used queries in the past. In order to construct the query column sets, we extract the meta-data for query column sets over the entire original tables. The set of query column sets are updated both with the arrival of new data, and when the query workloads changes.

Query Column Sets Constructor: This block maintains the query column sets as cache tables, and manages the mapping data between the original tables and the cache tables. Query column sets are created, and updated based on statistics collected from the base data and historical queries. When a query arrives at runtime, it is re-written to run against the cache tables instead of the original tables. The KIWI workload manager evaluates the query augmented with cache table selection operations at runtime.

Figure 1 illustrates query processing workflow in our system using the query column sets. In the first step, the query workload

¹KIWI is the abbreviation for "Key Impact on data Warehouse Infrastructure", which is our project code name.

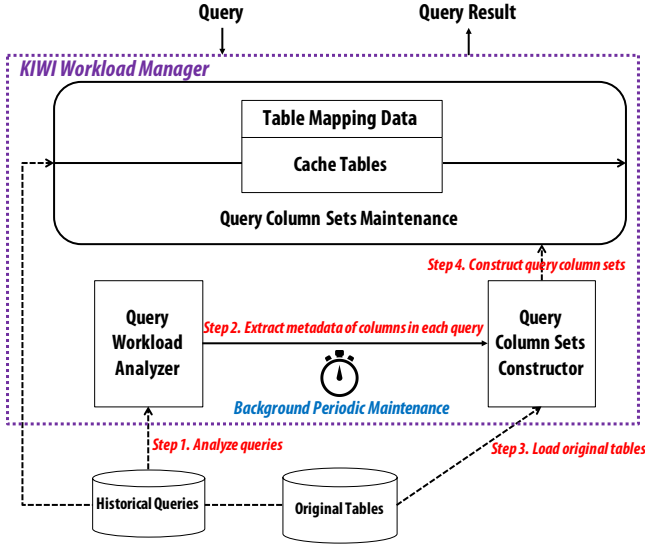

Figure 1: Sweet KIWI Architecture.

analyzer performs historical query analysis. In the second step, it extracts metadata of columns in each query. In the third step, the query column sets (QCS) constructor loads original tables in database to create query column sets. Finally, the QCS constructor inserts the QCS tables and the table mapping data into the database.

2.1 Query Column Sets

Let $\xi(T, S)$ be the memory space needed to store all data items in a column set S of a table T . Let φ be the storage system's space limit for materialized column sets. Let ω be possible column sets of table T . The sum of the memory space of possible column sets, $\sum_{S_i \in \omega} \xi(T, S_i)$ is exponentially large. Let Q_p be the set of queries issued in the past. Let $\mathcal{V}(T, S_i)$ be the value obtained for future queries if S_i is materialized.

Problem Definition: Given a table T and a query Q , find a collection of optimal column sets, $S_{opt} = \{S_1, \dots, S_k\}$ consisting of k column sets, such that $\sum_{S_i \in \omega} \xi(T, S_i) \leq \omega$ and $\mathcal{V}_{opt} = \sum_{S_i \in \omega} \mathcal{V}(T, S_i)$ is maximized.

Algorithm 1 Find optimal column sets (S_{opt}).

```

1: procedure FINDOPTIMALCOLUMNSETS( $S_a, Q$ )
2:   List $\langle S \rangle L_s = \text{constructColumnSets}(S_a, Q)$ ;
3:    $L_s.\text{sortByAppearanceFrequency}(\text{DESCENDING})$ ;
4:   for each node  $S_j \in L_s$  do
5:     if  $\sum_{S_i \in S_{opt}} \xi(T, S_i) + \xi(T, S_j) > \omega$  then return
6:     else
7:        $S_{opt}.\text{add}(S_j)$ ;
8:        $S_a.\text{remove}(S_j)$ ;
9:     end if
10:  end for
11: end procedure

```

Our Approach: From the set of historical queries Q_h extracts a set of distinct column sets S_a that appear in Q_h . $\forall S_i \in S_a$, compute the memory space $\xi(T, S_i)$, remove from the column set S_a if $\xi(T, S_i) > \omega$. $\forall S_i \in S_a$, compute the appearance frequencies $f(S_i)$, remove from the column set S_a if $\xi(T, S_i) > \omega$. Let n be the number of column sets in S_a . For an arbitrary column set S ,

$\xi(T, S)$ can be approximated as:

$$\xi(T, S) = r \times \sum_{i=1}^{|S|} \mathcal{I}(C_i) \quad (1)$$

where r denotes the number of rows in T , $|S|$ denotes the number of columns in S and $\mathcal{I}(C_i)$ denotes the average size of a data item in C_i (e.g., if data type of C_i is double, then $\mathcal{I}(C_i)$ is 8 bytes). **Algorithm 1** shows how optimal column sets, S_{opt} , can be evaluated progressively for a given query Q . The time complexity of this algorithm is $O(n \log n)$, where n is the size of the database.

3. EXPERIMENTAL RESULTS

To evaluate the performance of the KIWI for analytic workloads, we loaded the industry-standard TPC-H data set at scale factor 10 on a node. The server has dual 2.66GHz Intel Xeon CPUs with 128GB RAM, and runs Mac OS X. We compared the wall time of each TPC-H query between original DB and QCS DB.

Table 1: Runtime for TPC-H queries (unit: seconds)

Query	Q1	Q2	Q3	Q4	Q5	Q6	Q7	Q8
Original DB	137	18.6	130	181	28	174	91	176
QCS DB	68.8	11.6	67.9	123	17	84.4	62	87.9

The experimental results demonstrate that our system can provide improved performance in terms of query processing speed on TPC-H 10GB dataset. There were performance improvements of 1.77x on average compared to the original DB as shown in Table 1.

4. CONCLUSION

We present a statistics-driven OLAP acceleration in SQL-on-Hadoop system architecture for data-intensive applications. Our main contribution in this work has been to propose a new unified approach for supporting *dual-mode* (interactive and deep) analytics at scale. Our work concludes with the following take-away messages: (1) It is beneficial to have an *unified* query processing engine in the KIWI SQL-on-Hadoop system, (2) *Sweet KIWI* is a general purpose system that constructs the query column sets of historical queries for deep analytics, and (3) the vertical sampling method using *query column sets* is intuitive to use.

Acknowledgments. This work was supported by ETRI R&D program ("Development of Big Data Platform for Dual Mode Batch · Query Analytics, 16ZS1400") funded by the government of South Korea.

ABSTRACT

Mobile location tracking becomes ubiquitous in many applications, which raises great interests in trajectory data analysis and mining. Most existing work tackled the problem of offline trajectory pattern mining. Dynamic discovery and updates of patterns in trajectory data streams in (quasi) real time is a more complex task. In this paper, we propose an incremental algorithm to solve this problem, while maintaining the evolution of the patterns as well as the membership of the moving objects to their patterns.

1. INTRODUCTION

The huge volume of collected trajectories opens new opportunities for discovering the hidden patterns about mobility behaviors. These patterns may apply to characterize individual mobility as well as groups sharing similar trajectories for a certain time period. Usually, this analysis is done off-line, i.e., by applying data analysis and mining techniques on the previously collected data [1]. This allows characterizing the past movements of the objects but not the current mobility patterns. Nowadays, many services exist that involve moving objects (e.g., persons, vehicles, animals) to report their trajectory continuously (e.g., every second or every minute). Analyzing these data in real time may bring a real added-value in the comprehension of the city dynamics, and the detection of regularities as well as anomaly, which is essential for decision making. Among these patterns, we consider in this paper the trajectory group constitution and evolution, based on sub-trajectory cluster analysis. Such discovery may help the search for effective re-engineering of traffic, or dynamically detecting events or incidents, e.g., at a city level.

One important property of tracking application is the incremental nature of the data. The data will grow to reach a huge size as time goes. Finding patterns in these data in (quasi) real time is challenging. Since all the tracked moving

Figure 1: Steps of our proposed framework

objects change their positions over time, movement patterns also evolve in time. Furthermore, new moving objects may start sending their positions while others may stop. There exist approaches for online clustering of moving objects position, but they are restricted to instantaneous positions. Subsequently, they fail to capture the displacement behavior along time. By continuously tracking moving objects sub-trajectories at each time window, rather than just the last position, it becomes possible to gain insight on the current behavior, and potentially detect suspicious behaviors in real time. Although analyzing historical (sub)trajectory data is the majority of mobility patterns approaches today (including trajectory clustering, flocks, convoys, swarms, gathering [1]), no solution exist for clustering and maintaining clusters of sub-trajectories in real time. That is why we believe that our study is relevant.

In this paper, we address the problem of online discovery of mobility patterns and their evolution by tracking the sub-trajectories of moving objects at each time window. To solve this problem, we propose a framework discussed on the next section. Since all the objects change their sub-trajectories data from time to time, new moving objects appear as well as others disappear from the system during a time window. We define a new structure, called micro-group, to incrementally maintain the relationship among moving objects.

2. FRAMEWORK

Our framework (see Figure 1) follows these main steps: (i) collect trajectory data stream at each time window, (ii) apply the similarity measure, (iii) maintain the micro-group(s), and (iv) discover the mobility patterns.

A trajectory is a sequence of the locations of a moving object at each time-stamp and is denoted by $TR_j = p_1 p_2 \dots p_r \dots p_{len_j}$. Here, p_k ($1 \leq k \leq len_j$) is a point (x_k, y_k, t_k) in a three dimensional space, where (x_k, y_k) indicates the

location of the object at time t_k . The length len_j of a trajectory can be different from those of other trajectories.

First step. Consider $i = [t, t + \delta t]$ be the time window observed for the set of moving objects sub-trajectory I_i . Let $I_i = \{(o_1, ST_{1,i}), (o_2, ST_{2,i}), \dots, (o_n, ST_{n,i})\}$, where $ST_{j,i}$ is the sub-trajectory of the moving object o_j on I_i . Therefore, I_i is the stream at the time window i .

Second step. To measure the similarity between two moving objects sub-trajectories $ST_{k,i}, ST_{j,i}$ at the time window i , we implement the synchronous Euclidean distance, which accounts for time, space, and direction. However, our framework is suitable to any distance function for trajectories. Through this paper, $distance(ST_{k,i}, ST_{j,i})$ denotes the distance function between sub-trajectories.

From a group of moving object sub-trajectories $S_i = \{(o_1, ST_{1,i}), (o_2, ST_{2,i}), \dots, (o_m, ST_{m,i})\}$ at the time window i , we define the representative trajectory as a pair composed by one moving object and its sub-trajectory which is similar to the major behavior of S_i . To choose $(o_j, ST_{j,i})$ as the representative, our approach checks the number of moving objects that have their sub-trajectory similar to $ST_{j,i}$ and also uses a Gaussian kernel function (our voting function) to estimate the representativeness of $ST_{j,i}$. This voting function is also used on [2], and it has been widely used in a variety of applications of pattern recognition.

Definition 2.1. For a set of moving object sub-trajectory $S_i = \{(o_1, ST_{1,i}), (o_2, ST_{2,i}), \dots, (o_m, ST_{m,i})\}$ at the time window i , ρ be a representativeness threshold, ϵ be a given distance threshold and τ be a size/density minimum threshold, $(o_j, ST_{j,i})$ is a **representative trajectory** of S_i if and only if:

1. $\forall(o_k, ST_{k,i}) \in S_i$,

$$\text{voting}(ST_{j,i}, ST_{k,i}) = e^{-\frac{distance^2(ST_{j,i}, ST_{k,i})}{2\sigma^2}} > \rho$$
2. $N_\epsilon(o_j) = \{(o_k, ST_{k,i}) \in S_i | distance(ST_{j,i}, ST_{k,i}) \leq \epsilon\}$, then $|N_\epsilon(o_j)| \geq \tau$

The parameter σ shows how fast the function "voting" decreases with the distance. The intuition behind the relationship of "distance" and "voting" function is: If "distance" is close to zero, the "voting" is close to its maximum value. This means that if $ST_{j,i}$ is very close (in time, space and direction, for example) to $ST_{k,i}$, then $(o_j, ST_{j,i})$ is a candidate to be the representative. Otherwise, if the distance is high, the "voting" function is close to its minimum value, meaning that $ST_{j,i}$ is very far away from $ST_{k,i}$, so $ST_{k,i}$ is ill-represented by $ST_{j,i}$.

We define a new structure called micro-group, based on the concept of representative trajectory.

Definition 2.2. For a set of moving object sub-trajectory $S_i = \{(o_1, ST_{1,i}), (o_2, ST_{2,i}), \dots, (o_m, ST_{m,i})\}$ at the time window i , let O_i be the set of moving objects in S_i , ϵ be a distance threshold, τ be a size/density minimum threshold, ρ be a representativeness threshold. A **micro-group** g is defined as a set of objects satisfying:

1. $g \subseteq O_i$
2. $\exists o_j \in g$, such that $R_g^{traj} = (o_j, ST_{j,i})$ is a representative trajectory of g w.r.t. ϵ, τ and ρ .

The ρ value can be chosen according to the maximum allowed distance between the representative sub-trajectory

and the farthest member of a micro-group. The ϵ and τ thresholds captures the density around the representative trajectory, similarly to DBSCAN.

Third step. We propose an algorithm to incrementally maintain each micro-group (since all the moving objects update their sub-trajectories, some moving object may leave or join a micro-group) and to capture its evolution patterns. At the initialization phase (i.e., a cold-start of the clustering) the representative trajectories are randomly chosen among the core objects (as defined in DBSCAN). Micro-groups are first derived as the objects that vote for these representatives. The most important contribution is the maintenance phase. The intuition behind is: (i) to check for each micro-group whether the representative is still valid in the next time window (it survives), otherwise, the micro-group disappears or splits, (ii) to track moving object sub-trajectories that are likely to join the micro-group (e.g., outliers, new objects, and other objects migrating from another micro-group), (iii) for the remaining objects, a similar process to the initialization allows creating new micro-groups.

When a micro-group g_i survives, the algorithm checks for each moving object $o_k \in g_i$ if it is still well represented by $(o_j, ST_{j,i})$. If it is not, o_k is deleted from g_i and either it migrates to another micro-group, or it becomes an outlier, or it forms a new micro-group with other outliers. A micro-group g_i splits or disappears when it changes its representative trajectory. If g_i splits, new micro-groups have to be computed using the g_i data. However, if g_i is not dense enough to generate micro-group(s), its moving objects become outliers and g_i disappears.

Fourth step. We use the maintained micro-groups to discover mobility patterns, by capturing the evolution of micro-groups over time. Since each micro-group is density based, it is suitable to find sub-trajectory density based clustering (for example, merging micro-groups results in density based sub-trajectory clusters). Furthermore, this paves the way for online discovery of more complex patterns, such as flocks, convoys, leadership. Indeed, flocks could be derived from micro-groups by a light post-processing since it is a subset of the later. The convoys are also similar to the density based clusters generated by our algorithm. The representative is a close notion to leadership. Hence, this information could enrich a Moving Object Database, allowing new query and visualization types.

3. CONCLUSION

In this paper, we have present a framework to track and discovery mobility patterns in moving objects trajectory data streams. We also proposed an incremental algorithm to maintain the patterns evolution from time to time. It is noteworthy that we evaluated our approach on real data sets, which shows its effectiveness and its efficiency.

ABSTRACT

The Linked Open Data (LOD) cloud brings together information described in RDF and stored on the web in (possibly distributed) RDF Knowledge Bases (KBs). The data in these KBs are not necessarily described by a known schema and many times it is extremely time consuming to query all the interlinked KBs in order to acquire the necessary information. To tackle this problem, we propose a method of summarizing large RDF KBs using approximate RDF graph patterns and calculating the number of instances covered by each pattern. Then we transform the patterns to an RDF schema that describes the contents of the KB. Thus we can then query the RDF graph summary to identify whether the necessary information is present and if so its size, before deciding to include it in a federated query result.

Keywords

Linked Open Data; RDF Summarization; Query Processing

1. INTRODUCTION

The amount of RDF (Resource Description Framework, www.w3.org/RDF/) data available on the semantic web is increasing fast both in size and complexity, e.g. more than 1000 datasets are now published as part of the Linked Open Data (LOD) cloud, which contains more than 62 billion RDF triples, forming big and complex RDF data graphs. It is also well established that the size and the complexity of the RDF data graph have a direct impact on the evaluation of the RDF queries we express against these data graphs. Especially on the LOD cloud, we observe that a query against a big and complex RDF Knowledge Base (KB) might retrieve no results at the end because either (a) the association between the different RDF KBs is weak (is based only on a few associative links) or (b) there is an association at the schema level that has never been instantiated at the actual data level. Thus we can conclude that having information

on the content of a KB and statistical information on the number of instances described under various concepts will allow us to decide on whether or not to post a query based on the availability of the necessary information.

By creating summaries of the RDF KBs, we allow the user or the system to decide whether or not to post a query, since (s)he knows whether information is present or not. This would provide significant cost savings in processing time since we will substitute queries on complex RDF KBs with queries first on the summaries (on much simpler structures with no instances) and then with queries only towards the KBs that we know will produce significant results. We need to compute the summaries only once and update them only after significant changes to the KB. Given the (linked) nature of LOD this will speed up the processing of queries in both centralized and distributed settings.

Moreover, many RDF KBs are suffering from a total or partial absence of schema information. By applying RDF summarization techniques, we can extract, at least, a subset of the schema information and thus facilitate the query building for the end users with the additional benefit of categorizing the contents of the KB based on the summary. We can envision similar benefits when KBs are using mixed vocabularies to describe their content. In all these cases we can use the RDF summary to concisely describe the data in the RDF KB. Thus in this work we study the problem of LOD/RDF graph summarization that is: given an input RDF graph, find the summary graph which reduces its size, while preserving the original inherent structure and correctly categorizing the instances included in the KB.

Two main categories of graph summarization have been proposed to date: (1) aggregation and grouping approaches [3, 5], which are based on grouping the nodes of input RDF graph G into clusters/groups based on the similarity of attributes' values and neighborhood relationships associated with nodes of G and (2) structural extraction approaches [1, 2] which are based on extracting some kind of schema where the summary graph is obtained based on an equivalence relation on the RDF data graph G , where a node represents an equivalence class on nodes of G . To the best of our knowledge, few of these approaches are concentrating on RDF KBs and only one of them [1] is capable of producing a RDF schema as result, which would allow the use of RDF tools (e.g. SPARQL) to query the summary. Our approach provides comparable or better results in most cases.

In summary, our solution is responding to all the require-

ments by extracting the best approximate RDF graph patterns, construct a summary RDF schema out of them and thus concisely describe the RDF input data. We offer the following features: (1) The summary is a RDF graph itself, which allows us to post simplified queries towards the summarizations using the same techniques (e.g. SPARQL), (2) statistical information (number of class and property instances per pattern) is included in our summary graph, which allows us to estimate a query’s expected results’ size, (3) the summary is much smaller than the original RDF graph, contains all the important concepts and their relationships based on the number of instances, (4) schema independence: it summarizes an RDF graph regardless of having or not schema and RDFS triples and (5) heterogeneity independence: it summarizes an RDF graph regardless if it is hetero- or homo-geneous.

2. RDF-GRAPH PATTERNS COMPUTATION

We present in this section our approach of RDF graph summarization, based on mining a set of approximate graph patterns (an error-tolerant pattern mining technique). It aims at discovering the smallest set of k patterns that best describe the input dataset, where the quality of the description is measured by an information theoretic cost function. We use a modified version of the PaNda+ algorithm [4], which uses a greedy strategy to identify the k patterns that best optimize the given cost function. Even if we do not fix the input parameter k , PaNda+ can stop producing further patterns when the cost of a new pattern is more than the corresponding noise reduction. Our approach works in three independent steps that are described below and in Figure 1.

Binary Matrix Mapper: We transform the RDF graph into a binary matrix D , where the rows represent the subjects and the columns represent the predicates. We preserve the semantics of the information by capturing distinct types (if present), all attributes and properties and also reverse properties (so as to capture both subject and object of a property). We extend the RDF URI information by adding labels that represent the different predicates carrying this information into the patterns. *No* schema information is required for the algorithm to work adequately well.

$$D[i; j] = \begin{cases} 1, & \text{the } i\text{-th URI has } j\text{-type of or is } j\text{-property's} \\ & \text{domain/range or is } j\text{-attribute's domain} \\ 0, & \text{otherwise} \end{cases}$$

Graph Pattern Identification: The binary matrix created in step 1 is used in a calibrated version of the PaNda+ [4] algorithm, which allows us to experiment with different cost functions while retrieving the best approximate RDF graph patterns. Each extracted pattern identifies a set of subjects (rows) all having approximately the same properties (cols). The patterns are extracted so as to minimize errors and to maximize the coverage (i.e. provide a richer description) of the input data. A pattern thus encompasses a set of concepts (type, property, attribute) of the RDF dataset, holding at the same time information about the number of instances that support this set of concepts.

Constructing the RDF summary graph: We have implemented a process, which reconstructs the summary as a valid RDF graph using the extracted patterns. For each pattern in step 2 we generate a node labeled by a URI (minted from a hash function) and we add an attribute with the

Figure 1: Our RDF Summarization Approach.

bc:extent label representing the number of instances for this pattern. Then we use the labels generated at step 1 to understand the type of predicate involved and to generate the proper links. The process exploits information already embedded in the binary matrix and tries to construct a valid RDF schema to represent the KB.

3. PRELIMINARY RESULTS

We evaluated so far our approach on variations (e.g. with or without any schema information) over two datasets. An artificial one, which consists of 2000 triples, classified under 8 classes and 9 properties. And a real one, called *Jamendo*, which consists of 11 classes and 25 properties and 1.05 M triples. In both cases 89% of the classes and properties is correctly identified (are the same with the original schema of the dataset even if the schema is not used as a part of the calculation) and the corresponding instances are correctly classified. We produce a summary which is still valid RDF/S and thus can be queried by the same tools.

4. CONCLUSIONS AND FUTURE WORK

In this work we apply an approximate graph pattern mining algorithm in order to extract a summary of an RDF KB. The summary is not necessarily the complete schema of the KB but it always remains a valid RDF/S graph. We plan to test our approach on more complex and bigger datasets (billion of triples); the results so far are promising. We plan to integrate additional RDF knowledge into the algorithm and allow for personalized summaries of RDF KBs.

ABSTRACT

This paper presents a new model to detect and explain customer defection in a grocery retail context. This new model analyzes the evolution of each customer basket content. It therefore provides actionable knowledge for the retailer at an individual scale. In addition, this model is able to identify customers that are likely to defect in the future months.

CCS Concepts

•Information systems → Data mining;

Keywords

Data mining; Attrition modeling; Grocery retail

1. INTRODUCTION

In grocery retail context, customer defection is partial [1], in the sense that a customer will usually lower his purchases, instead of totally leaving the store. Moreover, no contract binds the customer to the retailer, so customer defection is not clearly signaled through contract ending, like it is in other businesses such as banks or phone operators. Customer defection (also called attrition) is therefore difficult to detect because there is no clear definition of when a customer is defecting.

Attrition in grocery retail environments has mainly been studied through the RFM model [3], based on behavioral variables (recency, frequency and monetary value). RFM demonstrated good performances in partial attrition detection [1] but is limited to building groups of customers which provide few explanations of attrition causes.

Building comprehensive attrition models is of interest because retailers want to lower their retention marketing expenses, by deploying accurate targeted marketing. Models using first and last sequences of purchased products have been proposed [2] and improved attrition detection, while

providing more information about attrition causes. Nevertheless, these models do not explain attrition at an individual level.

Understanding attrition at the customer level is necessary to do efficient targeted marketing. This work presents a model of customer stability that allows for analyzing the evolution of individual customer's purchases to understand attrition causes, at an individual level.

2. ATTRITION MODEL

We want to characterize important items, that are bought by a given customer during successive periods. Moreover, we want to detect an evolution in this item set to model and understand customer stability.

Let $\mathcal{I} = \{i_1 \dots i_n\}$ be the set of all items. The purchases of customer i can be represented by a chronologically ordered list $\mathcal{D}_i = \langle (b_1, t_1), \dots, (b_N, t_N) \rangle$, with $b_j \subset \mathcal{I}$ being the content of basket j and t_j its timestamp.

Let w be a window. We divide \mathcal{D}_i in consecutive non overlapping windows of time span w to define the windowed database of customer i , denoted \mathcal{D}_i^w , as an ordered list of tuples (t_k^B, t_k^E, u_k) . k is the window number and \mathcal{D}_i^w is ordered in chronological order on t_k^B . u_k is the set of all products bought during window k , delimited by t_k^B and t_k^E .

Let $p \in \mathcal{I}$ be an item, $c(k)$ be the number of windows prior to window k that contain p , $c(k) = |\{u_v | v < k, p \in u_v\}|$ and $l(k)$ be the number of windows prior to window k that do not contain p , $l(k) = |\{u_v | v < k, p \notin u_v\}|$.

We define the **significance** of p in window k as $S(p, k) = \alpha^{c(k)-l(k)}$ if $c(k) > 0$ and $S(p, k) = 0$ otherwise. α is a parameter of the method. The usual expected behavior is to increase the item significance when incrementing $c(k)$. Therefore, we generally fix $\alpha > 1$.

We define the **stability of customer** i in window k as $Stability_i^k = \sum_{p \in u_k} S(p, k) / \sum_{p \in \mathcal{I}} S(p, k)$.

If all products are contained in window k , the stability of the customer is equal to 1. This stability decreases when products are not contained in window k . This decrease is proportional to the significance of missing products. The more significant a product is, the more the stability will decrease if this product is not present in window k .

When the stability of some customer decreases, we can identify which product mainly caused this decrease. This product is defined as $\arg \max_{p \notin u_k} S(p, k)$, which is the most significant product that was not bought in window k . This

Figure 1: Performance of the attrition detection.

attrition explanation can be easily extended to a set of products.

3. EXPERIMENTS

The dataset provided by a major French retailer contains anonymized receipts of 6 millions customers, from May 2012 to August 2014. Each timestamped customer receipt describes a related basket content. A taxonomy is also provided that enables abstracting products in segments. The dataset contains 4 millions products, that are grouped into 3 388 segments.

Customer selection: Our main goal is to explain attrition. It is especially important for defecting loyal customers. The retailer provided us with the IDs of loyal customers, and of loyal customers that defected in the last 6 months. The beginning of the defection, given by the retailer, is indicated in Figure 1 by the vertical line at month 18.

3.1 Attrition prediction

The first experiment attempts to validate our model for separating loyal customers from the ones that defected during the last 6 months. To assess the relevance of our model, we use the area under the ROC curve for different window indices. We chose the AUROC because it evaluates the discrimination ability of our model. The points on these curves are obtained using different thresholds β for the customer stability. If $Stability_i^k > \beta$ the customer is considered loyal. Otherwise, the customer is considered as defecting on window k . The window length for this experiment is set to two months and the α parameter is set to 2. These values were chosen after performing a 5-fold cross-validation search. We compare our model to the standard RFM model, that uses recency, frequency and monetary variables to identify defecting customers. This RFM model is built using a logistic regression on these three types of variables. The methodology we used to compute the RFM model is similar to the one presented in [1], but we only used predictors associated to the recency, frequency and monetary variables. For each window, we compute the AUROC of our model and of the RFM model. Their evolution is plotted in Figure 1.

Figure 1 shows that our model accurately identifies customers that are in attrition in the last 6 months. This identification takes place in the first months of the customer defection. Two months after the start of attrition, our model scores an AUROC of 0.79, indicating a rather accurate detection of defecting customers. Our model and the RFM model have similar performances. This shows that our model is not only able to provide information about attrition, but is also able to detect customer attrition, with performances similar

Figure 2: Defecting customer stability value example.

to standard attrition models such as RFM.

3.2 Attrition explanation

The second experiment aims to show the value of our model to explain attrition at an individual level, by illustrating that it provides actionable knowledge about the products responsible for individual customer attrition. We illustrate this on a use-case study of a defecting customer.

In Figure 2 the stability value indicates that the customer is loyal in the first months, and defecting starting from month 20. The upside of the stability value is that it can link each decrease to a loss of significant products.

For example, we can link the decrease in month 20 to the fact that the customer stopped buying coffee during this window. In month 22, the decrease is sharper because the customer lost several significant products: milk, sponge and cheese. We can perform this precise analysis for each window where our model suggests that the customer is not as loyal as he was before. This information is of interest for the retailer because he can then target his marketing on significant products that this customer is not buying anymore.

4. CONCLUSION

In this paper, we presented a new model to analyze customer attrition in a grocery retail context. This model is based on the customer basket content evolution and provides precise information about individual defecting customer. It can also reliably detect customer defection.

In the future, we plan to deepen the study of the characterization of significant products that can explain customer defection.

5. ACKNOWLEDGMENTS

We would like to thank the french retail company that provided the data and funded this work.

ABSTRACT

Almost all activities observed in nowadays applications are correlated with a timing sequence. Users are mainly looking for interesting sequences out of such data. Sequential pattern mining algorithms aim at finding frequent sequences. Usually, the mined activities have timing durations that represent time intervals between their starting and ending points. Most sequential pattern mining approaches dealt with such activities as a single point event and thus lost many valuable information in the collected patterns. We present the PIVOTMiner, an efficient interval-based sequential pattern mining algorithm using a geometric representation of intervals. The interestingness level is not necessarily positively correlated with the frequency of the patterns. In many applications, users are seeking for rare patterns that considerably deviate from the majority. Simply delivering the bottom- k patterns does not guarantee their high outlieriness (or deviation) from the frequent ones. We propose additionally the PIVOTRanker, the first scalable algorithm for ranking rare interval-based sequential patterns based on their outlieriness. Our experimental results on both synthetic and real-world datasets show that PIVOTMiner spends considerably less time than two state-of-the-art competitors, and that PIVOTRanker delivers a meaningful and useful ranking of rare patterns.

1. INTRODUCTION AND PIVOTMINER

Available interval-based approaches (e.g. [2]) employ the Allen's relationship [1] to model the event patterns. They lose the quantitative information and thus the outlieriness ranking can not be applied. [6] represents interval events as parallel aligned sequences. [4] introduces end point sequence with additional quantitative information. However, these algorithms did not focus on outlier ranking.

We present our PIVOTMiner: **Paradigm of Intervals as Vectors and Origin Transformation**. It is an interval-based frequent pattern mining approach. This approach is introduced here to model the interval-based event pattern for

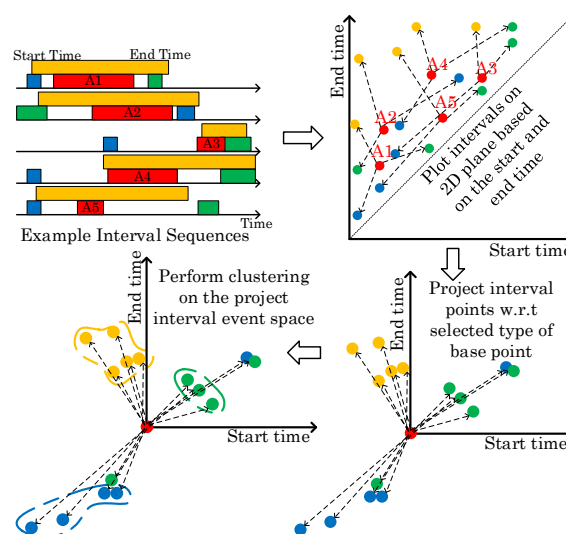

Figure 1: Workflow of PIVOTMiner

outlier ranking. The work flow of the PIVOTMiner is illustrated in Figure 1. Event intervals are modeled as points on 2D plane where the start times and the end times are depicted on the horizontal and vertical axes, respectively. The relationships between events can be considered as vectors. We select one event type as the source type and other event types as the target type. Vectors are constructed within each sequence from point with source type to point with target type. By projecting each source point to the origin, semi-supervised clustering can be applied to group similar patterns that consist of the current source type and each target event type. We repeat the step described above for each event type to generate all binary patterns.

With the idea of PIVOTMiner, we convert the relationship between interval events into vectors. Different distance measure could be employed and normal outlieriness ranking algorithms can be applied as we show in Section 2. Section 3 presents our first results on running time evaluation of PIVOTMiner and on ranking rare patterns using the PIVOTRanker. Section 4 concludes the paper with an outlook.

2. PIVOTRANKER: RANKING PATTERNS

Let the prototype pattern in Figure 2 represent the overlapping of symptoms that leads, in theory, to a certain disease. Specialists would be interested in having an overview of pos-

Figure 2: PIVOTRanker output of rare patterns (bottom) ranked according to their outlierness score deviating from the ground truth prototype (top).

itive objects with a deviating pattern, in practice, from the assumed one. The relationship between two interval events is modeled as vectors and a interval-based pattern can be seen as a combination of vectors. In the new representation, and after performing the clustering, some sparse intervals (and thus patterns) deviate from all available clusters and are not dense enough to form a new cluster. These objects are called outliers and they usually do not belong to any of available clusters. The *outlierness* level of those patterns varies according to their densities and to their degree of deviation from available dense clusters, as proposed by [3]. Its value is computed based on the set of vectors with the same source and target event type. We use this outlierness value in our PIVOTRanker to rank rare interval-based patterns.

Since a vector can only describe binary patterns, an overall ranking score needs to be computed for interval-based patterns with more than two events. One method is to use the average value of all vectors belonging to the same sequence. Another method is to select the minimum set of binary vectors that can cover the whole pattern and take the average value as the score for pattern. Since one pattern can be covered by different combinations of binary vectors, we need to find out the set which gives the highest value.

3. EXPERIMENTAL EVALUATION

We tested the PIVOTMiner for efficiency and the PIVOTRanker for effectiveness using synthetic and real data sets. To check the capability of the PIVOTRanker realistically, we modeled a data prototype with multiple interval-based noise effects. The real data set is introduced by [5]. Figure 2 illustrates a set of sequences with the corresponding outlier ranking score as an example. The score is computed based on the minimum set of vectors with the highest average score. As shown in the figure, sequences with a higher outlier ranking score deviate much more than lower ones from the original prototype.

We evaluated the efficiency of the PIVOTMiner against the TPrefixSpan [7] algorithm and the QTIPrefixSpan [4] using the real dataset in Figure 3 and a synthetic one in Figure 4. As it is clearly depicted in the two figures, PIVOTMiner scales well with the size of the dataset and is not sensitive to the selection of the minimum support.

Figure 3: Runtime evaluation w.r.t. *minsup* using the American Sign Language real dataset [5].

Figure 4: Scalability test using a synthetic dataset.

4. CONCLUSION AND OUTLOOK

In this paper we presented our novel efficient algorithm PIVOTMiner for interval-based sequential pattern mining using a geometric representation of intervals. Additionally, we have presented the PIVOTRanker that ranks rare patterns found using the first algorithm using their outlierness score. The source codes and the datasets are available under: <http://dme.rwth-aachen.de/en/PIVOT>. In the future, we will advance the geometrical representation of the PIVOTMiner to include additional information for finding multiple-event patterns. We will also advance the outlierness ranking method to that case.

ABSTRACT

Recent years have seen the rise of Web data, in particular Linked Data, with, up to now, more than 1000 datasets in the Linked Open Data Cloud (LOD). These datasets are mostly of entity-centric nature and are highly heterogeneous in terms of domains, language, schema, etc. Hence, the vision of uniformly querying such resources in the LOD has a long way to go. While equivalent *entity instances* across datasets are often linked by *sameAs* links, *relations* from different datasets and schemas are usually not aligned.

In this paper, we propose an on-line *instance-based* relation alignment approach. The alignment may be performed during query execution and requires partial information from the datasets. We align *relations* to a target dataset using association rule mining approaches. We sample for equivalent entity instances with two main sampling strategies. Preliminary experiments, show that we are able to align relations with high accuracy, even if accessing the entire datasets is impossible or impractical.

1. INTRODUCTION

As of April 2015, the publicly accessible part of the LOD project counts more than 1000 datasets, which together store more than 30 billion facts. The datasets span across different domains, such as social Web, government data, geographic data, or the life sciences. Moreover, the datasets are highly heterogeneous in terms of schemas, of quality of the data, and only 2% of the schemas are aligned across different datasets [6]. Many of these datasets are accessible through *SPARQL endpoints*, yet uniformly querying them remains a long way to go.

Motivation. Successful examples include well known knowledge bases (KB) like DBpedia, YAGO, and Freebase, which comprise factual statements about real world entities. These facts are typically stored as triples $\langle \text{subject}, \text{relation}, \text{object} \rangle$ (e.g. $\langle \text{Frank_Sinatra}, \text{wasBornIn}, \text{USA} \rangle$). Yet, even for such KBs, the same entity can have different identifiers (e.g. $\text{Frank_Sinatra_}(Singer)$ or Sinatra). Similarly, equivalent relations across KBs use different names (e.g., wasBornIn and bornInCountry), hence makes them non-interoperable, such that queries cannot join information across KBs.

Challenges. Several approaches have been proposed to align relations across datasets [9, 7, 3], but in all these cases alignment is

performed on the entire KB snapshot. In the real world, however, one may not always have access to the entire dataset. First, KBs are typically quite large (e.g. YAGO, requires 100GB of space on disk), and it is rather impractical to download several entire KBs just to answer a single query. Second, performing relation alignment on KB snapshots, may miss out KB updates. For time-sensitive data, it is better to query the data dynamically. Finally, not all KBs can be freely downloaded. Some providers allow users to issue a limited number of queries to KB via a SPARQL endpoint, but do not allow them to download the entire dataset. In this line, [5] focus on discovering schema alignment on data streams, however, this does not represent any guarantee that one can align any relation given the stream of data.

Contributions. In this paper, we propose an *instance-based on-the-fly* approach for relation alignment between two KBs. Our method requires only a SPARQL endpoint for each dataset. Given a relation name in a source KB, e.g. coming from a query on that KB, our method automatically finds corresponding relations in the target dataset, without any need to download the data. Since our method works with few queries, it could be used at query time.

The main idea behind our approach is to use samples of data from both KBs in order to identify candidate relations, then rely on inductive logic programming (ILP) to validate them. Existing works [1, 8], use ILP to mine rules in order to align hierarchies of entities. We go beyond this goal, and want to express more complex mappings, by mining logical rules such as $\text{kb1} : \text{wasBornIn}(x, y) \Rightarrow \text{kb2} : \text{bornInCountry}(x, y)$.

In particular, we perform two types of alignments, *subsumption* and *equivalence*, which can be expressed as logical rules. However, as we will show below, such rules cannot be solely mined with standard ILP approaches from small samples of instances. Hence, we develop smart sampling methodologies that are geared to this type of problems. Experiments with real-world datasets show that we can align relations with more than 90% precision, based on only very small samples.

2. APPROACH

2.1 Rule Mining

Given two KBs K and K' , a relation r in K and the set E of *sameAs* entity equivalences, we want to find rules r' in K' subsumed by r , i.e. $r' \Rightarrow r$. Candidate relations r' may be found by sampling $r(x, y)$, then considering all r' such that $r'(x, y)$ for some sample. Equivalence of relations is expressed as a double subsumption: $r' \Leftrightarrow r$, iff $r' \Rightarrow r$ and $r \Rightarrow r'$.

In this work we use two ILP techniques to validate subsumption between relations. A vanilla association rule mining approach [2] could simply regard all absent data as counter-examples (closed world assumption), which yields the following confidence measure:

$$cwaconf(r' \Rightarrow r) := \frac{\#(x, y) : r'(x, y) \wedge r(x, y)}{\#(x, y) : r'(x, y)} \quad (1)$$

where $\#(x, y) : A$ is the number of pairs (x, y) that fulfill A .

The second technique [4], works under a open world assumption and considers that a KB knows either *all* or *none* of the r -attributes of some x . In this case, we count as counter-examples for a rule $r'(x, y) \Rightarrow r(x, y)$ only instances (x, y) such that x has r relations, but not $r(x, y)$. The confidence measure is:

$$pcaconf(r' \Rightarrow r) := \frac{\#(x, y) : r'(x, y) \wedge r(x, y)}{\#(x, y) : \exists y' : r'(x, y) \wedge r(x, y')} \quad (2)$$

2.2 Instance Sampling

Simple Sample Extraction. We propose a baseline solution that computes a (pseudo-) random set of samples to check if a candidate relation r_{sub} from K' satisfies $r_{sub} \Rightarrow r$. First, we extract from K' a set of samples entities that are subjects in r_{sub} facts:

$$S_{r_{sub}} = \{x_1 \mid r_{sub}(x_1, y_1) \in K', \exists x_2, y_2 \in K : x_1 \equiv x_2 \wedge y_1 \equiv y_2\}$$

The same query extracts the actual r_{sub} facts where the sample entities occur. More precisely, it extracts the set:

$$K_S^{r_{sub}} = \{r_{sub}(x_1, y_1) \mid x_1 \in S_{r_{sub}} \wedge r_{sub}(x_1, y_1) \in K'\}$$

The actual SPARQL queries that are used to extract the two sets depend on the nature of the relation r_{sub} . For *entity-entity* relations, we select for a subject x_1 all the facts r_{sub} for which there are *sameAs* links to entities in K for both the subject and the object. Since we do not want to punish the score of the alignment because of incomplete information, we ignore the r_{sub} facts where the *sameAs* links to entities in K are missing.

In the next step the subject and the object of a r_{sub} are translated to the equivalent entities in K and create the set:

$$P_S^{r_{sub}} = \{(x_2, y_2) \mid \exists x_1, y_1 : x_2 \equiv x_1, y_2 \equiv y_1, r_{sub}(x_1, y_1) \in K_S^{r_{sub}}\}$$

then corresponding r instances are extracted:

$$K_S^{r_{sub}} = \{r(x_2, y_2) \mid r(x_2, y_2) \in K, \exists y'_2 : (x_2, y'_2) \in P_S^{r_{sub}} \wedge r(x_2, y'_2)\}$$

Note that if for some pair (x_2, y'_2) from $P_S^{r_{sub}}$ a fact $r(x_2, y'_2)$ is discovered in K , then we need to select all the other facts $r(x_2, y_2)$ of x_2 . This is required by the *pcaconf* measure. For simplicity, in this presentation we assumed that the inverse relations have been added to the two KBs. This is why we only consider direct relations.

If r_{sub} is an *entity-literal* relation, we retrieve from K facts of the samples $S_{r_{sub}}$ and apply string similarity functions to align the literals. Once the sets $K_S^{r_{sub}}$ and $K_S^{r_{sub}}$ are retrieved, we can run the *pcaconf* and the *cwaconf* scores on the coalesce of the two sets.

Unbiased Sample Extraction (UBS). The random selection of the samples is a fair objective approach, but several cases require a more careful selection of unbiased samples when using *pcaconf*.

Mining subsumptions that are not equivalences. Consider the example of a mined subsumption $K' : composerOf \Rightarrow K : creatorOf$. When checking the reverse implication to test equivalence, if the sample includes composers that only created musical compositions, we will find that the two relations are equivalent under *pcaconf*, while if a composer is also a writer the reverse implication is false. A way to avoid such missing samples is to discover in K' a relation subsumed by $K : creatorOf$ whose domain overlaps with the domain of $K' : composerOf$. For instance, we can take the relation $K' : writerOf$ and consider for sampling the composers that are also writers.

Mining overlappings that are not subsumptions. Consider in K' the relations *hasDirector* for movies and their directors and *hasProducer* for movies and their producers, then in K the relation *directedBy* for movies and their directors. Since it often happens that the same person directs and produces the same movie, we might wrongly infer that $K' : hasProducer \Rightarrow K : directedBy$. To filter out such cases even under *pcaconf*, we may include in the sample movies whose producer and director are different.

To deal with both unbiased samples cases above, our method lays on candidate relations $K' : r'$ and $K' : r''$, subsumed by $K : r$ for simple samples. Unbiased samples will include facts for $K' : r'$ and $K' : r''$ that share the same subjects but have different objects.

More precisely, unbiased samples would contain x such as $r'(x, y_1), r''(x, y_2), \neg r'(x, y_2)$. In the first case, the existence of $r(x, y_1)$ and $r(x, y_2)$ filters out the wrong equivalence. In the second one, the condition to filter out the wrong subsumption is to have $r(x, y_1)$ but not $r(x, y_2)$. We used here the same identifiers for equivalent entities in K and K' .

3. EXPERIMENTAL EVALUATION

Datasets. We conduct our experiments on two KBs, with 92 relations from YAGO2 and 1313 relations from DBpedia.

Baselines. As baseline solution we consider the (pseudo) random selection of *Simple Sample Extraction* described in Section 2. On the coalesce of the sets of samples retrieved from the two KBs, we have run the two ILP techniques *cwaconf* and *pcaconf*.

We evaluate the algorithms for a sample size of 10 samples (subject entities). Table 1 reports our preliminary results. For the two measures *cwaconf* and *pcaconf*, we have selected the thresholds τ that led to the highest average F1 score for both ways implications, $yago \subset dbpd$ and $dbpd \subset yago$.

Unbiased Sample Extraction. The method that we propose extends the baseline solution of *pcaconf* by implementing the two strategies for filtering wrong candidates. To eliminate a “wrong” relation we need only one case which shows that there is a contradiction. The results of this method are indicated by the label **UBS** in Table 1. The results suggest that our method consistently prunes wrong candidates.

Table 1: Alignment subsumptions – YAGO and DBpedia relations

	ILP		yago \subset dbpd	dbpd \subset yago
$\tau > 0.3$	pcaconf	P	0.55	0.51
		F1	0.58	0.48
$\tau > 0.1$	cwaconf	P	0.56	0.55
		F1	0.59	0.53
UBS	pcaconf	P	0.95	0.91
		F1	0.97	0.82

Model Kit for Lightweight Data Compression Algorithms

Juliana Hildebrandt, Dirk Habich, Patrick Damme, Wolfgang Lehner
 Technische Universität Dresden
 Database Systems Group
 01189 Dresden, Germany
 firstname.lastname@tu-dresden.de

ABSTRACT

Modern database systems are very often in the position to store and efficiently process their entire data in main memory. Aside from increased main memory capacities, a further driver for in-memory database systems has been the shift to a column-oriented storage format in combination with lightweight data compression techniques. In recent years, a lot of lightweight data compression algorithms have been developed to efficiently support different data characteristics. Therefore, database systems should include a large number of these algorithms. To enable this, we introduce our novel modularization concept including our model kit implementation for lightweight data compression algorithms.

1. MOTIVATION

With an ever increasing amount of data in almost all application domains, the storage requirements for database systems grow quickly. In the same way, the pressure to achieve the required processing performance increases, too. To tackle both aspects in a uniform way, data compression plays an important role. On the one hand, data compression drastically reduces storage requirements. On the other hand, data compression also is the cornerstone of an efficient processing capability by enabling "in-memory" technologies. As shown in different papers, the performance gain of in-memory data processing is massive because the operations benefit from its higher bandwidth and lower latency [1].

Especially for the use in in-memory database systems, a variety of lightweight compression algorithms have been developed. These algorithms achieve good compression rates with little computational effort for compression as well as decompression. The main classes of lightweight data compression techniques are dictionary compression (DICT), delta coding (DELTA), frame-of-reference (FOR), null suppression (NS), and run-length encoding (RLE) [2, 3]. The algorithms in each class evolve further and the development activities increase over the years, whereas the concept of the classes are interweaved in new algorithms.

Generally, this multitude of algorithms exists because it is impossible to design an algorithm that automatically produces optimal results for any data. In order to support and to implement a wide range of these algorithms in a database system, a unified approach for the specification or engineering is desirable. In our current research, we have focused on that aspect by developing a novel compression scheme consisting of a few number of modules. Our poster presentation at EDBT comprises an in-depth explanation of this compression scheme. As we are going to show, our compression scheme is quite suitable to modularize a variety of lightweight data compression algorithms in a systematic manner. That means, our approach offers an efficient and an easy-to-use way to describe, to compare, and to adapt lightweight data compression techniques. Furthermore, we want to introduce our model kit implementation that is founded on that compression scheme.

2. MODULARIZATION CONCEPT

Our novel compression scheme consists of four main modules as shown in Figure 1; the arrows indicate the data flows. The input is a sequence of uncompressed values, the output is a sequence of compressed values. Our whole scheme is a **Recursion** module. The first module in each **Recursion** is a **Tokenizer** splitting the input sequence in finite subsequences or single values. For that, a **Tokenizer** can be parametrized with a calculation rule. Its output is a token, a finite sequence of values that serves as input for our second module, the **Parameter Calculator**. Parameters are often required for the encoding and decoding. This module follows special rules (parameter definitions) for the calculation of several parameters. We summarize different data structures like single values calculated from sequences, dictionaries or vectors as parameters belonging to a token. Our third module is the **Encoder**, which can be parametrized with a

Figure 1: Modularized compression scheme

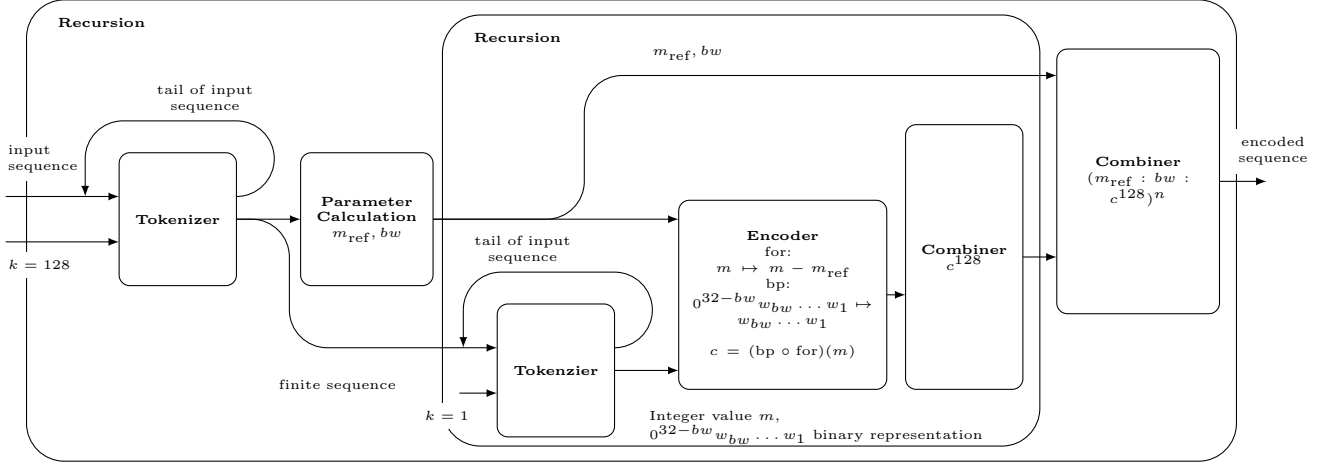

Figure 2: Modularized scheme for the frame-of-reference technique with binary packing

calculation rule for the processing of an atomic input value, whereas the output of the **Parameter Calculator** is an additional set of parameters needed for the calculation inside the **Encoder**. The fourth module is the **Combiner**. It determines how to arrange the output of the **Encoder**. For a more sophisticated hierarchical data partitioning and parameter calculation, we are able to replace the **Encoder** with a **Recursion** module.

3. POSTER PRESENTATION DETAILS

Our EDBT poster presentation comprises an in-depth explanation of the compression scheme. In particular, we want to show the applicability by the transcription of a variety of lightweight data compression algorithms. Due to space constraints, we only present one example transcription in this paper: *semi-adaptive frame-of-reference algorithm with binary packing for the compression of positive integer values*. For each set of 128 values, the algorithm calculates the minimum value as reference value. Then, each single integer value is mapped to the offset to the reference value at the logical level. This technique leads to smaller numbers. Then, all 12 offset values are encoded with the same bit width on the physical level. That means, the algorithm has to calculate it. For each compressed sequence of 128 values, we have to store the reference value and the bit width as meta data. Otherwise we are not able to decode the values.

Figure 2 shows the algorithm in our novel compression scheme, which can be directly mapped to our model kit implementation. The first **Tokenizer** is parametrized with a calculation rule that determines that the **Tokenizer** has to output the first 128 32-bit integer values of the input sequence. The tail of the sequence serves as further input for the **Tokenizer** and is processed in the same way in a next step. The **Parameter Calculator** determines the minimum of the 128 values as reference value m_{ref} and the needed bit width bw to encode all 128 offset values. Instead of an **Encoder** we use a **Recursion** module. Inside that recursion, we have a **Tokenizer** outputting single integer values. Logically, we have a **Parameter Calculator**. But at that level, we do not need to calculate any parameter here. The **Encoder** manages the logical level of encoding as well as the

bit level. It uses the reference value m_{ref} and the calculated bit width bw as parameters. At the logical level it calculates with the function *for* the offset to the common reference value for each of the 128 values. At the bit level, it determines the binary representation of the offset with the help of the bit width. The inner **Combiner** concatenates all physical representations of the 128 offset values to a compressed sequence. Out of the inner **Recursion** the outer **Combiner** concatenates the compressed sequence with the physical representation of m_{ref} and bw as long as all input has been processed.

4. MODEL KIT AND CONCLUSION

Based on our novel modularized scheme, we also developed an appropriate model kit on the implementation level using C++. Our defined modules are available as building blocks, which can be parameterized with certain calculation rules. The building blocks can be orchestrated to data flows, so that complete lightweight data compression algorithms can be realized. Next, we want to optimize the building blocks, so that the algorithms can be efficiently executed. Furthermore, we want to use the model kit to integrate a large number of algorithms in a database system.

To summarize, in our EDBT poster presentation, we introduce our novel developed compression scheme for lightweight data compression algorithms. In particular, we want to show that our approach offers an efficient and an easy-to-use way to describe, to compare, to adapt, and to implement lightweight data compression techniques.

ABSTRACT

In this paper we present our work in progress on revisiting traditional DBMS mechanisms to manage space on native Flash and how it is administered by the DBA. Our observations and initial results show that: the standard logical database structures can be used for physical organization of data on native Flash; at the same time higher DBMS performance is achieved without incurring extra DBA overhead. Initial experimental evaluation indicates a 20% increase in transactional throughput under TPC-C, by performing intelligent data placement on Flash, less erase operations and thus better Flash longevity.

1. INTRODUCTION

We argue that the design of the storage architecture is not well suited for new kinds of memory in terms of both software and hardware. Flash memory has significant performance potential, which is underutilized due to the present architecture of Flash SSDs and the way they are used by the DBMS. To provide backwards compatibility with magnetic drives, modern Flash SSDs implement legacy block-device interfaces, supporting *reading* and *writing* at *Flash page granularity* from *immutable device addresses*. As a result a black-box abstraction over the Flash memory is created inside the device by the so called Flash Translation Layer (FTL). Although, this has facilitated the widespread use of SSDs, it results in: (i) significant overhead primarily due to limited on-device resources available to the FTL; (ii) unpredictable performance caused by the background FTL processes (wear-levelling (WL) and garbage collection (GC)) [1]; (iii) inability to optimize the DBMS I/O behavior for new kinds of storage due to an additional level of indirection.

To overcome these disadvantages we recently proposed the NoFTL approach [2], which assumes native Flash as secondary DBMS storage. NoFTL removes all intermediate abstraction layers along

the critical I/O path (block device interface, file system and FTL), and enables the DBMS to control the physical address space of Flash storage directly (see Figure 1). Under NoFTL the DBMS is not confronted with the intricate low-level NAND control. The Flash device is still assumed to have a thin hardware management layer (a low-level controller).

Figure 1: General NoFTL Architecture including Regions.

The major advantages of NoFTL over the traditional FTL-based Flash SSD are the following: (i) usage of the more powerful computational and memory resources of the host system for complex Flash maintenance tasks; (ii) utilization of the DBMS run-time information and knowledge about the stored data and I/O for optimization of GC, WL and the address mapping scheme; (iii) better utilization of available Flash parallelism through intelligent data placement; (iv) direct control over the out-of-place updates, which allows implementing short atomic writes without additional overhead; (v) elimination of redundant functionality along the I/O path.

In the present paper we revisit traditional methods for physical space management on Flash under NoFTL. *The central questions are: how can native Flash comprising a loose set of Flash chips be organized and utilized by the DBMS; do we need new logical storage structures; will they overcomplicate the job of the DBA?*

2. LOGICAL STORAGE STRUCTURES AND DATA PLACEMENT ON FLASH

We introduce the concept of **NoFTL regions** as a new physical storage structure, to simplify the organization and management of native Flash storage. A *region* comprises multiple Flash chips or dies, over which the data is evenly distributed. The number of

dies in each region, as well as the structure of their set is dynamic and can change over time depending on different factors: size of objects, required level of I/O parallelism and global wear-levelling.

```
CREATE REGION rgHotTbl (
  MAX_CHIPS=8, MAX_CHANNELS=4, MAX_SIZE=1280M);
CREATE TABLESPACE tsHotTbl (
  REGION=rgHotTbl, EXTENT SIZE 128K );
CREATE TABLE T(t_id NUMBER(3))TABLESPACE tsHotTbl;
```

One or more database objects with similar access properties can be physically placed in a *region*; this holds for complete objects or partitions of them. Objects with different properties are placed in different physically separate *regions* to account and optimize for the specific access characteristics. This gives us two distinct advantages discussed in detail below: (a) coupling of regions and existing logical structures to simplify database administration, and (b) ability to perform intelligent data placement to increase performance and improve Flash longevity.

Logical Storage Structures and NoFTL Regions.

Existing logical DBMS storage structures can be defined on top of NoFTL regions. Consider the above example: a region of a certain size *rgHotTbl* is defined over 8 chips. A tablespace *tsHotTbl* is defined on top of *rgHotTbl*, where a newly created table *T* is placed. The DBA can continue using established logical storage structures such as *tablespaces* or *extents*, which can be effectively coupled to *regions*. Hence, no new logical structures are needed to manage, organize native Flash storage. *The administration of native Flash does not confront the DBA with additional complexity.*

Data Placement and NoFTL Regions.

It is well known that Flash memory can perform random access almost as fast as sequential (which is not always true for SSDs). Thus, keeping logically adjacent blocks, physically distributed has negligible performance implications. Furthermore, the distribution over available Flash data channels, dies or planes allows for better I/O parallelism than storing those blocks in sequential order physically on Flash. On the other hand, the database knowledge about the data, about its properties and access patterns can be used to perform smarter data placement and optimize important Flash maintenance algorithms, such as WL, GC and address mapping scheme.

For instance, it is proven that the overhead of garbage collection, which is the major factor for unpredictable performance on SSDs, is highly dependent on the ability to separate between hot and cold data [4, 3]. The limited on-device SSD resources rarely allow for maintaining comprehensive statistics about access patterns and access frequencies over the whole logical address space. At the same time, the DBMS maintains such and other statistics and metadata for each particular database object. Since under NoFTL the DBMS has full control over the physical Flash address space and can perform direct data placement, it becomes easy to utilize the DBMS knowledge. Regions, therefore, allow the DBA and DBMS to control physical data placement on the device in order to optimize Flash management. Intelligent data placement using regions is in the general case an optimal trade off between the provided I/O-parallelism and the overhead of GC.

3. PRELIMINARY EVALUATION

We implemented and integrated *regions* in the NoFTL architecture [2] under Shore-MT. Our initial results indicate that the concept of intelligent data placement on Flash has big potential. For instance, under TPC-C we could achieve about 20% increase in transactional throughput (Figure 3) by applying multi-region data place-

ment configuration (Figure 2). In this configuration we have divided database objects of TPC-C based on their I/O properties into 6 regions. Further we have distributed 64 dies of Flash SSD over those regions based on sizes of objects and their I/O rate (required level of I/O parallelism). In addition to performing 20% more transactions than traditional data placement and 20% more READ and WRITE I/Os, the GC performs almost 20% less COPYBACKs and 4.3% less ERASEs. This reduction in write-amplification of multi-region configurations leads to lower I/O latencies and consequently to lower transaction response times. The second effect of decreased write-amplification of multi-region data placement configurations is the better longevity of the Flash devices.

Tablespace/ Region	DB-Objects	Num. of Flash dies
0	DBMS-metadata; HISTORY NEW_ORDER; ORDER	2
1	ORDERLINE	11
2	CUSTOMER	10
3	OL_IDX; STOCK	29
4	C_IDX; I_IDX; S_IDX; W_IDX C_NAME_IDX; ITEM; D_IDX	6
5	WAREHOUSE; DISTRICT NO_IDX; O_IDX; O_CUST_IDX	6

Figure 2: Multi-region data placement configuration for TPC-C

		Traditional data placement	Data placement using Regions
Response Time	TPS	595.42	720.43
	READ 4KB (μs)	531.00	318.63
	WRITE 4KB (μs)	904.00	564.83
	NewOrder TRX (ms)	61.43	58.45
	Payment TRX (ms)	8.88	6.99
	StockLevel TRX (ms)	437.30	293.97
Number of ...	Transactions	359,725	433,192
	Host READ I/Os (4KB)	19,017,255	23,329,310
	Host WRITE I/Os (4KB)	2,740,236	3,259,162
	GC COPYBACKs	4,326,612	3,496,984
	GC ERASEs	110,410	105,564

4. CONCLUSIONS

The black box architecture of modern Flash SSDs does not allow to utilize the rich DBMS knowledge about stored data and I/O for optimization of complex Flash maintenance functionality such as garbage collection, wear-levelling and address mapping scheme. In pursuit of a solution, we extend our NoFTL approach with the notion of *regions* for allowing the DBMS to control the physical placement based on the properties of database objects. *NoFTL Regions* can be easily mapped to existing DBMS structures such as tablespaces. Our initial results indicate that intelligent data placement can significantly improve the performance of the DBMS as well as the longevity of Flash devices.

ABSTRACT

Discrimination discovery is the data mining problem of unveiling discriminatory practices by analyzing a dataset of historical decision records. In this paper, we focus on discovering discrimination from tweets using deep learning models. One challenge here is that it is difficult to obtain a large well-labeled dataset required by the training of deep learning models for the purpose of discrimination analysis. We develop a two-phase deep learning model to address this challenge. Our model first learns text representations based on weakly-labeled tweets (containing some specific hashtags), then trains the classifier on a small set of well-labeled training data. Experimental results show that: (1) the proposed method can be successfully used for discrimination identification; (2) pre-training text representations, which utilizes weakly-labeled tweets, can significantly improve the accuracy of discrimination detection.

Keywords

deep learning; discrimination analysis; two phase learning

1. INTRODUCTION

Discrimination generally refers to an unjustified distinction of individuals based on gender, race, or religion, and often occurs when the group (e.g., female) is treated less favorably than others. Discrimination discovery and prevention from historical databases has been an active research area recently. In this paper, we are focused on a related but different problem, i.e., how to identify discriminatory tweets. For example, if an individual publishes a tweet saying “*Want to learn photography or how to use photo shop? It’s men’s lifestyle interest. Not for girls!*”, obviously this tweet contains discrimination against female. Identifying discrimination from text is an important task in user-generated content (UGC) mining as discrimination has increasingly become a hotspot of social attention nowadays.

Recent work in natural language processing has shown that deep learning models could learn meaningful representations

(or features) of text and train to classify text on top of text representations with high accuracy in applications like text classification and sentiment analysis. In this paper, we examine the use of deep learning models for discrimination analysis of tweets. However, existing deep learning models require large amounts of training data and it is difficult to obtain such a large well-labeled training dataset (each tweet is clearly marked with discrimination or non-discrimination by domain users) because labeling manually a large number of tweets is time-consuming.

We develop a two-phase deep learning model to detect discrimination from tweets. In the first phase, the model focuses on learning semantic representations of tweets using the large amount of weakly-labeled tweets. In Twitter, users often add hashtags, which mark keywords or topics, in their tweets. We consider tweets containing hashtags like “*#sexism*”, “*#racism*” are weakly-labeled discrimination tweets and those tweets likely contain discrimination information. One example is “*Why are female cabinet members suspect but male ones are not? #bias #sexism*”. However, not all tweets containing such hashtags can be considered as discrimination. For example, the tweet “*#sexism is an important research in behavior research*” is not discriminatory. In general, the tweets that are weakly-labeled by discrimination-related hashtags are likely to be discriminatory than those without discrimination-related hashtags. Hence we train our model to learn the good text representations based on the similarity between the weakly-labeled tweets and well-labeled tweets. In the second phase, we use the representations of tweets trained from the first phase as inputs to train the logistic regression classifier and fine-tune the whole model using the small set of well-labeled tweets.

2. THE MODEL

In this section, we describe the two-phase deep learning model to identify discrimination tweets.

2.1 Phase One

In the first phase, we first model tweets representations based on semantic composition ideas [4]. Semantic composition aims to understand the text by composing the meaning of each word through a composition function. In our work, we use the Long Shot-Term Memory (LSTM) [3] recurrent neural network as the composition function to model the features of tweets. LSTM is able to model a tweet by sequentially processing each word and mapping a tweet to a low dimensional representation vector. LSTM has various variations. In our work, we adopt a widely used LSTM model

[2] but without peephole connections. In order to learn a tweet representation, the model first maps each word w_i in a tweet into a d -dimensional real vector $x_w \in \mathbb{R}^d$, also called word embeddings [1]. For a tweet with n words, a sequence of word embeddings $\mathbf{x} = (x_1, x_2, \dots, x_n)$ are passed into the LSTM one by one to compute the sequential hidden feature vectors $\mathbf{h} = (h_1, h_2, \dots, h_n)$. Then, the model combines the hidden vectors by mean operation $r = \text{mean}(h_1, h_2, \dots, h_n)$ to get one vector r as representation of the tweet.

We further need to model the feature of discrimination and non-discrimination category. In order to build the discrimination features, we consider all the discrimination tweets as a document and use the features of each tweet as input to compose the discrimination features of each category. Given a set of discrimination tweets $T^+ = \{t_1^+, t_2^+, \dots, t_m^+\}$, after computing the representations of tweets $R^+ = \{r_1^+, r_2^+, \dots, r_m^+\}$, we composite the representations of discrimination by Equation 1.

$$Q^+ = \frac{1}{m} \sum_{i \in [1, m]} r_i^+. \quad (1)$$

To build the representations of non-discrimination $Q^- \in \mathbb{R}^d$, the framework follows the same procedure.

The objective of our model is to let the representations of weakly-labeled tweets close to the representations of similar category and far away to the representations of their opposite category. For example, if a tweet contains hashtag “#sexism”, we want the representation of this tweet close to the representation of discrimination and far from the representation of non-discrimination. Our model uses cosine function $\text{sim}(r, Q^+)$ ($\text{sim}(r, Q^-)$) to measure the similarity between a weakly-labeled tweet representation r and representation of discrimination (non-discrimination) category. If r is a weakly-labeled discrimination tweet, we set $\delta = \text{sim}(r, Q^+) - \text{sim}(r, Q^-)$. If r is weakly-labeled as non-discrimination tweet, we set $\delta = \text{sim}(r, Q^-) - \text{sim}(r, Q^+)$. The loss function is $L(\delta) = \log(1 + \exp(-\gamma\delta))$, where γ is a scaling factor. To train the model, we use the back-propagation algorithm by Adadelta [5] to update the parameters of the LSTM model.

2.2 Phase Two

In the second phase, we aim to learn the logistic regression classifier to identify discrimination. After the pre-training, the LSTM model which contains word embeddings to the semantic representations of tweets is already well-trained. We stack the logistic regression layer on the LSTM layer and feed the tweets representations as inputs to logistic regression classifier. We use the well-labeled small dataset as training dataset in this phase. The model is to predict whether a tweet contains discrimination \hat{y} . The logistic regression function is:

$$P(\hat{y}|r, U_l, b_l) = \frac{1}{1 + e^{-(U_l \cdot r + b_l)}}, \quad (2)$$

where r is the representation of a tweet, and U_l, b_l are the parameters of logistic regression. We use negative log likelihood as the loss function to train the classifier and fine-tune the whole architecture.

3. EXPERIMENTS

We crawled tweets online and labeled 300 discrimination tweets and 300 non-discrimination tweets as the well-labeled

Table 1: Comparisons of accuracy of our two-phase training deep learning model against other methods

Methods	Number of training data		
	240	360	480
Our model	0.887	0.901	0.910
Without pre-training	0.870	0.872	0.900
SVM (1-gram)	0.521	0.725	0.713
SVM (2-gram)	0.736	0.756	0.765
Naive Bayes (1-gram)	0.827	0.839	0.860
Naive Bayes (2-gram)	0.852	0.875	0.870

dataset. Meanwhile, we treated 2000 tweets with “#sexism” or “#racism” as weakly-labeled discrimination data and 2000 tweets with “#news” as weakly-labeled non-discrimination data. To evaluate the performance, we split the well-labeled dataset into training data and test data with different sizes and use 5-fold cross validation to evaluate the classification performance. We compare our model with several baselines, which include the deep learning without pre-training the tweets representations, SVM, and Naive Bayes classifiers. We use 1-gram and 2-gram as features of SVM and Naive Bayes classifiers. The prediction results are shown in Table 1. We observe our deep learning model significantly outperforms SVM and Naive Bayes classifiers and the pre-training further improves the accuracy.

4. CONCLUSIONS AND FUTURE WORK

We presented a two-phase deep learning model for discrimination analysis of tweets. Our model first learns text representations based on weakly-labeled tweets (containing some specific hashtags), then trains the classifier on a small set of well-labeled training data. The preliminary experiments showed that pre-training text representations by weakly-labeled tweets could improve the accuracy of discrimination detection. Meanwhile, our model can be easily extended to other applications that are restricted by lack of a large amount of training data. In the future, we plan to extend our method to identify more fine-grained discrimination text.

Top-k Dominating Queries, in Parallel, in Memory

Sean Chester, Orestis Gkorgkas, Kjetil Nørnvåg

ABSTRACT

Top- k dominating queries return the k points that are better than the largest number of other points. Current methods for answering them focus on indexed data and sequential algorithms. To exploit modern-day parallelism and obtain order-of-magnitude improvements in execution time, we introduce three algorithms, the respective strengths and potential of which are revealed experimentally.

1. INTRODUCTION

Top- k dominating queries [6] elegantly fuse top- k queries [4] with skyline queries [2] to produce ranked data without user intervention. Intuitively, a point is ranked highly if it is unequivocally better than many other points. Unsurprisingly, however, it is expensive to evaluate which k points are better than the most others.

Given the recent emergence of manycore architectures, terabyte-sized RAM, and low-latency, non-volatile memory, it is natural to ask whether top- k dominating queries can be answered more efficiently in a shared, main-memory parallel context. Until now, research has focused on sequential computation in high-latency, disk-based settings [5, 8] and on parallel computation in large, distributed systems [1], or on applications such as web-service ranking [7] and network analysis [5]. This paper investigates how significant efficiency improves can be had on just a single machine.

More formally, a data point *dominates* another, distinct data point if it has equal or better values on every attribute. The *dominance score* of a point p is simply the number of other points that it dominates. The responses to a top- k dominating query are the k points with the highest dominance scores. Given an unindexed, memory-resident dataset, we wish to find those k points as fast as possible.

This paper presents preliminary work towards that goal. In the absence of previous ones, we define three quite distinct algorithms for answering top- k dominating queries on multicore architectures and explore their relative strengths experimentally. We find that each shows promise for maturation, while already executing quickly.

2. THREE PROPOSED ALGORITHMS

For multicore top- k dominating queries, we introduce an adaptation of the sequential state-of-the-art and two novel algorithms.

FILTER As a baseline, we adapt the sequential, filter-and-refine algorithm for non-indexed data [8]. The algorithm consists of three passes: 1) build a static grid over the data and calculate score bounds for every grid cell; 2) for every cell that cannot be immediately pruned, iterate the points in the cell and filter out those that clearly cannot be in the solution; and 3) refine the solution by computing the exact score for the remaining candidates. The counting and refining steps parallelise readily, since processing is local to each point, but the filtering step would incur a lot of write contention between threads: processing for each point p will update scores for other points in addition to p . Therefore, we select the faster but $\approx 2\times$ less effective filter option (Algorithm 5) of [8] to adapt: within reason, it is better to process excess points in the high-throughput refinement phase than filter them sequentially.

SORTED Our next algorithm maximises throughput, but with heuristics to improve efficiency. We first sort the data by Manhattan Norm. Then, for each point in parallel, we iterate the sorted list. For a point p at index i , we conduct one-sided dominance tests with points at index $< i$ to count how often p is *dominated*. Clearly, if p is dominated by at least k other points, it cannot be a top- k solution; so, we break if the count reaches k . Points that reach their own index are candidates for the solution. Over the remaining indexes $> i$, we flip the dominance test and instead count how many points *are dominated by* p as a score. Finally, we re-sort the data based on the scores; the solution consists of the first k sorted points.

PIVOTED Multicore skyline algorithms benefit from pivot-based partitioning to identify incomparability in addition to dominance [3]; this algorithm attempts it for top- k dominating queries. We will select a series of pivot points (those with the largest dominance area) one-by-one, and use them to globally, dynamically split the data space into a non-uniform grid. We maintain the set of points independently of the grid. Each pivot point newly partitions the entire set of points and the number that end up in the resultant north-east quadrant is exactly the dominance score of that pivot.¹ Meanwhile, the grid is further sub-divided and upper bounds of scores for points in each sub-partition can be updated. Once no cell has an upper bound score better than that of the k 'th best pivot that we have seen, we terminate. The intuition of the algorithm is that partitioning is easy to parallelise and that the continual fracturing of the data space quickly introduces more knowledge of incomparability and thus very quickly drives down all the upper bound estimates.

3. EXPERIMENTS

This section empirically compares our three parallel proposals.

Setup We implement the three algorithms in C++ using OpenMP

¹We describe this in two dimensions for simplicity.

	CORRELATED				INDEPENDENT				ANTICORRELATED			
	1	14	28	56	1	14	28	56	1	14	28	56
FILTER	1929	669	535	568	13412	2672	1935	1861	86369	21056	17762	16745

PIVOTED	812	715	732	789	964	810	842	833	48008	4870	3115	2579

Table 1: Execution time of each algorithm when run on a single core ($t = 1$), single socket ($t = 14$), all physical cores ($t = 28$), and all virtual cores ($t = 56$). Data distribution varies, but $n = 10^6$, $d = 3$, and $k = 16$ are fixed to match [8]. Times are reported in milliseconds.

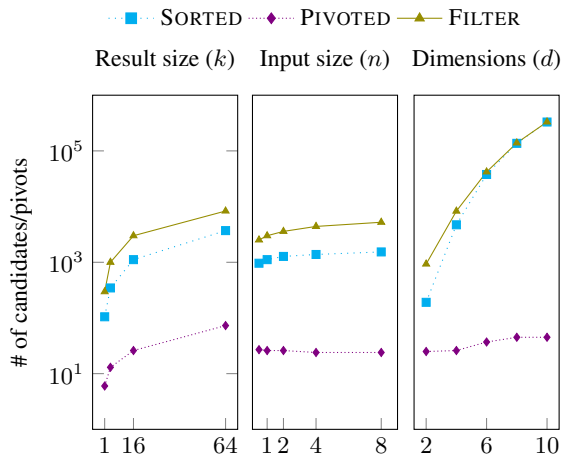

Figure 1: The number of candidates generated by each algorithm as a function of the input data and result size. Independent data.

by extending the openly available *SkyBench* suite [3] and compile with GNU `gcc-4.9.3`. We run experiments on a dual socket, 28-core Intel Xeon E5-2683 v3 at 2 GHz that is running Ubuntu 14.04 and has hyperthreading enabled. Time is measured for each algorithm after loading the input from files into a flat array. Ties in dominance score are broken by the order in which candidate points are processed so as not to bias the preferred order of any algorithm.

For comparability with Section 8.3 of [8], we use standard synthetic datasets with defaults of $k = 16$, $n = 10^6$, and $d = 3$.

Performance of algorithms Table 1 shows the execution time of the three algorithms relative to the data distribution and number of threads. In general, we observe the typical pattern that all algorithms perform best on correlated data and worst on anticorrelated data. This is unsurprising because: a) the dominance scores for the top- k points is higher on correlated data, increasing the bounds used for pruning; and b) more points are dominated by at least k other points and so can be discarded from processing earlier. With additional computational work on anticorrelated data more parallelism can be exposed, thereby achieving more parallel scalability.

The PIVOTED algorithm typically performs best at low thread counts, whereas the SORTED algorithm exhibits very good parallel scalability, even across NUMA nodes, and is consistently the fastest when using all threads. The FILTER method is limited by Amdahl’s Law because of the sequential second phase, so experiences diminishing returns with increasing thread counts. The PIVOTED method struggles to utilise all threads on such low-dimensional correlated and independent data, because there are not enough partitions to iterate and the partitions are quite imbalanced.

The performance of PIVOTED on anticorrelated data is disappointing, given the success that other pivot-based methods (e.g., [3]) have had for standard skyline queries. We will in the future investigate whether better choices of pivot points and the discarding of

some unpromising partitions can improve performance here. Similarly, somehow parallelising the second phase of FILTER could yield sizeable improvements for that algorithm.

On filters and pivots Figure 1 internally inspects the performance of the algorithms by counting “important” points. For PIVOTED, these are the *pivots*. For the other methods, these are the *candidate* points that cannot be pruned. The pivots and candidates are exactly those points for which the dominance score is expensive, explicitly computed. We study how variations in k , n (measured in millions), and d (all on independent data) affect this value.

While it is clear from Figure 1 that PIVOTED computes by far the fewest exact scores, each pivot additionally further partitions the grid, creating much more overhead than evaluating candidates in the other algorithms; so, it is dangerous to compare these values directly across algorithms. Nonetheless, the low number of explicit counts required does suggest that PIVOTED could emerge as the clear best algorithm if the partitioning overhead can be reduced.

The filtering of the other methods is very sensitive to d , filtering less than 65% of the input at $d = 10$, but for $d \leq 5$, both prune $\geq 99\%$. This indicates a reasonable trade-off for FILTER, because sophisticated pruning replaces parallel work with sequential work.

Summary and future work SORTED outperforms the other methods on account of good throughput, but we plan to further develop FILTER (perhaps by trading off more filtering granularity for parallelism) and PIVOTED (trying to bridle the exponential growth of explicitly managed partitions) to see if this result can be overturned. The strong single-threaded performance of PIVOTED in particular, especially on less extreme workloads, suggests that improving its parallel scalability could lead to an extremely fast algorithm.

ABSTRACT

NoSQL data stores are becoming more and more popular. Graph databases are one of this kind of data stores. Neo4j is a very popular graph database. In Neo4j all operations that access a graph must be performed in a transaction. Transactions in Neo4j use read-committed isolation level. Higher isolation levels are not available. In this paper we present an overview of the implementation of snapshot isolation (SI) for Neo4j. SI provides stronger guarantees than read-committed and provides more concurrency than serializability.

Keywords

NoSQL, transaction processing, graph databases.

1. INTRODUCTION

Graph databases such as Neo4j [1], Titan [2] and Sparksee [3] are being adopted to represent data that is more naturally captured as a graph than with structured or semi-structured data models such as the relational model or key-value models. Graph databases also provide either query languages or APIs that enable for traversing graphs, running the whole query on the data store, therefore, resulting in an efficient traversal of the graph. The use of other data management technology for representing and traversing graphs then becomes very inefficient because it implies executing many iterative queries to extract the adjacent nodes to a given one, what results in a huge overhead.

Some of these graph databases provide transactions, like Neo4j. Neo4j implements a basic isolation level: read-committed. Unfortunately, read committed suffers from many anomalies including unrepeatable reads and phantom reads. Unrepeatable reads allows that a transaction observes different values for a given data item in the same transaction. In the case of graphs, it means that a path that has been traversed might not exist when trying to go through it later in the same transaction. Phantom reads affect to the selection of items with a predicate. This affects a transaction that performs a predicate selection multiple times, since it might observe a different result set each time, resulting in inconsistent behavior. A higher isolation level avoiding these two anomalies is highly recommended.

Snapshot isolation (SI) [4] is an isolation level that has become

very popular since it provides an isolation very close to the one provided by serializability while avoiding read-write conflicts. Snapshot isolation provides a snapshot of the committed state to transactions. SI splits the atomicity of a transaction in two points. The start of the transaction, where logically all reads happen, and the commit of the transaction, where logically all writes happen. SI only can suffer from an anomaly avoided by serializability known as write skew. The anomaly is not exhibited by all applications, for instance, the TPC-C benchmark never observes an anomaly when running on an SI database.

This paper presents how we have designed and implemented a multi-version concurrency control for Neo4j that provides snapshot isolation, avoiding the unrepeatable and phantom reads phenomena that currently affect Neo4j. This work has been performed in the context of the European project CoherentPaaS [5] that provides transactional behavior to NoSQL data stores and global transactions and queries across NoSQL and SQL data stores.

2. Neo4j ARCHITECTURE

Neo4j Architecture

Figure 1: Neo4j Architecture

Neo4j is a graph database, as such, the entities it handles are nodes and relationships (edges in graph jargon) among them. It also allows defining properties and labels. Labels are used to associate a “role” to a node. Properties can be associated to both nodes and relationships.

¹ This research has been partially funded by the European Commission under projects CoherentPaaS and LeanBigData (grants FP7-611068, FP7-619606), the Madrid Regional Council, FSE and FEDER, project Cloud4BigData (grant S2013TIC-2894), and the Spanish Research Agency MICIN project BigDataPaaS (grant TIN2013-46883).

Neo4j architecture is similar to the one of a traditional database, although it differs quite a bit in the details (Figure 1). Overall, the architecture has an object cache and a persistent store as a traditional database. However, the internal representation is optimized for graphs.

Nodes are kept in a file whose position is determined by the node identifier. That position in the file contains the ID of the first relationship of the node and the ID of its first property. Relationships are stored in a different file. The source node of the relationship and the destination node are stored. Properties of nodes and relationships are stored in a different file.

Neo4j also uses indexes to optimize some of the accesses. It has two indexes for nodes, one for labels and another one for properties that map them to the set of nodes associated to them. It also maintains one index for relationships, mapping properties to nodes holding those properties.

3. SNAPSHOT ISOLATION

Snapshot isolation is typically implemented as a multi-version concurrency control (MVCC). It requires keeping track of multiple versions per entity. This means that updating in place is not especially convenient and a mechanism is needed to maintain multiple versions of each data item, either physically or logically.

SI can be implemented by enforcing two rules. The read rule states that a transaction should observe the most recent committed version of each data item at the time the transaction start. The write rule states that no two concurrent transactions can update the same data item.

SI requires a way to remove obsolete versions of the data items that will never be read by active transactions. Another important issue to take into account is that versions of uncommitted data items should be kept private, but they should be read by the transaction that wrote them to guarantee that a transaction reads its own writes.

4. SNAPSHOT ISOLATION FOR Neo4j

Transactions are assigned a start timestamp that corresponds to the most recent committed state. The commit timestamp is given to a transaction when it commits. This commit timestamp is used to tag each item (version) the transaction has updated. We have versioned both nodes and relationships. Versions are implemented as an additional property for both of them. This property stores the commit timestamp. Another property has been added to indicate if a data item has been deleted. A deleted data item has to be kept till no previous version can be read by an active transaction. This mechanism is also called tombstone versions. Versions are kept in the Object Cache of Neo4j. In particular, each object representing a node or relationship stores a list of versions. In that way, when a transaction reads a node, the right version for the reading transaction can be obtained by traversing the list of versions.

Neo4j uses an iterator to traverse the persistent state when needed to answer queries. We have enriched this iterator to take into account the versions kept in the cache in order to guarantee read-your-own writes behavior.

Neo4j implements read-committed isolation with a traditional locking mechanism with short read locks and long write locks. We have removed the short read locks since they are not needed for snapshot isolation. The implementation of long write locks has been modified to perform write-write conflicts implementing a first-updater wins strategy.

Multi-versioning has also been applied to indexes. Properties and labels are never deleted in Neo4j even if no node/relationship is using them. We version them to know whether they should be visible or not for a particular transaction. When a property or label has been created by a transaction with a higher timestamp than the start timestamp of the reader transaction, it can simply discard them. If the timestamp is equal or lower than the start timestamp of the reading transaction then the list of associated nodes/relationships is traversed. The nodes/relationships are tagged with the commit timestamp of the transaction that associated the label/property to the node/relationship. In this way, it is possible to discard those nodes/relationships that do not correspond to the snapshot to be observed by the transaction (those with a higher commit timestamp than the start timestamp of the reading transaction).

The most difficult question to provide snapshot isolation in Neo4j is how to implement multi-versioning in an efficient way. One of the most common inefficiencies introduced by multi-versioning is the version garbage collection process. The approach we have adopted avoids this issue by only writing to the persistent data store the most recent committed version of each data item. The other versions are kept in memory. In order to make the version garbage collection efficient, they are threaded with a double linked list sorted by timestamp to enable to perform the garbage collection just traversing those versions that must be garbage collected. In this way, the cost of garbage collection is reduced to the minimum.

Figure 2: Performance Results

We have performed a preliminary performance evaluation comparing the original implementation of transactions in Neo4j with our SI implementation. The database has 12.3MB and stores movies (from <http://neo4j.com/developer/example-data/>). The workload executes 50% updates and 50% reads. Read transactions read a random node. Update transactions read a random node and modify a random property of the node. In Fig. 2 the results of the micro-benchmark are shown. The response time is similar for both implementations, updates last 100-200 ms and reads below 50 ms.

ABSTRACT

Skyline queries represent a dataset by the points on its pareto frontier, but can become very large. To alleviate this problem, representative skylines select exactly k skyline points. However, existing approaches are not *scale-invariant*, not *stable*, or must materialise the entire skyline.

We introduce the *maximum coverage representative skyline*, which returns the k points collectively dominating the largest area of the data space. It satisfies the above properties and reflects a critical property of the skyline itself.

1. INTRODUCTION

Grasping large datasets can be overwhelming. The skyline query [2] helps by summarizing a dataset with only those points that represent the pareto frontier of the data. A point p is on the pareto-frontier (and thus in the skyline) if it is not *dominated* by some other point q , i.e., p is better than all non-equal points in at least one attribute. However, even this is often not enough. The skyline may grow quite large: e.g., on high dimensional data, points have more opportunities (dimensions) on which to be better than other points.

In order to solve this, several approaches have been proposed. Given an integer k , a *ranking skyline* [3, 9, 10] returns the k points with the highest score according to a skyline-based utility function. However, the full skyline must be retrieved, which, even using highly parallel computation on a GPU, can still take several seconds [1].

Regret minimising sets [4, 7] return the k points for which a worst-case linear utility function evaluates to a score on the subset as closely as possible to the one on the skyline. Computing such a set also requires knowing the skyline.

Existing approaches for *representative skylines* [5, 6, 8] return the k skyline points best *representing* the full skyline, but require knowing the skyline to be calculated: the number of skyline points between all pairs of representative skyline points [6]; the maximum distance from any non-representative skyline point to its nearest representative [8]; or the k skyline points maximising the number of non-skyline

points dominated [5]. Also, [8] is not *scale-invariant*, e.g., scaling miles to kilometres distorts the result, and [5] is not *stable*, i.e., “junk” non-skyline points can be added to manipulate the representative skyline. In this paper, we introduce the first representative skyline to avoid all of these pitfalls.

2. MAXIMIZING COVERAGE

The skyline is defined as the subset of non-dominated points [2]. The skyline also has various interesting properties, e.g. that it dominates the rest of the dataset. In [5], this property is emphasized and a representative skyline is developed, but it is not stable as mentioned above.

Another property is that no other subset of points dominates a larger area of the data space. I.e., the skyline captures *the contour of the data space occupied by the data*. This property is agnostic to non-skyline points, suggesting inherent stability. Thus we introduce the *maximum coverage representative skyline* (MCRS): the size- k set that dominates the largest area of the data space. It is the set of k points that best achieves this critical property of the skyline.

Note that the MCRS is necessarily a subset of the skyline (at least if k is smaller than the size of the skyline), since every non-skyline point dominates less area than the skyline points that dominate it. The MCRS is also both stable and scale-invariant, since neither adding/removing non-skyline points nor scaling the dataset in any dimension affects the relative size of the dominance area. Perhaps most appealingly, the MCRS is skyline-agnostic: there is no inherent dependence on knowing the skyline to compute the optimal MCRS: the size of the area collectively dominated by any given set of points is unrelated to knowing the full skyline.

Formally, if $\text{dom-area}(p)$ denotes the area occupied by the (infinitely many) points $q \in \mathbb{R}^d$ dominated by p , then the MCRS of size k on dataset \mathcal{D} is¹:

$$\text{MCRS}(\mathcal{D}, k) = \underset{S \subseteq \mathcal{D}, |S|=k}{\operatorname{argmax}} \left| \bigcup_{p \in S} \text{dom-area}(p) \right| \quad (1)$$

Figure 1 gives an example: the MCRS of size 2 is $\{p_1, p_3\}$, since p_1 and p_3 cover an area of 42, whereas p_1 and p_2 only cover 40 and p_2 and p_3 only cover 34.

An algorithm for 2d In the following, we show that in two dimensions, the MCRS can be computed in time $\mathcal{O}(m^3k + n \log n)$ and space $\mathcal{O}(mk + n)$, where $n = |\mathcal{D}|$ and

¹Note, importantly, that this set formulation avoids multiply counting area dominated by more than one point in a set S .

Figure 1: Three skyline points p_1 , p_2 , and p_3 and their corresponding dominance areas. The optimal size-2 MCRS is indicated by the striped area.

$m = |\text{skyline}(\mathcal{D})|$. This is a nice asymptotic result given that the naive search space is $\mathcal{O}(n^k)$. The algorithm proceeds in three steps: First, sort $\mathcal{D} \cup \{(1, 0)\}$ so that $p_0 \leq \dots \leq p_n$; then, discard points dominated by their predecessors and relabel points p_0, \dots, p_m ; the MCRS will now be the value of $\text{MCRS}(m, m, k + 1) \setminus \{p_m\}$ in the following recursion:

$$\begin{aligned} \text{MCRS}(x, y, 0) &= \{p_y\} \\ \text{MCRS}(x, y, \kappa), y \geq \kappa, &= \{p_0, \dots, p_{\kappa-1}\} \\ \text{MCRS}(x, y, \kappa) &= \underset{s \in \{\text{MCRS}(x, \hat{y}, \kappa) \cup \{p_y\}, \text{MCRS}(x-1, y, \kappa)\}}{\text{argmax}} |dom\text{-}area(s)|, \end{aligned}$$

where:

$$\hat{y} = \underset{0 \leq y' < y}{\text{argmax}} \left(\langle p_x.x, p_{y'}.y \rangle, \langle 1, p_y.y \rangle \right) + |dom\text{-}area(\text{MCRS}(x, y', \kappa - 1))|.$$

The intuition behind the recursion is to sweep through all pairs of skyline points, calculating for each pair the best solution that dominates all the space that it dominates. Because dominance is transitive, the result for each pair of points is very similar to those for nearby pairs of points. One can see this as traversing column-by-column the intersection points of the grid-partitioning induced by the skyline. (In Figure 1 the sequence $[(9, 0), (9, 3), (7, 0), (7, 3), (7, 4), (3, 0), (3, 3), (3, 4), (3, 8), (0, 0), (0, 3), (0, 4), (0, 8)]$.)

By adding the sentinel $p_m = \langle 1, 0 \rangle$ with $|dom\text{-}area(p_m)| = 0$ to the end of the list, the last column aggregates the best solution from the entire grid. Using dynamic programming to solve the recursion leads to the asymptotic results.

This non-indexing algorithm first computes the skyline to improve efficiency. However, that does not imply computing the skyline first is always more efficient; an index may permit prioritising promising regions of the data space. Also, this algorithm computes the *optimal* solution, not a greedy approximation, thereby allowing us to study the proposed model itself (rather than just the algorithm's efficiency).

3. REPRESENTATIVENESS OF AN MCRS

In this section, we evaluate the MCRS concept and algorithm. We generate independent (I) and anti-correlated (A) datasets of 1 million 2-dimensional points as per [2], which have 17 and 64 skyline points each.² We implement the algorithm in C++ and execute it on a machine with an Intel Core i7-4770K 3.50GHz CPU and 16GB of memory.

Figure 2a shows the dominance area of the MCRS relative to the skyline and Figure 2b shows execution time, both as

²Correlated 2d skylines are already sufficiently small.

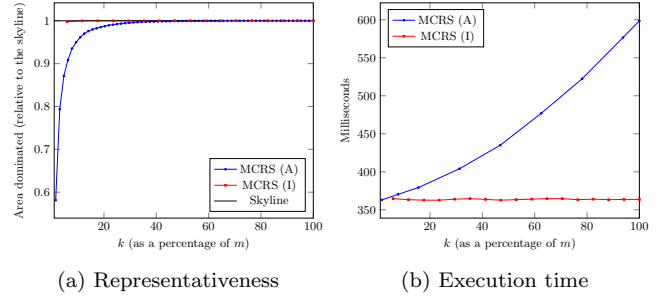

Figure 2: Evaluation of the MCRS

a function of k . (I): The MCRS almost exactly represents the skyline, even at $k = 1$, with stable execution time. (A): It quickly approaches the skyline, dominating $> 90\%$ with fewer than 10% of the points. Computing representations with $\leq 60\%$ of the skyline takes less than a half-second.

4. CONCLUSION AND FUTURE WORK

We introduced the *maximum coverage representative skyline* (MCRS), a scale-invariant, stable, skyline-agnostic representative skyline, achieving what the skyline achieves. We gave an efficient algorithm to compute an optimal 2d MCRS with which we illustrated that the MCRS covers much of the data space as the full skyline, even for small k .

We will extend this work with algorithms for $> 2d$ and multi-dimensional indexes, e.g. R-tree extensions, that can exploit the independence of the MCRS from the skyline.

ABSTRACT

We propose a new on-line ϵ -approximation algorithm for mining closed itemsets from a transactional data stream, which is also based on the incremental/cumulative intersection principle. The proposed algorithm, called LC-CloStream, is constructed by integrating CloStream algorithm and Lossy Counting algorithm. We investigate some behaviors of the LC-CloStream algorithm. Firstly we show the incompleteness and the semi-completeness for mining all frequent closed itemsets in a stream. Next, we give the completeness of ϵ -approximation for extracting frequent itemsets.

Keywords

On-line algorithm, approximation, closed itemset, intersection, completeness

1. INTRODUCTION

Intersecting transactions in a data set is an alternative characterization of closed itemsets [1, 3, 4], which naturally leads to an incremental/cumulative computation of closed itemsets in a transaction data stream. CloStream [6] is an exact-computing on-line mining algorithm, which is a direct implementation of the incremental intersecting approach. Such an incremental intersection approach, however, has great difficulties, in practice, for quitting or breaking intersections in early stages, because it is difficult to predict in advance that current intersection operations never produce any frequent closed itemsets[1].

In this paper, we propose a new on-line ϵ -approximation algorithm for mining closed itemsets from a stream, which is also based on the incremental/cumulative intersection principle. The proposed algorithm, called LC-CloStream, is constructed by integrating CloStream [6] algorithm and Lossy Counting algorithm [2]. LC-CloStream succeeded in overcoming the above difficulties using ϵ -approximation [2, 5].

We study fundamental properties of LC-CloStream algorithm. Firstly we show the incompleteness and the semi-completeness for mining all frequent closed itemsets in a stream. Next, we give the completeness of ϵ -approximation

for extracting frequent itemsets from a transaction streams.

2. PRELIMINARIES

Let $I = \{e_1, e_2, \dots, e_r\}$ be a set of items. A non-empty subset A of I is called an *itemset* (or *transaction*). A *transaction stream* of length N is a sequence of N transactions $\langle A_1, A_2, \dots, A_N \rangle$. In this paper, we denote items as a, b, c, \dots , and itemsets as A, B, C, \dots . We also abbreviate an itemset $\{e_1, e_2, \dots, e_m\}$ as $e_1 e_2 \dots e_m$, for simplicity.

Let S be a stream $\langle A_1, \dots, A_N \rangle$ and B be an itemset. We define a multiset $\mathcal{K}(B, t)$ at time t ($1 \leq t \leq N$) as $\mathcal{K}(B, t) = \{A_j \in S \mid B \subset A_j, 1 \leq j \leq t\}$. The *frequency* of B at time t , denoted as $\text{sup}(B, t)$, is $|\mathcal{K}(B, t)|$. Given a minimal frequency threshold σ ($0 < \sigma < 1$), B is *frequent* at time t in S if $\text{sup}(B, t) \geq \sigma \cdot t$. An itemset B is *closed* at time t in S if there is no itemset C such that $B \neq C$ and $B \subset C$ and $\text{sup}(B, t) = \text{sup}(C, t)$.

The following recursive relation makes it possible to incrementally compute closed itemsets in a stream S . Let $CIS(S)$ be a set of all closed itemsets in S and \circ be a well-known concatenation operator of two sequences.

PROPOSITION 1 ([1, 3]). Let S be a stream $\langle A_1, \dots, A_N \rangle$. We have:

$$\begin{aligned} CIS(\langle A_1 \rangle) &= \{A_1\} \\ CIS(S_k) \circ \langle A_{k+1} \rangle &= CIS(S_k) \cup \{A_{k+1}\} \cup \\ &\quad \{B \mid \exists C \in CIS(S_k) : B = C \cap A_{k+1}\}, \end{aligned}$$

where S_k is the k element prefix of S , i.e., $\langle A_1, \dots, A_k \rangle$.

CloStream [6] is an on-line exact counting algorithm for mining closed itemsets in a stream, which uses the above recursive relation in a straightforward way, and thus cannot avoid a combinatorial explosion problem caused by $CIS(S)$.

3. LC-CLOSTREAM

The LC-CloStream algorithm maintains an internal *frequency table* TS . Formally, TS is a set of tuples $\langle B, f(B), \delta(B) \rangle$, where B is an itemset, $f(B)$ is the number of occurrences of B after the time t_B when B was lastly stored in TS , and $\delta(B)$ is the maximal error count at time t_B . We write the frequency table TS at time t as $TS(t)$, and similarly for $f(B, t)$ and $\delta(B, t)$. Let $\mathcal{SP}(B, t)$ denote the set of supersets of B belonging to the frequency table $TS(t)$, that is, $\mathcal{SP}(B, t) = \{C \in TS(t) \mid B \subset C\}$. We define $\max\mathcal{SP}(B, t)$ as follows:

$$\max\mathcal{SP}(B, t) = \underset{C \in \mathcal{SP}(B, t)}{\operatorname{argmax}} (f(C, t) + \delta(C, t))$$

The former part of LC-CloStream algorithm, i.e., in lines 5 to 18, performs the incremental intersection and the latter

Algorithm 1 LC-CloStream algorithm

Input: a stream $\mathcal{S} = \langle A_1, A_2, \dots, A_N \rangle$,
a relative minimal frequency threshold σ ($0 < \sigma < 1$),
a maximal permissible error ratio ϵ ($0 < \epsilon < \sigma$).
Output: a family \mathcal{FCS} of frequent closed item sets in \mathcal{S}

```
1:  $t \leftarrow 1$  ▷  $t$  is a current time
2: Initialize the frequency table  $TS$ .
3: while  $t \leq N$  do
4:   Read  $A_t$ .
5:   for each  $B \in TS$  do
6:      $C \leftarrow B \cap A_t$ 
7:     if  $C \neq \emptyset$  then ▷ i.e. the case of  $\mathcal{SP}(C, t) \neq \emptyset$ 
8:        $D \leftarrow \max\mathcal{SP}(C)$ 
9:       if  $C \notin TS$  then ▷ register  $C$  as a new entry
10:         $TS \leftarrow TS \cup \{ \langle C, f(D) + 1, \delta(D) \rangle \}$ 
11:       else ▷ increase the frequency value of  $C$ 
12:         $TS \leftarrow (TS - \{ \langle C, f(C), \delta(C) \rangle \}) \cup \{ \langle C, f(D) + 1, \delta(D) \rangle \}$ 
13:       end if
14:     end if
15:   end for
16:   if  $A_t \notin TS$  then ▷ register  $A_t$  as a new entry
17:      $TS \leftarrow TS \cup \{ \langle A_t, 1, \epsilon \cdot (t - 1) \rangle \}$ 
18:   end if
19:   for each  $B \in TS$  do ▷  $\epsilon$ -elimination
20:     if  $f(B) + \delta(B) \leq \epsilon \cdot t$  then
21:        $TS \leftarrow TS - \{ \langle B, f(B), \delta(B) \rangle \}$ 
22:     end if
23:   end for
24: end while
25: return  $\mathcal{FCS}(N) = \{ B \in TS \mid f(B) + \delta(B) \geq \sigma \cdot N \}$ 
```

part in lines 19 to 23 executes the ϵ -elimination operation, which involves an ϵ -approximation computation.

Notice that Algorithm 1 is described declaratively for simplicity, thus has the time complexity $O(k^2)$ where k is the total number of entries in TS , while [6] gave an optimized procedural form of the complexity $O(k)$.

Unfortunately, LC-CloStream algorithm has a counterexample for the completeness, as shown in Example 1. We can, however, give the semi-completeness for LC-CloStream.

Example 1. Let \mathcal{S}_1 be a stream $\langle a, b, b, b, b, b, ac, ac, ac \rangle$ of length 9. We suppose $\sigma = 0.3$ and $\epsilon = 0.2$. Then, the frequent closed itemsets in \mathcal{S}_1 are three itemsets a, b, ac . At time $t = 1$, LC-CloStream algorithm processes the first transaction a and store the set a , as a new closed itemset, into the frequency table TS . At time $t = 2$, LC-CloStream adds the set b into TS , and so on. At time $t = 6$, LC-CloStream firstly increase the frequency counter $f(B)$ in TS , then the table TS becomes to $\{ \langle a, 1, 0 \rangle, \langle b, 5, 1 \rangle \}$ at this point. Next LC-CloStream performs the ϵ -elimination rule to TS , and delete the tuple of the closed set a since $f(a, 6) + \delta(a, 6) = 1 < 1.2 = \epsilon \cdot 6$ holds. At time $t = 7$, LC-CloStream registers the set ac to TS as a new closed set, but cannot increase the frequency counter of the set a , because TS has the tuple of a no longer. Thus, LC-CloStream eventually returns the set $\mathcal{FCS}(9) = \{ b, ac \}$ and fails to produce the frequent closed itemset a .

Next, we show a semi-completeness theorem which partially overcomes the deficit shown above in LC-CloStream. Furthermore, we give completeness theorem of LC-CloStream for frequent itemsets mining based on ϵ -approximation.

Definition 1. Let \mathcal{S} be a stream of length N , B be a closed itemset and ϵ be a maximal error ratio. We say, B is ϵ -extendable on \mathcal{S} if there is a closed itemset C such that $B \subset C$, $B \neq C$ and $\sup(B) - \sup(C) \leq \epsilon N$

THEOREM 1 (SEMI-COMPLETENESS FOR CLOSED ITEMSETS). *Let \mathcal{S} be a stream of length N and B be a frequent closed itemset in \mathcal{S} . If B is NOT ϵ -extendable, then $B \in \mathcal{FCS}(N)$.*

Definition 2. Let \mathcal{S} be a stream of length N , σ be a minimal frequency threshold and $\mathcal{FCS}(N)$ be a output produced from \mathcal{S} by LC-CloStream algorithm. Then we define $\mathcal{RS}(N)$ as follows:

$$\mathcal{RS}(N) = \mathcal{FCS}(N) \cup \{ C \mid \exists B \in \mathcal{FCS}(N) : C \subset B, C \neq \emptyset \}$$

THEOREM 2 (COMPLETENESS FOR ITEMSETS). *Let \mathcal{S} be a stream of length N and B be a frequent itemset in \mathcal{S} . Then $B \in \mathcal{RS}(N)$.*

Definition 3. Let \mathcal{S} be a stream of length N and ϵ be a maximal error ratio. For any itemset B at time t ($1 \leq t \leq N$), we define $F(B, t)$ and $\Delta(B, t)$ as follows:

1. if $\mathcal{SP}(B, t) = \emptyset$, then $F(B, t) = 0$, $\Delta(B, t) = \epsilon \cdot t$

2. if $\mathcal{SP}(B, t) \neq \emptyset$, then

$$F(B, t) = f(\max\mathcal{SP}(B, t), t), \quad \Delta(B, t) = \delta(\max\mathcal{SP}(B, t), t).$$

We call $F(B, t) + \Delta(B, t)$ the *estimated frequency* of B at time t .

Notice the estimated frequency $F(B, t) + \Delta(B, t)$ is defined based on $TS(t)$ of time t , while the counting frequency $f(B, t) + \delta(B, t)$ depends just on $TS(t - 1)$ of the previous time $t - 1$.

THEOREM 3 (ϵ -APPROXIMATION OF FREQUENCY). *Let \mathcal{S} be a stream of length N and ϵ be a maximal error ratio. For any itemset B , we have*

$$F(B, N) \leq \sup(B, N) \leq F(B, N) + \epsilon \cdot N$$

4. CONCLUSIONS

LC-CloStream can avoid a part of combinational explosion problems in a bursty transactional data stream [5]. In the future, we will study an efficient implementation using a sophisticated data structure, and also have a plan to investigate a more advanced framework where the frequency table has a fixed constant size [5].

ABSTRACT

The IBM DB2 Analytics Accelerator (IDAA) integrates the strong OLTP capabilities of DB2 for z/OS with very fast processing of OLAP workloads using Netezza technology. The accelerator is attached to DB2 as analytical processing resource – completely transparent for user applications. But all data modifications must be carried out by DB2 and are replicated to the accelerator internally. However, this behavior is not optimized for ELT processing and predictive analytics or data mining workloads where multi-staged data transformations are involved. We present our work for extending IDAA with accelerator-only tables, which enable direct data transformations without any necessary interventions by DB2. Further, we present a framework for executing arbitrary in-database analytics operations on the accelerator while ensuring data governance aspects like privilege management on DB2 and allowing to ingest data from any other source directly to the accelerator to enrich analytics e.g., with social media data. The evolutionary framework design maintains compatibility with existing infrastructure and applications, a must-have for the majority of customers, while allowing complex analytics beyond read-only reporting.

Keywords

analytics, data mining, db2, mainframe, idaa

1. INTRODUCTION

The IBM DB2 Analytics Accelerator (IDAA) [1] is an extension for IBM's® DB2® for z/OS® database system. It's primary objective is the extremely fast execution of complex, analytical queries on a snapshot of the data copied from DB2. However, when it comes to more complex, multi-staged data analysis tasks like data mining, the accelerator can often provide limited improvements only. Predictive analytics tools like SPSS [4] resort to multiple SQL statements, each implementing a step or stage in a chain of data preparation, transformation, and evaluation tasks. For each stage,

base data needs to be transferred to IDAA before mining algorithms can be run and result data has to be materialized within DB2 before it can be used as input for the next stage or iteration. A key requirement for enhancing these workloads is to minimize data movement while still exploiting the accelerator for this task. We solve this issue with accelerator-only tables (AOTs) which are discussed in Sec. 2. The second use case is the application of the analytic algorithms in the pipeline. A generic framework is required which allows to pass code for arbitrary algorithms to IDAA while still implementing data governance aspects correctly. A seamless approach, completely transparent to user applications is discussed in Sec. 3.

2. ACCELERATOR-ONLY TABLES AND DATA INGESTION

Maintaining a copy of the DB2 data in the accelerator for query processing is the main use case of IDAA. However, this design involves a lot of data movements in case of multi-staged algorithms that require result materialization inside DB2 before the next step can be executed. The first building block in our current efforts are accelerator-only tables (AOTs), i.e., tables whose data solely resides inside IDAA (cf. Fig. 1), and DB2 only keeps a *proxy* or *table reference* which is usually named *nickname* in federation contexts [5]. This proxy is used for storing meta data in the DB2 catalog and acts as indicator for delegating any query on the corresponding AOT to IDAA. For creating AOTs the **CREATE TABLE** statement was extended by an additional **IN ACCELERATOR** clause. AOTs are populated with **INSERT** statements comprising a list of values or a sub-select which might invoke arbitrary transformation procedures (cf. Sec. 3), retrieving the data from other regular accelerated tables or AOTs. Likewise, **UPDATES** and **DELETES** are handled. The second way for populating AOTs is the new IDAA Loader [2] (cf. Fig. 1). The data to be loaded can originate from a variety of sources, even from applications not running on System z which opens up a wide range of new use cases. Data can be ingested in both, regular DB2 tables and AOTs. In the past, IDAA was not concerned about transactions because only the cursor stability isolation level was supported. Queries were executed under snapshot isolation in Netezza. With AOTs, IDAA has to be aware of the DB2 transaction context so that correct results are guaranteed, i.e., uncommitted data modifications of the own transaction are handled. At the same time, concurrent execution of multiple queries in a single transaction are also supported.

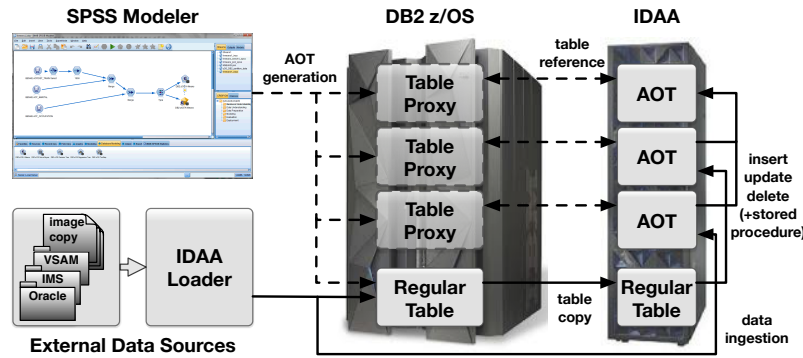

Figure 1: Overview IDAA with Accelerator-Only Tables

3. IN-ACCELERATOR ANALYTICS

IDAA has now a framework for invoking generic, customer-specific stored procedures (SPs). A SP can be called in DB2z, and IDAA forwards the procedure execution to the Netezza backend (cf. Fig. 2 and Fig. 3). We integrated the Netezza analytics package [3] which is used by SPSS [4]. The SPSS modeler provides means to define nodes, to create and populate AOTs, e.g., by joining accelerated tables, and then to invoke an analytics SP running in IDAA. Such a scenario is illustrated in Fig. 1 where the k-means clustering algorithm is applied on some filtered, enriched, and sampled input data. Intermediate results are materialized into AOTs and finally fed to the k-means SP. However, two challenges occur here. First, user privileges need to be verified for all data sources referenced by such a black box SP. Therefore, IDAA resolves all dependencies without executing the SP code. These table references are passed to DB2 which in turn validates necessary user privileges before the actual operation is carried out. The second issue arises from views existing on the DB2 side, which are not present on the accelerator. The framework exploits DB2's query acceleration capabilities to extract the view definition and implicitly translate it to the Netezza SQL dialect. A temporary view is created in the Netezza backend using that definition.

4. RELATED WORK

Using accelerator-only tables is similar to the concept of pass-through functionality in federated systems based on SQL/MED [5]. However, the overall use case for AOTs is quite different. AOTs are conceptually DB2 tables and can be manipulated using DB2's SQL dialect. It is just that AOTs store all their data in the analytics-optimized query engine and not in the transactional storage engine of DB2

for z/OS itself. Contrary to that, federated systems provide a means to access tables and data residing in another, stand-alone database system. The integration of the different query engines is on a much deeper level in IDAA.

MySQL provides an internal interface to plugin different storage engines with different characteristics [6]. IDAA in DB2 for z/OS implements a similar architecture by combining DB2's and Netezza's characteristics and the respective underlying storage mechanisms. However, the integration of both happens on the SQL dialect and SQL optimizer layer and not on the buffer pool and storage layers.

ABSTRACT

By the events in the past years, the integration of data protection mechanisms into information systems becomes a central research problem again. In this poster, we show how query rewriting can be used to maintain privacy of users in smart (or assistive) environments. We developed a privacy respecting query processing and a vertical fragmentation of queries, processing maximal parts of the query as close to the sources of the data (e.g. sensors) as possible.

Categories and Subject Descriptors

H.2.4 [Database Management]: Systems—*Query Processing*; K.4.1 [Computer and Society]: Public Policy Issues—*Privacy*

General Terms

Privacy Enhancing Technologies, Database Systems

1. PRIVACY

Smart Metering, Internet surveillance, motion profiles, biometric databases, data retention: In the digital world steadily more and more information about ourselves and our environment is collected. Besides “classical” personal information, such as the name, age or gender, a plurality of sensors records our activities and inclinations. Active and passive RFID tags, cameras, microphones, but also sensors on light switches and power sockets capture the current situation in the ubiquitous environments, up to 100 times per second.

Especially smart environments such as assistive systems using activity and intention recognition [4] are a possible cause of privacy violations, especially if the query realizing the recognition analysis is performed on a cloud server.

To reduce privacy violations, it is necessary

*A full version of this paper is available as a Technical Report at www.ls-dbis.de/digbib/dbis-tr-cs-01-16.pdf

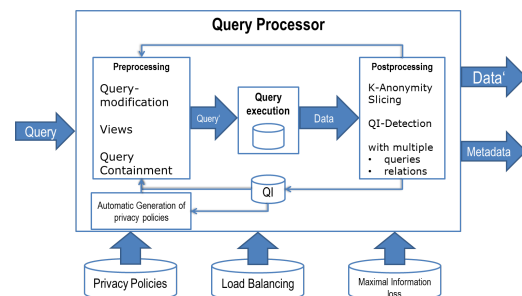

Figure 1: The concept of the privacy-aware query-processor.

- to decrease collected personal information, i.e. to apply the principle of data avoidance (except where data are required),
- to process data with personal references as less as possible or — at least — as close to the local data sources (sensors) as possible and
- to anonymize, pseudonymize and delete personal data, unless it is used for further processing and necessary to realize the aim of the assistive environment.

Data minimization and data avoidance are therefore prescribed, indispensable requirements for the design of smart systems. This requirement can be achieved in databases by transforming both queries and query results, as well as using views [3].

2. PRIVACY-AWARE QUERY PROCESSING

The PARADISE¹-approach aims to withdraw the burden of respecting privacy constraints from the assistive systems by adding privacy protection mechanisms to those systems storing and analyzing the data: database systems on different levels. PARADISE combines performance aspects of big data analytics (by using massively parallel database technology [5]) and privacy protection. Our privacy-aware query-processor (see Figure 1) generates anonymized result sets. These data maintain a high degree of value for the initial query generated by the assistive system. On the opposite, additional knowledge can hardly be derived.

¹Privacy Aware Assistive Distributed Information System Environment

The preprocessor allows the analysis and the rewriting of database queries regarding user-defined privacy policies [2]. During the execution of the request, it is decided whether the request will be answered and anonymized directly on the current network peer, or is sent to lower nodes (vertical fragmentation, see below). The postprocessor executes the anonymization of the query results, taking into account various criteria of quality and privacy. For this, several data protection metrics and algorithms are provided. The module for the automatic generation of privacy settings produces and adapts existing user-defined privacy policies to new devices and changing requirements and queries.

3. QUERY REWRITING BY VERTICAL FRAGMENTATION

The smart environment or assistive system sends a query request Q to the database d integrating the entire sensor data recorded in our environment. The result of Q is needed to perform the activity and intention recognition. The data sources are sensors being located in appliances in apartments and buildings. Instead of shipping d to the cloud server sending the request, maximal parts of Q will be evaluated as close to the sensor as possible. As can be seen in Figure 2, instead of performing $Q(d)$ in the cloud, the maximal subquery Q_j will be shipped to the next lower node of the processing chain, in the case of the example a PC located in our apartment. While Q performs an iterative machine learning algorithm implemented in R and SQL, and Q_j being a complex SQL query with recursion, the lowest node in the processing chain (the sensors) can only compute some filter mechanisms (simple selections) and some simple aggregations over the last values generated (window function: average of last minute). Each of the nodes will ship the query result d_j to the node sending the request. After a final anonymization step A , the data “leaving our apartment” d' will only be a small subset of the original data d .

We assume that the lower nodes will each have less query computing power than the higher nodes: while sensors are only performing simple filters / selections and aggregations, an appliance like a TV or a smart network music player will be able to perform simple (SQLsuperlight) database queries, an Android-based home media server even more complex SQL queries.

The whole query processing procedure

$$Q(d) := d_j = Q_j(\dots d'_i = A(d_i = Q_i(\dots (d_1 = Q_1(d)) \dots))$$

is transformed in a way, that the cloud server will perform a remainder query Q_δ on d' instead of performing Q on d , hence resulting in the privacy protecting query rewriting $Q(d) \rightarrow Q_\delta(d')$. In other words, the query Q is fragmented in queries Q_j (that can be performed at a lower node) and a remainder query Q_δ that can only be performed at the more powerful node of our vertical fragmentation of query processors.

Since recognizing the maximal SQL queries in an R machine learning algorithm is undecidable in general, we try to detect some larger “SQLable” patterns in the activity and intention recognition procedures described in [4]. Other aspects of our privacy-aware query-processor are described in, e.g. [1].

By rewriting the query Q into Q_j and Q_δ and only performing Q_δ outside our “privacy protected” appliance en-

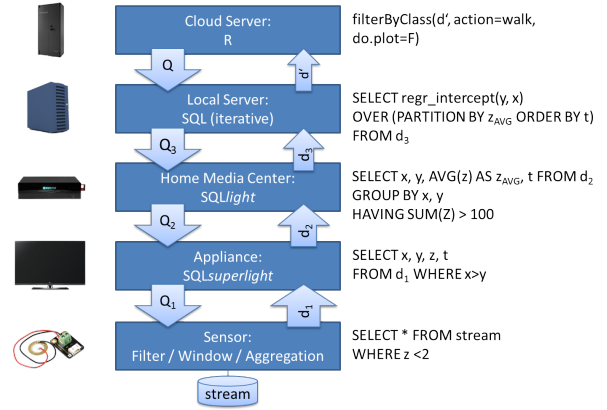

Figure 2: Vertical Query Fragmentation: Query and query result transformation on different peers.

semble in our apartment, we hope to automatically prevent the service provider of our assistive system to use our personal data in a way we did not consider to be possible when starting to use his smart service. A remaining open problem is to decide whether a privacy-violating query Q_\downarrow can be performed even on d' instead of d . In this case, we have to extend the anonymization step A already performed. This open problem results in a query containment problem of Q , Q_\downarrow and Q_j that will be part of our further research.

1. INTRODUCTION

Online social networks (OSN) are one of the most successful applications that have been created this last decade. Central to these applications is the problem of sharing data, such as texts, photos, geolocation, etc. In most cases, this data is private, and thus is only shared with “friends”, a loose concept. Some OSN, such as Google+ let you define *circles* in order to categorize your friends: friends, close friends, acquaintances, etc. Data can then be shared on finer grain using these circles. However, there is no automatic way to control the simultaneous sharing of data to several circles, with different data precision granularities, such as in the following scenario: *Alice wants to share a set of photos with her family, photos with no metadata with her close friends, photos without faces (and without metadata) in a reduced definition with her acquaintances, and does not want to share anything with anyone else.*

In this article, we will show how the use of a data sharing algebra to write a variety of *access control plans* (ACP) can overcome these current limitations of OSN access control. Moreover, by using an algebra, it becomes simple to modify, compose, and share these ACPs. Thus less advanced users can easily reuse ACPs shared on a marketplace by more experienced users. A prototype of the DatShA system has been implemented using XQuery 3.0 and is briefly described.

2. OVERVIEW OF DatShA

In current OSNs, users have on one side vast quantities of personal data, and on the other side numerous “friends” with whom they wish to share (or sometimes hide) this data. In the current systems, it is not simple to share a specific piece of data while modifying it (e.g. changing its precision or removing some information) depending on the target with whom it is to be shared.

Consider the examples mentioned in the introduction. The ACP related to Alice’s close friends should transform a set of photos to another set where metadata is removed. This could be done by simply specifying a regular expression to identify images files to be shared (FileSearch operator – see Figure 1.e), “type” this file to images (PathToImage operator – see Figure 1.e), then remove metadata (RemoveMeta operator). For Alice’s acquaintances, other operators could be invoked: ExtractFaces, ExtractMeta, Select and ReduceDefinition operators (not detailed here).

Thus the objective of DatShA is to provide the infrastructure and an extensible set of generic operators to describe how users want to process their data before sharing it. The operators must be able to be combined on any sort of (semi-structured) data to form an algebra. Finally, ACP may include user-dependent data (e.g., contact files) such that it can also compute the set of users with whom the data is shared, thus linking a *plan* with its *grantee*.

Published in Proc. 19th International Conference on Extending Database Technology (EDBT), March 15-18, 2016 – Bordeaux, France: ISBN 978-3-89318-070-7, on OpenProceedings.org. Distribution of this paper is permitted under the terms of the Creative Commons license CC-by-nc-nd 4.0

3. BACKGROUND AND RELATED WORKS

Access Control. Many different access control models exist, such as DAC, MAC, or RBAC. Many works exist on enforcing such models in OSN [1]. We adopt a complementary approach: the goal of DatShA can be seen as helping the user to write complex views of her data, on which she can then apply any existing AC model (most often, DAC or RBAC).

Data Sharing on OSN. Current works on secure data sharing in OSNs consider various problems such as securing communications, i.e. how to securely share data, once access control has been checked [2], or how to write access control policies over data concerning several users [3].

XQuery 3.0. XQuery 3.0. is not only a declarative query language, it is also Turing complete. Rather than using a traditional language such as Java or C, we have chosen to use XQuery and XQuery Update Facility 3.0. Indeed, evaluating an ACP is done through modifications to a structured document (that we chose to code in XML). Generic operators can be completed by snippets of XPath or XQuery code referring to this data structure, which are directly evaluated by the DatShA system.

4. THE DATA SHARING ALGEBRA

4.1 General principle

An ACP is seen as a set of sequences of (polymorphic) operators, serialized as an XML file (see Figure 1.a). It takes as input an XML file containing or referencing private sensitive data and produces an XML file containing or referencing data that can be shared or published (See Figure 1.c). Users or sets of users (such as G+ circles) can be given access rights both on atomic data, and on ACPs. As with traditional access control through views, when access rights are given on an ACP, the data accessed during the process is done with the rights of the *grantor*. For example, if Alice grants Bob the right to view the country she is in, which is computed using her precise GPS coordinates, the execution of the ACP will use Alice’s rights, but only return to Bob the final result.

4.2 Sharing ACPs through a marketplace

Operators and ACPs can be published on a “marketplace”, and described by a short text explaining their goal. They can be downloaded by users in order to fine tune their data sharing policies. Thus, it is possible, even for non-expert users to apply complex access control policies, by combining existing operators or using existing policies. Search, recommendation, or ranking of ACP or operators based on their level of intrusiveness or their usability is possible within the marketplace. The only complexity is to link groups of users to their ACPs, but as the data shared is defined *intentionally* rather than *extensionally*, we believe this is much easier to do than with current privacy settings in OSN.

4.3 ACP Example

We propose the following example which illustrates well DatShA potential : *Alice wants to participate in a survey to determine the*

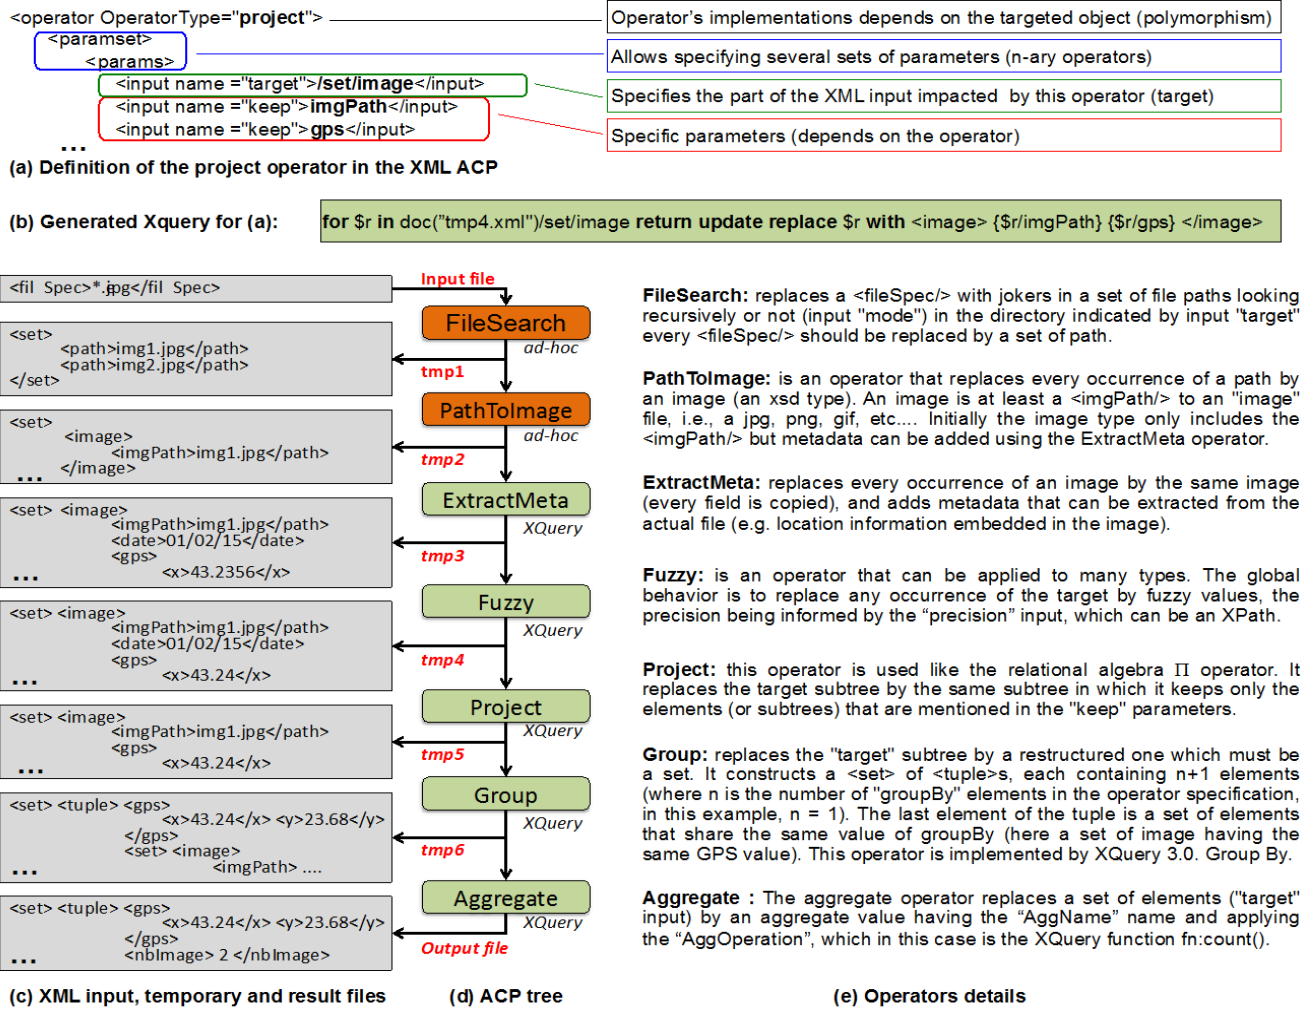

Figure 1: A detailed example of an ACP delivering statistics (number of photos by fuzzy location)

most photographed place on Earth, which can be done by computing a "fuzzy" location of all her photos, where the "fuzzy" location is defined by GPS coordinate and an error bar e.g. $X=45.23 \pm 0.01$ $Y=27.67 \pm 0.01$. Note that this error bar could also be function of the density of photos in a given area.

We present, in Figure 1, the corresponding ACP.

This ACP can be written as a sequence of operators (Due to space limitations, the actual XML ACP file is available online at: <http://www.benjamin-nguyen.fr/data/ACP.xml>). Each operator takes as input an XML file, and produces as output an XML file. It is possible to type-check the ACP at compile time, given that the operators are typed, but this discussion is beyond our scope here. The sequence is the following: for every image in the file path given in the input file, meta-data of the image is extracted, and an operator to reduce the precision of the GPS coordinates is executed. All meta-data apart from the blurred GPS coordinates is removed, pictures are grouped together by fuzzy GPS location, then counted.

Operators can in most cases be implemented in XQuery 3.0 but they can also be *ad-hoc* operators. Note that DatSha also defines many other operators, including binary (or even n-ary) operators such as the join operator which can be used to join two different sequences, thus needing two input files, and producing a single output file. All these operators have been implemented using XQuery. The framework executing a DatSha ACP has been written in Java, using eXistDB to execute the XQuery fragments.

We believe that the use of operators to build ACPs drastically simplifies the creation, reuse, combination and correctness checking of ACPs.

5. CONCLUSION AND FUTURE WORK

DatSha can be used to create ACPs to manage access control to one's data. We believe that the full power of DatSha appears when users start sharing ACPs between each other, either by simply reusing an ACP written by another user, or by integrating such an ACP into a more complex one. Indeed, any ACP can be encapsulated as a DatSha operator. Creating an online marketplace, and testing its usability and adoptability by real users is the next step of our work.

Cluster-based Contextual Recommendations

Kostas Stefanidis
ICS-FORTH, Greece

Leibniz Universität
Hannover, Germany
ntoutsis@kbs.uni-hannover.de

ABSTRACT

In this work, we address the problem of contextual recommendations by exploiting the concept of subspace clustering. Specifically, we pre-partition users that have rated subsets of data items similarly into clusters and we associate a context situation with each cluster. The cluster context is defined as any internally stored information that can be used to characterize the cluster members per se. Then, given a query context, we identify the clusters with the most similar context, and we use their members for making suggestions in a collaborative filtering manner.

1. DESCRIPTION

Recommender systems have become indispensable for several Web sites, such as Amazon, Netflix and Google News, helping users to navigate through the infinite number of available choices. Motivated by the fact that often users have different preferences under different context situations, several approaches, e.g., [1], extend recommender systems beyond the two dimensions of users and items to include further contextual information. Context can be defined as any *external* to the database information that can be used to characterize the situation of a user, such as the location, time or companion of the user, or any internally stored information that can be used to characterize the data per se [6]. In our work, we follow an internal contextualization approach, and infer context from the data itself. A simple way to express an internal context is by specifying conditions for the presence of particular attribute values in the data. For example, for a movies recommender, an internal context can be: *genre=comedy & production-year=2015*. It is clear that such a context characterization cannot be done upon the whole database, as the data display a lot of variability. Rather, we should look for contextual information in smaller, homogeneous subgroups of the data.

*Work done while with the Ludwig-Maximilians University, Munich.

To extract contextual information, we rely on similarities on the user ratings. Intuitively, users close together in their ratings, share the same context, let it be the preference for similar movie genres, or preferences towards specific directors or actors. Typically the user similarity is evaluated w.r.t. the full dimensional feature space, i.e., all available items. Finding similar users for all different items though is hard, while it is more reasonable to find users similar w.r.t. a subset of the items. A straightforward approach to derive such subsets is to categorize the items based on some domain knowledge. In case of movies, for example, the movie genre can be used and items that belong to the same genre can form a subset. A problem with this approach is that such categories are quite vaguely defined, diverse and also overlapping. For instance, the movies *Ted* and *My big fat Greek wedding* are both classified under *comedy*, the later however can be also found under *romance*. For a user interested in comedies it is not clear whether she would equally appreciate a suggestion on *Ted* and *My big fat Greek wedding*. Such a general item categorization, does not reveal much about the aspects that bring users together. Moreover, such aspects might be beyond some given categorization, like the movie genre and also, they might involve more than one dimension, e.g., movie genre and director. Ideally, we want to find subsets of items which are rated similarly by some users; such a subset implies that these items have something in common which brings these users together. This does not need to be that generic as the genre, but it might be some other common property of the items, like the director, the story, or even a mixture of them.

In [4], we locate such user-item groups by exploiting (fault-tolerant) subspace clustering. Subspace clustering is a popular approach for clustering high dimensional data which discovers, except for the cluster members, the dimensions upon which these members form a cluster. Different subspace clusters might be defined upon different subspaces and member and subspace overlap among the different clusters is allowed. In our case, subspace clustering identifies groups of users with similar behavior w.r.t. a set of items. We employ the items of a subspace cluster to build its context and use it to locate, at query time, clusters with context similar to the query context. In contrast to our prior work [4] that considers all user-related clusters for recommendations, here we define the notion of cluster context and we consider only context-related clusters for the specific user.

Recommendations Basics: Assume a recommender system, where I is the set of items and \mathcal{U} is the set of users. Each item $i \in I$ is described as a set of (attribute, value)

pairs; let \mathcal{D} be the set of all distinct (attribute, value) pairs appearing in all data items. For instance, for a movies application, an attribute can be the director or the production year of a movie. A user u might rate an item i with a score $rating(u, i)$ in $[0.0, 1.0]$; let R be the set of all ratings recorded in the system. Typically, the cardinality of I is high and users rate only a few items. For an i , unrated by u , with N_u representing u 's most similar users (neighbors), its relevance score is computed as:

$$relevance(u, i) = \frac{\sum_{u' \in N_u} simU(u, u') rating(u', i)}{\sum_{u' \in N_u} simU(u, u')} \quad (1)$$

where the similarity function $simU(u, u')$ evaluates the proximity between u and u' . The most prominent items, i.e., those with the higher relevance, are suggested to the user.

Fault-tolerant Subspace Clustering: Subspace clustering aims at detecting clusters embedded in subspaces of a high dimensional dataset. Clusters may consist of different combinations of dimensions, while the number of relevant dimensions per cluster may vary strongly. A *subspace* S describes a subset of items, $S \subseteq I$. A subspace cluster C is then described in terms of both its members $U \subseteq \mathcal{U}$ and the subspace of dimensions $S \subseteq I$ upon which it is defined as $C = (U, S)$. Typically, subspace clustering does not deal with missing values, which is a key problem for recommendations. Fault tolerant subspace clustering [3] deals with this issue by allowing a certain amount of missing values per items, users and ratings in a subspace cluster.

In [4], we use fault tolerant subspace clustering to locate users with similar preferences to a query user, for computing her recommendations. In particular, for a query user u we locate its similar users via the subspace clusters where the user belongs to. These are locally similar users, the term “locally” meaning that they are similar w.r.t. a set of dimensions (those in their corresponding subcluster). We refine this set of users based on their common ratings to u ; this is a “global” evaluation aiming to check their overall proximity, i.e., over all items. This local-global refinement results in a more qualitative set of friends N_u for recommendations. The new set N_u is plugged in Formula 1 for issuing recommendations. Our results show that this careful selection of friends, is reflected in more qualitative recommendations.

Inferring the Cluster Context: We consider that the context of a subspace cluster $C = (U, S)$ expresses the most significant parts of the items S within the cluster; these are captured through the attribute values of the items of S , upon which C is defined and are therefore sets of (attribute, value) pairs. Similar to [5], we ground the significance of each (attribute, value) pair on its frequency in the data appearing in the cluster. By post-processing the (attribute,value) pairs in S , we rank these pairs based on their frequency in C ; the significance of a pair is normalized taking into account its frequency in the whole database, so as to downgrade global popular pairs corresponding to common trends and focus on cluster-specific context. This way, we define the context of a cluster as an expression containing one or more significant (attribute,value) pairs. For instance, the context of a movie cluster could be: *genre=comedy & actor=Meryl Streep*.

Luckily, our subspace clustering is offline and therefore there is no need to compute at query time the context of the produced clusters. This fact allows us to resorting to non-approximate solutions for context identification.

Contextual Recommendations: Given a user u along with a query with context p , expressed as a set of (attribute, value) pairs with attributes in \mathcal{D} , for computing contextual recommendations for u , we first locate the users that exhibit the most similar behavior to u under p . These are the members of the clusters for which u is also a member; we denote them by C_u . Due to the context-constraints though, not all clusters are relevant as some of them describe a different context than p . Therefore, we need a way to evaluate the relevance of a cluster context to p . We distinguish between:

- *Exact context match:* If there are clusters in C_u that match exactly the query context p of u , i.e., C_u^p , then the members of these clusters comprise the set of friends N_u upon which the recommendations for u will be computed.

- *Partial context match:* If there is no cluster with context equal to p , we relax our context relevance evaluation by looking for context-similar clusters, instead of context-identical clusters. To determine how close a context query p and a cluster context c are, we rely on a vector-based approach. Let \mathcal{D} be the set of all N distinct (attribute, value) pairs appearing in all data items. A vector representation of p is a binary vector V_p of size N , whose j -th element corresponds to $\mathcal{D}[j]$. If $\mathcal{D}[j]$ appears in p , then $V_p[j] = 1$; otherwise it is 0. Analogously, the vector representation of a cluster context w is a binary vector V_w of size N , where $V_w[j] = 1$, if $\mathcal{D}[j]$ appears in w ; otherwise it is 0. The similarity between p and w is then defined using their vector representations V_p and V_w as:

$$sim(p, w) = \cos(V_p, V_w) = \frac{V_p \cdot V_w}{|V_p||V_w|} \quad (2)$$

Having located the clusters C_u^p with the most similar contexts to p , we employ their members as the set of the most similar users to u and compute recommendations based on them. Actually, we apply a weighted ranking approach to refine the set of like-mined users according to the similarity of the context of the cluster they belong to, to p .

Next Steps: We are working on improving our cluster context description, by a better aggregation of the attribute values within the cluster and by using item hierarchies, and on more sophisticated methods for context matching and user aggregation. Also, we are working on the scalability aspect to parallelize the subspace cluster and context extraction parts. Preliminary results with MapReduce appear in [2].

ABSTRACT

Traditional indices in relational databases are designed for queries that are *selective by value*. However, queries can also retrieve records on their *relational structure*. In our research, we found that traditional indices are ineffective for structurally selective queries. To accelerate such queries, so-called ‘structural indices’ have been applied in graph databases. These indices group together structurally similar nodes to obtain a compact representation of the graph structure.

We studied how structural indices can be applied in relational databases and evaluated their performance. Guarded bisimulation groups together relational tuples with similar structure, which we use to obtain a guarded structural index. Our solution requires significantly less space than traditional indices. At the same time, it can offer several orders of magnitude faster query evaluation performance.

1. PROBLEM DEFINITION

Queries that are selective by value can be accelerated by using B-trees or Hash indices on attributes in the selection condition. The problem is that such indices cannot efficiently answer structurally selective queries. Consider a relation *customer*(*id*, *name*, *address*, *phone*) and a relation *order*(*id*, *status*, *total_price*, *customer_id*), where *id* denotes the primary key (PK) in both relations. Further, we have a foreign key (FK) from *order*(*customer_id*) to *customer*(*id*).

For example, we might want to retrieve all names of customers that do or do not have an order. To answer these queries, a semijoin or antijoin has to be processed. Semijoins and antijoins require table scans, index scans or index only scans on both relations. These operations are relatively expensive. Moreover, these are *tuple selecting queries*. The result is a subset of a *single* relation: the *customer* relation. No information from the *order* relation occurs in the output. However, the *order* relation or its index must be scanned to determine which tuples must be returned, which impacts the performance when the *order* relation is much larger than the *customer* relation.

Value-based indices are not directly useful in accelerating structurally-sensitive selections such as these.

2. BACKGROUND

The main concept of structural indices is to build a summary that is smaller than the original database, while preserving relevant structural properties. Bisimilarity and similarity are two formal notions of structural similarity in graphs which have been used for summarizing semi-structured and graph databases for structural indexing [3, 7]. Andréka et al. [2] and Otto [5] introduced guarded bisimulation and guarded simulation which extends these notions to relational databases. Picalausa et al. characterized query invariance under guarded (bi)simulation (i.e., for which query languages guarded (bi)simulation is the correct structural notion for indexing w.r.t. queries in the language), providing a formal basis for the engineering of guarded structural indices [6]. This abstract summarizes the main results of our empirical study of the practical feasibility of this novel approach to indexing; details can be found in [1].

3. APPROACH

Our approach to build a structural index can be summarized as follows: first we represent the relational database instance as a graph. Second, we apply an external memory bisimulation partitioning algorithm to group similar nodes. Third, we map the partitioning of the original tuples. We summarize each step in the following paragraphs.

Relational databases allow joins on any set of attribute pairs with equal types. Because FK constraints are popular candidates for join conditions, we only consider PK-FK joins. The graph is constructed as follows: we create a node for each PK value in the database. Then we create forward edges from PK to FK values and backward edges from FK to PK values. We use relation names as node labels and FK constraint names for edge labels.

We apply a localized version of bisimulation equivalence on the graph, namely, *k*-bisimulation. This equivalence relation induces a partitioning of nodes with respect to topological features of their *k*-neighborhoods. The *k*-neighborhood of a node *n* is the subgraph consisting of all nodes at most *k* edges away from *n*. The partitioning result consists of a mapping from nodes (tuples) to partition blocks, which represent *k*-bisimulation equivalence classes, and a reduced graph that summarizes the original structure. The mapping is stored by tagging each tuple in each relation (in an additional attribute) with the distinct identifier of the partition block to which the tuple belongs. The reduced

Table 1: Queries for TPC-H dataset

Query	description
FACQ 1	Select partsupp supplycosts having lineitem
FACQ 2	Select part names having a lineitem
FACQ 4	Select region having nation, customer, orders and lineitem
GF 1A	Select partsupp comment without lineitem
GF 1B	Select customers not having an order
GF 4	Select all suppliers that sell parts that are offered but not sold by other suppliers

graph is stored in an additional relation *edge_label(from_id, to_id)*. After construction of *edge_label*, the PK-FK graph is no longer needed and is discarded.

k -bisimulation structural indices allow the acceleration of semijoins and antijoins with join trees of height $h \leq k$. The reduced graph is used to determine which equivalence classes are selected. Then, the projected relation is scanned and tuples that are tagged with those equivalence classes are returned. Queries with join trees of height $h > k$ can be partially accelerated via query decomposition.

4. EXPERIMENTAL STUDY

Set up. We used the DBLP¹ data set and the TPC-H² data set with scale factor 1 to evaluate guarded structural indexing. PostgreSQL 9.3 and the external memory bisimulation partitioning solution of Luo et al. [4] were used. Table 1 lists the queries used in our evaluation.

Results. Figure 1 shows the number of partition blocks that are generated under k -bisimulation. A higher value of k leads to more equivalence classes, uses more disk space, and can accelerate higher join (sub)trees. Figure 2 shows the reduced graph under 2-bisimulation. We observe significant compression while preserving non-trivial structure.

Figure 1: Partition size under k -bisimulation

Figure 3 shows the speed-up of structural indexing over value-based B-trees on foreign keys. For $4 \leq k \leq 7$, this is between 4 and 190 times faster. We also observed that our index uses only 1 megabyte of disk space for these k

¹<http://dblp.uni-trier.de/xml/>

²<http://www.tpc.org/tpch/>

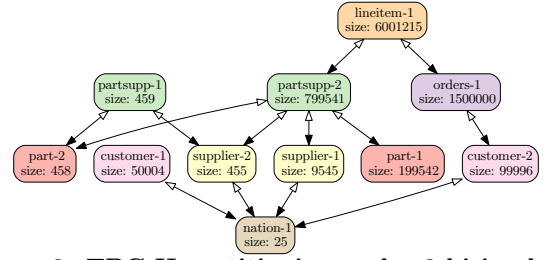

Figure 2: TPC-H partitioning under 2-bisimulation

values compared to the more than 450 megabytes required for value-based indexes.

Figure 3: Query running time speedup factor

Conclusions. Our results show that guarded structural indices can be orders of magnitude smaller and faster than traditional indexes. This indicates the significant promise of further study of this new approach to indexing.

Context-Dependent Quality-Aware Source Selection for Live Queries on Linked Data

<p>Barbara Catania DIBRIS University of Genova Genova, Italy barbara.catania@unige.it</p>	<p>Giovanna Guerrini DIBRIS University of Genova Genova, Italy giovanna.guerrini@unige.it</p>	<p>Beyza Yaman DIBRIS University of Genova Genova, Italy beyza.yaman@dibris.unige.it</p>

ABSTRACT

Source selection deserves attention for live query processing over distributed, poorly controlled data sources since it is the key to produce the best available information, in terms of relevance, trustness, and freshness, as query result. In this paper, we present an approach taking into account context-dependent data quality, according to different dimensions, during source selection, with the aim of selecting not only the most relevant but also the highest quality sources.

1. INTRODUCTION & BACKGROUND

In the last decade significant amount of Linked Data has been published to construct a global data space. However, it is still difficult to benefit from published data in an effective way because identifying the sources containing the most valuable results for a query is a non-trivial task. We propose an approach to select sources taking into account not only relevance but also quality in a context-dependent way.

Our approach fits in the general vision of Rekatsinas *et al.* [2] for a data source management system that enables users to discover the most valuable data sources for their applications. To characterize data source value, different *quality indicators* [1] can be used to assess the different quality dimensions (accuracy, freshness, completeness, etc), relying on data content, metadata (such as update times) and explicit user feedbacks. Data quality, however, may be different if assessed with reference to a geographical area, historical period, or type of content. As a result, it is not only impossible to assess quality in an absolute way, but it is difficult as well to assess a single quality dimension independently from the *context*. Quality indicators would then be associated with data according to the different contexts.

We adopt the notion of context proposed in [2] in terms of context clusters. A context cluster describes the data domain corresponding to a data collection and it is specified as a conjunction of a set of concept classes and a set of instances. In our approach, context clusters can specify information about *what* (the type of the described information), *where*

(spatial location), *when* (temporal location), and *why* (data motivations).

Each data item (i.e., each RDF triple) is associated with (one or more) context clusters. A source can include data items from different contexts. A (data source, context) pair intensionally characterizes a data collection, consisting of the set of triples in the source associated with the context. Quality indicators are associated, for the relevant quality dimension, with such data collections. A data source can thus exhibit different quality degrees, resulting in different indicator values, according to the different contexts.

Given a user query, the approach consists of four tasks: (i) context-dependent quality aware source selection to devise the most relevant and highest quality sources according to the query and its context; (ii) feedback from the user on the results obtained by the query evaluation; (iii) refinement/update of the data quality indicators according to such feedback; (iv) update of the auxiliary structures employed for source selection according to the refinement in (iii).

The proposed approach relies on two main notions, that are combined in an original way:

1. *Named Graphs*. Named Graphs [1] are useful structures for hierarchically composing subgraphs and building nested graphs. They allow to represent and exchange metadata.

2. *Data Summaries*. Data summaries [3] have been proposed to efficiently determine which sources may contribute answers to a query in live distributed query systems. They approximately describe the data provided by a source in an aggregated form, in much more detail than schema-level indexes. The QTree, specifically, is a data summary over Linked Data sources, seeing the data items (RDF triples) in the sources as points of a three dimensional numerical space, by applying hash functions to the triple components. Like the R-tree, a QTree is a tree structure consisting of nodes defined by minimal bounding boxes (MBBs). An MBB describes the multidimensional region in the data space that is represented by the node the subtree underneath. Leaf nodes in a QTree, however, rather than containing the data items that are contained in their MBBs as in R-trees, are buckets containing statistical information (e.g., count) that approximate the data items contained in their MBBs.

2. SOURCE SELECTION EXPLOITING CONTEXT-DEPENDENT QUALITY

Figure 1 provides a graphical overview of the approach. We first briefly describe the steps in the source selection process and then discuss its main components. First, the

Figure 1: Overview of the Approach

user query is submitted to the system (Edge 1) and a look-up is performed on an extended QTree, returning to the user a ranked list of high quality relevant sources (Edge 2). The extended QTree allows the retrieval of potentially relevant sources with quality indicators, for given quality dimensions in a given context, above a given threshold. Once query results are returned to the user, her feedback (if any, Edge 3) on the obtained results is considered, resulting in an update and refinement of the quality metadata associated with the sources according to the context (Edge 4). Such context-dependent metadata are maintained making use of Named Graphs. Named Graphs maintain detailed quality indicators and metadata, so that this knowledge is shared and easily accessible. Such detail quality information is the basis on which the numeric indicators in the extended QTree are computed. Finally, context-dependent numerical quality indicators are incrementally updated in the extended QTree according to the new metadata (Edge 5).

Query. The query is a conjunctive SPARQL query associated with context information and quality thresholds. Conjunctive SPARQL queries consist of so-called basic graph patterns (BGPs), i.e., sets of triple patterns in the *(subject, predicate, object)* form possibly containing variables. We assume that the BGPs come with context information in the form of context clusters. Moreover, thresholds can be specified with respect to one or several among the supported quality dimensions. Only sources associated with indicators with values above the thresholds for the specified dimensions will be considered as result, while the other ones are discarded.

Named Graph. We exploit Named Graphs to associate quality related metadata and indicators with data sources, in a context-dependent way, in order to make this knowledge shared and easily accessible. Context clusters are organized in a hierarchical structure enabling the support of different detail levels. For instance, referring to spatial location context clusters, the *{Rome}* cluster is more specific than the *{Central Italy}* cluster. A data source may contain data items from various contexts. For instance, a data source containing information about touristic attractions in central Italy may contain data items associated with the *{Museum}* (*what*) cluster as well as items associated with the *{Rome}* (*where*) cluster as well as items associated with the *{Florence}* (*where*) cluster.

A data source can be associated in the Named Graphs with different quality profiles corresponding to the different contexts of its triples. Inside Named Graphs, indeed, quality-related metadata w.r.t. different quality dimensions

are attached to each data collections characterized by data source and context. This allows a context-dependent quality assessment. Referring to the above mentioned data source, its freshness may be different according to the *{Rome}* or to the *{Florence}* context, and, similarly its trustness may be different according to the *{Museum}* or *{Rome}* context. We rely on metadata standard vocabularies to describe quality-related metadata [1]. For instance, freshness can be described by using access (*dc:date*) and creation dates (*dc:created*), while trustness can be related to the creator of the source (*dc:publisher*).

Extended QTree. The QTree index is extended to consider context as a fourth component associated with triples and to associate context-dependent numerical quality indicators with data collections. Contextualized data items are now seen as point of a four dimensional numerical space, since context clusters are hashed to a numerical value as the other triple components. Each four dimensional MBB, moreover, is now associated with a quality range for each of the quality dimension. Indicators are separately computed for each quality dimension from the quality information (metadata and indicators) in the Named Graphs. The approach is flexible, in that the employed indicators may be different from source to source.

Indicator ranges are used during source selection to prune the data sources with quality below the requested thresholds. Specifically, given a four dimensional region and the thresholds for quality dimensions resulting from a query, the extended QTree is employed by descending in a child node if the region is contained in the MBB and the quality ranges intersect the corresponding thresholds. Indicators are finally also employed to rank the retrieved data sources according to their quality w.r.t. the query context.

3. CONCLUSION

In this paper we propose an approach to select relevant sources from an arbitrary, unrestricted set of distributed, poorly controlled Linked Data sources, so that queries can be processed on these sources taking into account not only their relevance to the query but also their quality, in terms of a number of dimensions, with respect to the query context.

Technically, the proposed approach relies on the use of nested Named Graphs to associate quality metadata with data source according to different contexts and at different granularity levels, and on extended QTree enabling efficient source selection, not only relying on relevance, but also on context-based quality indicators.

ABSTRACT

Big data technology holds incredible promise of improving people's lives, accelerating scientific discovery and innovation, and bringing about positive societal change. Yet, if not used responsibly, this technology can propel economic inequality, destabilize global markets and affirm systemic bias. While the potential benefits of big data are well-accepted, the importance of using these techniques in a fair and transparent manner is rarely considered.

The primary goal of this tutorial is to draw the attention of the data management community to the important emerging subject of responsible data management and analysis. We will offer our perspective on the issue, will give an overview of existing technical work, primarily from the data mining and algorithms communities, and will motivate future research directions.

1. RESPONSIBLE DATA ANALYSIS

Big data technology holds incredible promise of improving people's lives, accelerating scientific discovery and innovation, and bringing about positive societal change. Yet, if not used responsibly, this technology can propel economic inequality, destabilize global markets and affirm systemic bias. While the potential benefits of big data are well-accepted, the importance of using these techniques in a fair and transparent manner is rarely considered.

We will start this tutorial with a brief introduction to foundational concepts of bias, positive and negative discrimination, redlining, and disparate impact. These legal and ethical issues have been attracting attention in the context of big data, and have been receiving coverage in the popular press. We will then identify key properties of responsible data analysis [2], outlined next.

The first property of responsible data analysis is **fairness**, by which we mean *lack of bias*. It is incorrect to assume that insights gained from computation on data are unbiased simply because data was gathered automatically or processing was performed algorithmically. Bias may come from the

data, e.g., if a questionnaire contains biased questions, or from the algorithm, reflecting political, commercial, sexual, religious, or other kinds of preferences of its designers.

The second property is **non-discrimination**. When tackling a technically challenging problem such as relevance ranking of Web search results, or news article recommendation, it is rational to first focus on meeting common needs well. However to afford equal advantage to a wide variety of users, it is important to support uncommon information and data analysis needs. Such tasks are said to be “in the tail” — they may not be common individually, yet together constitute the overwhelming majority. For instance, Lerman [22] argues that the use of big data can lead to data exclusion and therefore poses risks to those it overlooks.

The third property of responsible data analysis is **transparency**. Users want to know and control both what is being recorded about them, and how the recorded information is being used, e.g., to recommend content or target advertisement to them. However, while privacy is certainly an important part of the picture, there is far more to transparency than privacy. Transparent data analysis frameworks will require verification and auditing of datasets and algorithms for fairness, robustness, diversity, non-discrimination and privacy. An important ingredient in transparency is availability of provenance meta-data, which describes who created a dataset and how.

2. OVERVIEW OF TECHNICAL WORK

In a paper that pre-dates big data, Friedman and Nissenbaum [15] give a systematic account of bias in computer systems. The authors identify several representative examples of bias, and develop a taxonomy, classifying bias as pre-existing (societal), technical and emergent (based on use).

More recently, two kinds of technical approaches have been developed. The first are empirical studies that serve to underscore the lack of fairness and transparency in current data analysis practices. In the second category are proposals from the data mining and machine learning communities that aim to make some common task unbiased.

The empirical study of current data-intensive applications aims to identify fairness violations in data analysis practices. This work is critical for understanding the current practice and for motivating research into responsible data use. We will give an overview of existing studies, including the XRay project [21] and the study by Datta et al. [7]. Both studies point to the lack of transparency in the way personal data is used for online ad targeting. We will also present a study by Sweeney [25], which identifies cases of racial discrimination

in online advertising.

Recently, work is beginning to emerge in the machine learning and data mining communities that concerns detecting and avoiding discrimination in classification. Fairness in classification is understood in terms of two goals, namely, individual fairness and group fairness. Individual fairness states that two individuals who are similar w.r.t. a particular classification task should be classified similarly, while group fairness states that the proportion of members of a protected group who are classified positively should be statistically indistinguishable from the proportion of members of the overall population.

Dwork et al. [11] propose a framework for fair classification, based on identifying a probabilistic mapping from individuals to an intermediate representation that achieves both individual and group fairness. This framework assumes that a distance function in the space of the classification task is given. In a follow-up work, Zemel et al. [26] propose a method for learning a class of distance functions and formulate fairness as an optimization problem that both encodes the data, preserving necessary attributes, and obfuscates membership in a protected group.

Feldman et al. [14] propose a formalization of the legal doctrine of disparate impact in the context of classification, and study the problems of disparate impact certification and removal, linking disparate impact to a particular loss function, namely, to the balanced error rate.

Beyond classification, Pedreschi et al. [23] and Kamiran et al. [20] propose formalizations of discrimination in association rule mining and decision tree learning, respectively. The authors then develop ways to mediate the effects of discrimination in these settings.

3. RESEARCH DIRECTIONS

We will conclude the tutorial by surveying works that, while not specifically motivated by responsible data analysis, can be brought to bear on the problem.

We will mention works seeking to provide accurate data mining results about a population while protecting sensitive information about individuals, e.g., [9, 12]. We will also consider some extensive work on provenance [3, 17], especially in the context of data-intensive workflows [5, 8] and in distributed scenarios [18].

In general, the field of program verification is central to the issue of verifying properties such as fairness or non-discrimination. A broad survey of this field is beyond the scope of the tutorial. We will mention zero-knowledge proofs [6, 16], cryptographic techniques by which one party (the prover) can prove to another party (the verifier) that a given statement is true, without conveying any information apart from the fact that the statement is indeed true.

We will briefly discuss several topics related to supporting diverse preferences and information needs of users. This includes works on search result diversification [4] and rank-aware clustering [24]. We will consider another relevant line of work that concerns modeling, interpreting and aggregating user preferences, e.g., [10, 13, 19]. Finally, we will discuss recent work on personal information management [1], where the goal is to empower users to take control of their own data, so as to manage and disseminate it effectively.

ABSTRACT

Graph mining is an important research area with a plethora of practical applications. Core decomposition in networks, is a fundamental operation strongly related to more complex mining tasks such as community detection, dense subgraph discovery, identification of influential nodes, network visualization, text mining, just to name a few. In this tutorial, we present in detail the concept and properties of core decomposition in graphs, the associated algorithms for its efficient computation and some of its most important applications.

1. INTRODUCTION

Core decomposition is a well-studied topic in graph mining. Informally, the k -core decomposition is a threshold-based hierarchical decomposition of a graph into nested subgraphs. The basic idea is that a threshold k is set on the degree of each node; nodes that do not satisfy the threshold, are excluded from the process. There exists a rich literature studying algorithmic aspects of core decomposition by taking different viewpoints, such as distributed, streaming, disk-resident data, to name a few. In addition, core decomposition has been used successfully in many diverse application domains, including social networks analysis and text analytics tasks.

Next, we formally define the concept of k -core decomposition in graphs. Let $G = (V, E)$ be an undirected graph. Let H be a subgraph of G , i.e., $H \subseteq G$. Subgraph H is defined to be a k -core of G , denoted by G_k , if it is a maximal connected subgraph of G in which all nodes have degree at least k . The degeneracy $\delta^*(G)$ of a graph G is defined as the maximum k for which graph G contains a non-empty k -core subgraph. A node i has *core number* $c_i = k$, if it belongs to a k -core but not to any $(k+1)$ -core. The k -shell is the subgraph defined by the nodes that belong to the k -core but not to the $(k+1)$ -core.

Based on the above definitions, it is evident that if all the nodes of the graph have degree at least one, i.e., $d_v \geq 1, \forall v \in V$, then the 1-core subgraph corresponds to the whole graph, i.e., $G_1 \equiv G$. Furthermore, assuming that $G_i, i = 0, 1, 2, \dots, \delta^*(G)$ is the i -core of G , then the k -core subgraphs are nested, i.e., $G_0 \supseteq G_1 \supseteq G_2 \supseteq \dots \supseteq G_{\delta^*(G)}$. Typically, subgraph $G_{\delta^*(G)}$ is called *maximal k -core subgraph* of G .

Figure 1 depicts an example of a graph and the corresponding k -core decomposition. As we observe, the degeneracy of this graph

Figure 1: Example of the k -core decomposition.

is $\delta^*(G) = 3$; thus, the decomposition creates three nested k -core subgraphs, with the 3-core being the maximal one. The nested structure of the k -core subgraphs is indicated by the dashed lines. Furthermore, the color on the nodes indicates the core number c of each node. Lastly, we should note here that the k -core subgraphs are not necessarily connected.

2. GOALS AND OUTLINE

The goal of this tutorial is to present in detail the algorithmic paradigm of core decomposition in graphs. In particular, we will focus on the following points:

- (i) **Fundamental concepts of core decomposition.** We present the notion of k -core decomposition for unweighted and undirected graphs and then extensions for weighted, directed, probabilistic and signed ones. We also present generalizations of the decomposition to node properties beyond the degree.
- (ii) **Algorithms for core decomposition.** Computing the k -core decomposition of a graph can be done through a simple process that is based on the following property: to extract the k -core subgraph, all nodes with degree less than k and their adjacent edges should be recursively deleted. In the tutorial, we present efficient algorithms for the k -core decomposition. We also examine several extensions that have been proposed by the databases community for large scale k -core decomposition under various computation frameworks, including streaming, distributed and disk-based algorithms. We also examine how to estimate the k -core number of each node using only local information.
- (iii) **Applications.** We demonstrate applications of the k -core decomposition in various domains, including dense subgraph

detection, graph clustering, modeling of network dynamics and network visualization.

The outline of the tutorial has as follows:

1. Introduction

- Social network analysis
- Highlights of core decomposition

2. Fundamental Concepts of Core Decomposition

- k -core subgraph, k -shell subgraph, k -core number, degeneracy
- Weighted networks, directed networks, signed networks, probabilistic networks
- Generalized cores
- Truss decomposition
- Extensions of the core decomposition

3. Algorithms

- Baseline algorithm
- An $\mathcal{O}(|E|)$ algorithm for k -core decomposition
- Streaming k -core decomposition
- Distributed k -core decomposition
- Disk-based k -core decomposition
- Local estimation of k -core numbers

4. Applications in Complex Networks

- Dense subgraph discovery
- Community detection and evaluation
- Identification of influential nodes
- Dynamics of networks
- Modeling the Internet topology
- Network visualization
- Text mining

5. Open Problems and Future Research

- Algorithms and applications

ABSTRACT

This tutorial aims at providing an overview of the state-of-the-art approaches to distance-based multimedia indexing. This tutorial presents the fundamentals of (i) object representation, (ii) distance-based similarity models, (iii) efficient query processing, and (iv) indexing. It is intended for a broad target audience starting from beginners to experts in the domain of distance-based similarity search in multimedia databases and adjacent research fields which utilize distance-based approaches.

1. INTRODUCTION

Concomitant with the explosive growth of the digital universe [11], an immensely increasing amount of multimedia data is generated, processed, and finally stored in very large multimedia databases. The rapid expansion of the internet and the extensive spread of mobile devices allow users to generate and share multimedia data everywhere and at any time. As a result, multimedia databases tend to grow continuously without any restriction and are thus no longer manually manageable by humans. Automatic approaches that allow for effective and efficient information access to massive multimedia databases become immensely important.

Multimedia retrieval approaches are one class of information access approaches that allow to manage and access multimedia databases with respect to the users' information needs. These approaches deal with the representation, storage, organization of, and access to information items [2]. In fact, they can be thought of approaches allowing users to *search, browse, explore, and analyze* multimedia databases by means of similarity relations among multimedia objects.

One promising and widespread approach to define similarity between multimedia objects consists in automatically extracting inherent properties of multimedia objects and comparing them with each other. For this purpose, the content-based properties of multimedia objects are modeled by feature representations which are comparable by means of *distance-based similarity measures*. This class of similarity

measures follows a rigorous mathematical interpretation [19] and allows domain experts and database experts to address the issues of effectiveness and efficiency simultaneously and independently. In fact, it has become mandatory for current distance-based similarity measures to be indexable in order to facilitate large-scale applicability.

2. TUTORIAL OUTLINE

In this tutorial, we aim at providing an overview of the state-of-the-art approaches to distance-based multimedia indexing. We intend to cover a broad target audience starting from beginners to experts in the domain of distance-based similarity search in multimedia databases and adjacent research fields which utilize distance-based approaches. No prerequisite knowledge is needed.

2.1 Object Representation

In the first part of this tutorial, we will outline different approaches to object representations in order to answer the question of how to model multimedia data objects in a generic way. We will focus on a unified object representation model including fixed-binning feature histograms and adaptive-binning feature signatures [3]. In addition to these object representations, we will present the idea of probabilistic feature signatures [4, 5] and show how to approximate object representations by means of gradient-based signatures [7].

2.2 Distance-based Similarity Models

In the second part of this tutorial, we will provide an overview of state-of-the-art distance-based similarity measures for feature histograms and feature signatures in order to complete our understanding of a similarity model. Among the multitude of distance-based similarity measures applicable to feature signatures, we will present and discuss the Earth Mover's Distance [15], the Signature Quadratic Form Distance [8], and the Signature Matching Distance [6].

2.3 Efficient Query Processing

The third part of this tutorial is devoted to techniques and algorithms for efficient query processing. After introducing distance-based similarity queries, we show how to process such queries efficiently by means of multi-step filter-and-refinement algorithms including multi-step range query algorithms [10] and optimal multi-step k -NN query algorithms [18]. To this end, we elucidate the idea of lower bound approximations and present state-of-the-art lower bound approximations [1, 20, 21] for the Earth Mover's Distance.

2.4 Indexing

The last part of this tutorial finally covers indexing approaches for distance-based similarity models where we will give an insight into the fundamentals of spatial access methods [16, 22], metric access methods [9, 14, 17, 23], and ptolemaic access methods [12, 13].

3. FURTHER INFORMATION

Further information regarding this tutorial can be found at <http://dme.rwth-aachen.de/en/DBMI>.
